S_{av} shall not be less than one-half (1/2) of the corresponding S_a for horizontal components determined in accordance with the general or site-specific procedures of Section 11.4 or Chapter 21, respectively.

For vertical periods greater than 2.0 seconds, S_{av} shall be developed from a site-specific procedure; however, the resulting ordinate of S_{av} shall not be less than one-half (1/2) of the corresponding S_a for horizontal components determined in accordance with the general or site-specific procedures of Section 11.4 or Chapter 21, respectively.

In lieu of using the above procedure, a site-specific study may be performed to obtain S_{av} at vertical periods less than or equal to 2.0 seconds, but the value so determined shall not be less than 80 percent of the S_{av} value determined from Equations 23.1-1 through 23.1-4.

23.2 MCE_R VERTICAL RESPONSE SPECTRUM. The MCE_R vertical response spectral acceleration shall be 150 percent of the S_{av} determined in Section 23.1.

Commentary to New Chapter 23

Chapter 23 Commentary
VERTICAL GROUND MOTIONS FOR SEISMIC DESIGN

C23.1 DESIGN VERTICAL RESPONSE SPECTRUM

General. ASCE/SEI 7-05 and the earlier editions of the *Provisions* use the term $0.2S_{DS}D$ to reflect the effects of vertical ground motion. Where a more explicit consideration of vertical ground motion effects is advised—as for certain tanks, materials storage facilities, and electric power generation facilities—the requirements of this chapter may be applied. Historically, the amplitude of vertical ground motion has been inferred to be two-thirds (2/3) the amplitude of the horizontal ground motion. However, studies of horizontal and vertical ground motions over the past 25 years have shown that such a simple approach is not valid in many situations (e.g., Bozorgnia and Campbell, 2004, and references therein) for the following main reasons: (a) vertical ground motion has a larger proportion of short-period (high-frequency) spectral content than horizontal ground motion and this difference increases with decreasing soil stiffness and (b) vertical ground motion attenuates at a higher rate than horizontal ground motion and this difference increases with decreasing distance from the earthquake.

The observed differences in the spectral content and attenuation rate of vertical and horizontal ground motion lead to the following observations regarding the vertical/horizontal (*V/H*) spectral ratio (Bozorgnia and Campbell, 2004):

1. The *V/H* spectral ratio is relatively sensitive to spectral period, distance from the earthquake, local site conditions, and earthquake magnitude (but only for relatively soft sites) and relatively insensitive to earthquake mechanism and sediment depth;
2. The *V/H* spectral ratio has a distinct peak at short periods that generally exceeds 2/3 in the near-source region of an earthquake; and
3. The *V/H* spectral ratio is generally less than 2/3 at mid-to-long periods.

Therefore, depending on the period, the distance to the fault, and the local site conditions of interest, use of the traditional 2/3*V/H* spectral ratio can result in either an underestimation or an overestimation of the expected vertical ground motions.

The procedure for defining the design vertical response spectrum in the *Provisions* is based on the studies of horizontal and vertical ground motions conducted by Campbell and Bozorgnia (2003) and Bozorgnia and Campbell (2004). These procedures are also generally compatible with the general observations of Abrahamson and Silva (1997) and Silva (1997) and the proposed design procedures of Elnashai (1997).

General Design Procedure. In order to be consistent with the shape of the horizontal design response spectrum, the vertical design response spectrum has four regions defined by the vertical period of vibration (T_v). Based on the study of Bozorgnia and Campbell (2004), the periods that define these regions are approximately constant with respect to the magnitude of the earthquake, the distance from the earthquake, and the local site conditions. In this respect, the shape of the vertical response spectrum is simpler than that of the horizontal response spectrum.

The equations that are used to define the design vertical response spectrum are based on three observations made by Bozorgnia and Campbell (2004):

1. The short-period part of the 5 percent damped vertical response spectrum is controlled by the spectral acceleration at T_v = 0.1 second;
2. The mid-period part of the vertical response spectrum is controlled by a spectral acceleration that decays as the inverse of the 0.75 power of the vertical period of vibration ($T_v^{-0.75}$); and
3. The short-period part of the V/H spectral ratio is a function of the local site conditions, the distance from the earthquake (for sites located within about 60 km of the fault), and the earthquake magnitude (for soft sites).

The *Provisions* do not include seismic design maps for the vertical spectral acceleration at T_v = 0.1 second and do not preserve any information on the earthquake magnitudes or the source-to-site distances that contribute to the horizontal spectral accelerations that are mapped. Therefore, the general procedure recommended by Bozorgnia and Campbell (2004) was modified to use only those horizontal spectral accelerations that are available from the seismic design maps, as follows:

1. Estimate the vertical spectral acceleration at T_v = 0.1 second from the ratio of this spectral acceleration to the horizontal spectral acceleration at T = 0.2 second for the Site Class BC boundary (i.e., the boundary between Site Classes B and C ($\overline{v}_s = 760$ m/sec), the reference site condition for the 2008 U.S. Geological Survey National Seismic Hazard Maps). For earthquakes and distances for which the vertical spectrum might be of engineering interest (magnitudes greater than 6.5 and distances less than 60 km), this ratio is approximately 0.8 for all site conditions (Campbell and Bozorgnia, 2003).
2. Estimate the horizontal spectral acceleration at T = 0.2 second from the Next Generation Attenuation (NGA) relationship of Campbell and Bozorgnia (2008) for magnitudes greater than 6.5 and distances ranging between 1 and 60 km for the Site Class BC boundary ($\overline{v}_s = 760$ m/sec). The relationship of Campbell and Bozorgnia (2008), rather than that of Campbell and Bozorgnia (2003), was used for this purpose in order to be consistent with the development of the 2008 U.S. Geological Survey National Seismic Hazard Maps, which use the NGA attenuation relationships to estimate horizontal ground motions in the western United States. Similar results were found for the other two NGA relationships that were used to develop the seismic hazard and design maps (Boore and Atkinson, 2008; Chiou and Youngs, 2008).
3. Use the dependence between the horizontal spectral acceleration at T = 0.2 second and source-site distance estimated in Item 2 and the relationship between the V/H spectral ratio, source-site distance, and local site conditions in Bozorgnia and Campbell (2004) to derive a relationship between the vertical spectral acceleration and the mapped MCE_R spectral response acceleration parameter at short periods, S_S.
4. Use the dependence between the vertical spectral acceleration and the mapped MCE_R spectral response acceleration parameter at short periods, S_S, in Item 3 to derive a vertical coefficient, C_v, that when multiplied by 0.8 and the design horizontal response acceleration at short periods, S_{DS}, results in an estimate of the design vertical spectral acceleration at T_v = 0.1 second.

Detailed Design Procedure. The following description of the detailed design procedure listed in Section 23.1 refers to the illustrated design vertical response spectrum in Figure C23.1-1.

Vertical periods less than or equal to 0.025 second. Equation 23.1-1 defines that part of the design vertical response spectrum that is controlled by the vertical peak ground acceleration. The 0.3 factor was approximated by dividing the 0.8 factor that represents the ratio between the vertical spectral acceleration at T_v = 0.1 second and the horizontal spectral acceleration at T = 0.2 second by 2.5, the factor that represents the ratio between the design horizontal spectral acceleration at T = 0.2 second, S_{DS}, and the zero-period acceleration used in the development of the design horizontal response spectrum. The vertical coefficient, C_v, in Table 23.1-1 accounts for the dependence of the vertical spectral acceleration on the amplitude of the horizontal spectral acceleration and the site dependence of the V/H spectral ratio as determined in Items 3 and 4 above. The factors are applied to S_{DS} rather than to S_S because S_{DS} already includes the effects of local site conditions and the 2/3 factor that is required to reduce the horizontal spectral acceleration from its MCE_R value to its design value.

Vertical periods greater than 0.025 second and less than or equal to 0.05 second. Equation 23.1-2 defines that part of the design vertical response spectrum that represents the linear transition from the part of the spectrum that is controlled by the vertical peak ground acceleration and the part of the spectrum that is controlled by the dynamically amplified short-period spectral plateau. The factor of 20 is the factor that is required to make this transition continuous and piecewise linear between these two adjacent parts of the spectrum.

Vertical periods greater than 0.05 second and less than or equal to 0.15 second. Equation 23.1-3 defines that part of the design vertical response spectrum that represents the dynamically amplified short-period spectral plateau.

Vertical periods greater than 0.15 second and less than or equal to 2.0 seconds. Equation 23.1-4 defines that part of the design vertical response spectrum that decays with the inverse of the vertical period of vibration raised to the 0.75 power.

Limits Imposed on S_{av}. Two limits are imposed on the design vertical response spectrum defined by Equations 23.1-1 through 23.1-4 and illustrated in Figure 23.1-1. The first limit restricts the vertical period of vibration to be no larger than 2 seconds. This limit accounts for the fact that such large vertical periods are rare (structures are inherently stiff in the vertical direction) and that the vertical spectrum might decay differently with period at longer periods. There is an allowance for developing a site-specific design vertical response spectrum if this limit is exceeded (see Section 11.4 or Chapter 21 for guidance on applying site-specific methods). The second limit restricts the design vertical response spectrum to be no less than 50 percent of the design horizontal response spectrum. This limit accounts for the fact that a V/H spectral ratio of one-half (1/2) is a reasonable, but somewhat conservative, lower bound over the period range of interest, based on the results of Campbell and Bozorgnia (2003) and Bozorgnia and Campbell (2004).

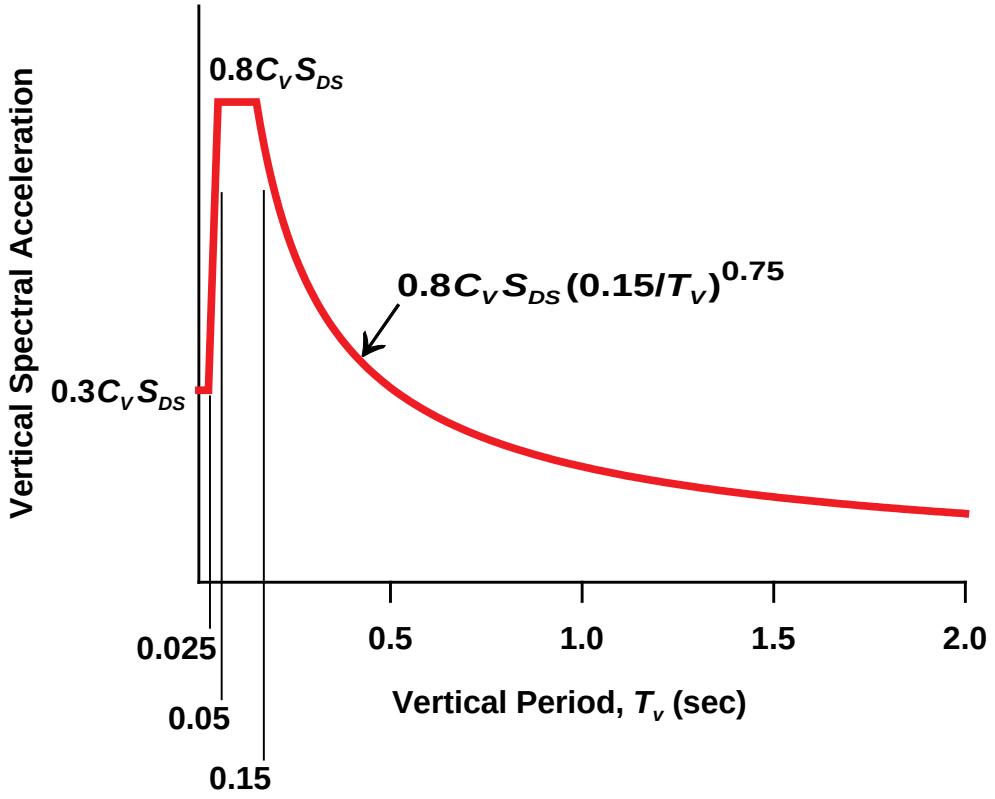

Figure C23.1-1 Illustrative example of the design vertical response spectrum.

2009 *NEHRP RECOMMENDED SEISMIC PROVISIONS FOR NEW BUILDINGS AND OTHER STRUCTURES*:

PART 2, COMMENTARY TO ASCE/SEI 7-05

This part of the 2009 NEHRP Recommended Seismic Provisions for New Buildings and Other Structures presents commentary to ASCE/SEI 7-05 utilizing the chapter and section numbers of that standard. Commentary to the modifications of the standard that appear in Part 1 of this Provisions volume is presented at the end of each chapter of modifications and can be used to replace or add to this Part 2 Commentary (e.g., this Part 2 Commentary addresses the maps that appear in ASCE/SEI 7-05, not the new risk-targeted maps and procedures presented in Part 1 of this volume).

This commentary is intended primarily for design professionals and members of the codes- and standards-development community. However, an understanding of the basis for the seismic regulations contained in the nation's building codes and standards is important to many outside this technical community including elected officials and other decision makers responsible for aspects of the built environment, the financial and insurance communities, and individual business owners and other citizens. These individuals and others who do not have in-depth technical knowledge may find a complementary report that presents a brief overview of the 2009 Provisions of interest. This overview is published as FEMA P-749, Concepts of Earthquake-resistant Design: An Introduction to the NEHRP Recommended Seismic Provisions for New Buildings and Other Structures.

COMMENTARY TO CHAPTER 11, SEISMIC DESIGN CRITERIA

C11.1 GENERAL

C11.1.1 Purpose. When prescribed wind loading governs the stress or drift design, the resisting system still must conform to the special requirements for seismic-force-resisting systems. This is required in order to resist, in a ductile manner, potential seismic loads in excess of the prescribed wind loads. A proper, continuous load path is an obvious design requirement, but experience has shown that it often is overlooked and that significant damage and collapse can result. The basis for this design requirement is two-fold:

1. To ensure that the design has fully identified the seismic-force-resisting system and its appropriate design level and
2. To ensure that the design basis is fully identified for the purpose of future modifications or changes in the structure.

Detailed requirements for analyzing and designing this load path are given in the appropriate design and materials chapters.

C11.1.2 Scope. The scope statement establishes in general terms the applicability of ASCE/SEI 7-05. Certain structures are exempt for the following reasons:

Exemption 1 – Detached one- and two-family dwellings in Seismic Design Categories A, B, and C, along with those located where $S_s < 0.4g$, are exempt because they represent low seismic risks.

Exemption 2 – Structures constructed using the conventional light-frame construction requirements in Section 12.5 are deemed capable of resisting the anticipated seismic forces. While specific elements of conventional light-frame construction may be calculated to be overstressed, typically there is a great deal of redundancy and uncounted resistance in such structures. Detached one- and two-story wood-frame dwellings generally have performed well even in regions of higher seismicity. Section 12.5 adequately provides the level of safety required for such dwellings without imposing any additional requirements.

Exemption 3 – Agricultural storage structures generally are exempt from most code requirements because of the exceptionally low risk to human life involved.

Exemption 4 – Bridges, transmission towers, nuclear reactors, and other structures with special configuration and uses are not covered. The regulations for buildings and building-like structures presented in this document do not adequately address the design and performance of such special structures.

ASCE/SEI 7-05 is not retroactive and usually applies to existing structures only when there is an addition, change of use, or alteration. Minimum acceptable seismic resistance of existing buildings is a policy issue normally set by the authority having jurisdiction. Appendix 11B of the standard contains rules of application for basic conditions. ASCE/SEI 31, *Seismic Evaluation of Buildings*, and ASCE/SEI 41, *Seismic Rehabilitation of Existing Buildings*, provide technical guidance but do not contain policy recommendations. A chapter in the *International Building Code* (IBC) applies to alteration, repair, addition, and change of occupancy of existing buildings, and the International Code Council maintains the *International Existing Building Code* (IEBC) and an associated commentary.

C11.1.4 Alternate Materials and Alternate Means and Methods of Construction. It is not possible for a design standard to provide criteria for the use of all possible materials and their combinations and methods of construction, either existing or anticipated. While not citing specific materials or methods of construction currently available that require approval, this section serves to emphasize that the evaluation and approval of alternate materials and methods require a recognized and accepted approval system. The requirements for materials and methods of construction contained within the document represent the judgment of the best use of the materials and methods based on well-established expertise and historical seismic performance. It is important that any replacement or substitute be evaluated with an understanding of all the ramifications of performance, strength, and durability implied by the standard.

It also is recognized that until needed standards and agencies are created, authorities having jurisdiction need to operate on the basis of the best evidence available to substantiate any application for alternates. If accepted standards are lacking, it is strongly recommended that applications be supported by extensive reliable data obtained from tests simulating, as closely as is practically feasible, the actual load and deformation conditions to which the material is expected to be subjected during the service life of the structure. These conditions, when applicable, should include several cycles of full reversals of loads and deformations in the inelastic range.

C11.4 SEISMIC GROUND MOTION VALUES[1]

The approach adopted in Section 11.4 is intended to provide for a uniform margin against collapse at the design ground motion. In order to accomplish this objective, ground motion hazards are defined in terms of maximum considered earthquake (MCE) ground motions, which are based on a set of rules that depend on the seismic hazard of a region. Design ground motions are based on a lower bound estimate of the margin against collapse inherent in structures designed to the seismic provisions in the standard. This lower bound was judged, based on experience, to correspond to a factor of about 1.5 in ground motion. Consequently, the design earthquake ground motion was selected at a ground shaking level that is 1/1.5 (or 2/3) of the MCE ground motion.

For most regions of the nation, the MCE ground motion is defined with a uniform probability of exceedance of 2 percent in 50 years (return period of about 2500 years). While stronger shaking than this could occur, it was judged that it would be economically impractical to design for such very rare ground motions and that the selection of the 2 percent probability of exceedance in 50 years as the MCE ground motion would result in acceptable levels of seismic safety.

In regions of high seismicity, such as in many areas of California, the seismic hazard is typically controlled by large-magnitude events occurring on a limited number of well-defined fault systems. Probabilistic ground motions calculated at a 2 percent probability of exceedance in 50 years can be much larger than deterministic ground motions computed based on the characteristic magnitudes of earthquakes on these known active faults. These probabilistic motions are greater if these major active faults produce characteristic earthquakes every few hundred years. For these regions, it is considered more appropriate to determine MCE ground motions directly by deterministic methods based on the characteristic earthquakes of these defined faults. In order to provide an appropriate level of conservatism in the design process when the deterministic approach is used to calculate MCE ground motion, the median ground motion estimated for the characteristic event is multiplied by 1.5.

C11.4.1 Mapped Acceleration Parameters. In the general procedure, these motions are computed from mapped values of the spectral response acceleration at short periods, S_S , and at 1 second, S_1 , for Class B sites. These S_s and S_1 values may be obtained directly from Figures 22-1 through 22-14 (in Chapter 22). Development of these maps is explained in detail in Appendix A of the *Part 2 – Commentary* volume of the 2003 *NEHRP Recommended Provisions*. The 2003 S_s and S_1 values also can be obtained from the U.S. Geological Survey (USGS) website: http://earthquake.usgs.gov/designmaps.

S_S is the mapped value of the 5-percent-damped MCE spectral response acceleration for short-period structures founded on Site Class B (firm rock) sites. The short-period acceleration has been determined at a period of 0.2 second because it was concluded that 0.2 second was reasonably representative of the shortest effective period of buildings and structures that are designed using the standard, considering the effects of soil compliance, foundation rocking, and other factors typically neglected in structural analysis.

Similarly, S_1 is the mapped value of the 5-percent-damped MCE spectral response acceleration at a period of 1 second on Site Class B. The spectral response acceleration at periods other than 1 second typically can be derived from the acceleration at 1 second. Consequently, for MCE ground shaking on Site Class B sites, these two response acceleration parameters, S_S and S_1, are sufficient to define an entire response spectrum for the period range of importance for most buildings and structures.

C11.4.3 and C11.4.4 Site Coefficients and Adjusted Acceleration Parameters. Using the general procedure to obtain acceleration response parameters that are appropriate for sites with a classification other than Site Class B, the S_S and S_1 values must be modified as indicated in Section 11.4.3. This modification is performed using two coefficients, F_a and F_v, that respectively scale the S_S and S_1 values determined for Site Class B to values appropriate for other site classes. The MCE spectral response accelerations adjusted for site class are designated S_{MS} and S_{M1}, respectively, for short-period and 1-second-period response. As described above, structural design in ASCE/SEI 7-05 is performed for earthquake demands that are 2/3 of the MCE response spectra. As set forth in Section 11.4.4, two additional parameters, S_{DS} and S_{D1}, are used to define the acceleration response spectrum for this design level event. These parameters are 2/3 of the respective S_{MS} and S_{M1} values and define a design response spectrum for sites of any characteristics and for natural periods of vibration less than the transition period, T_L. Values of S_{MS}, S_{M1}, S_{DS}, and S_{D1} can also be obtained from the USGS website cited above.

The site coefficients, F_a and F_v, presented respectively in Tables 11.4-1 and 11.4-2 for the various site classes are based on the results of empirical analyses of strong-motion data and analytical studies of site response.

The amount of ground-motion amplification by a soil deposit relative to bedrock depends on the wave-propagation characteristics of the soil, which can be estimated from measurements or inferences of shear-wave velocity and in turn the

[1] Note that this section focuses on the methods and design procedures of ASCE/SEI 7-05 and the 2003 edition of the *Provisions*; commentary on the new risk-targeted maps and design procedures is presented in Part 1 of this volume following the modifications to ASCE 7 Section 11.4 and Chapter 22.

shear modulus for the materials as a function of the level of shaking. In general, softer soils with lower shear-wave velocities exhibit greater amplifications than stiffer soils with higher shear-wave velocities. Increased levels of ground shaking result in increased soil stress-strain nonlinearity and increased soil damping which, in general, reduces the amplification, especially for shorter periods. Furthermore, for soil deposits of sufficient thickness, soil amplification is generally greater at longer periods than at shorter periods.

An extensive discussion of the development of the F_a and F_v site coefficients is presented by Dobry, et al. (2000). Since the development of these coefficients and the development of a community consensus regarding their values in 1992, earthquake events have provided additional strong-motion data from which to infer site amplifications. Analyses conducted on the basis of these more recent data are reported by a number of researchers including Crouse and McGuire (1996), Dobry et al. (1999), Silva et al. (2000), Joyner and Boore (2000), Field (2000), Steidl (2000), Rodriquez-Marek et al. (2001), Borcherdt (2002), and Stewart et al. (2003). Although the results of these studies vary, the site amplification factors are generally consistent with those in Tables 11.4-1 and 11.4-2.

C11.4.5 Design Response Spectrum. The design response spectrum (Figure 11.4-1) consists of several segments. The constant-acceleration segment covers the period band from T_o to T_s; response accelerations in this band are constant and equal to S_{DS}. The constant-velocity segment covers the period band from T_s to T_L, and the response accelerations in this band are proportional to $1/T$ with the response acceleration at 1-sec period equal to S_{D1}. The long-period portion of the design response spectrum is defined on the basis of the parameter, T_L, the period that marks the transition from the constant-velocity segment to the constant-displacement segment of the design response spectrum. Response accelerations in the constant-displacement segment, where $T \geq T_L$, are proportional to $1/T^2$. Values of T_L are provided on maps in Figures 22-15 through 22-20.

The T_L maps were prepared following a two-step procedure. First, a correlation between earthquake magnitude and T_L was established. Then, the modal magnitude from deaggregation of the ground-motion seismic hazard at a 2-second period (1-second period for Hawaii) was mapped. Details of the procedure and the rational for it are found in Crouse et al. (2006).

C11.4.7 Site-Specific Ground Motion Procedures. The objective of a site-specific ground-motion analysis is to determine ground motions for local seismic and site conditions with higher confidence than is possible using the general procedure of Sections 11.4.

Near-source effects on horizontal response spectra for periods of vibration greater than approximately 0.5 second include directivity, which increases ground motions for fault rupture propagating toward the site, and directionality, which increases ground motions normal (perpendicular) to the strike of the fault. These effects are discussed in Somerville et al. (1997) and Abrahamson (2000).

C11.5 IMPORTANCE FACTOR AND OCCUPANCY CATEGORY

Large earthquakes are rare events that will include severe ground motions. Such events are expected to result in damage to structures even if they were designed and built in accordance with the minimum requirements of the standard. The consequence of structural damage or failure is not the same for the various types of structures located within a given community. Serious damage to certain classes of structures, such as critical facilities (e.g., hospitals), will disproportionally affect a community. The fundamental purpose of this section and subsequent requirements that depend on this section is to improve the ability of a community to recover from a damaging earthquake by tailoring the seismic protection requirements to the relative importance of that structure. That purpose is achieved by requiring better performance of those structures that:

1. Are necessary to response and recovery efforts immediately following an earthquake,
2. Present the potential for catastrophic loss in the event of an earthquake, or
3. House a very large number of occupants or occupants less able to care for themselves than the average.

The first basis for seismic design in the standard is that structures will have a suitably low likelihood of collapse in the very rare event defined as the maximum considered earthquake (MCE) ground motion. A second basis is that life threatening damage, primarily from failure of nonstructural elements in and on structures, will be unlikely in an unusual but less rare earthquake ground motion, which is given as the design earthquake ground motion (defined as two-thirds of the MCE). Given the occurrence of ground motion equivalent to the MCE, a population of structures built to meet these design objectives will probably still experience substantial damage in many structures, rendering these structures unfit for occupancy or use. Experience in past earthquakes around the world has demonstrated that there will be an immediate need to treat injured people, to extinguish fires and prevent conflagration, to rescue people from severely damaged or collapsed structures, and to provide sustenance to a population deprived of its normal means. Experience also has shown that these needs are best met when structures essential to response and recovery activities remain functional.

The standard addresses these objectives by requiring that each structure be assigned to one of the four occupancy categories presented in Chapter 1 and by assigning an importance factor to the structure based upon that occupancy category. (The two lowest categories, Ordinary and Low Hazard, are combined for all purposes within the seismic provisions). The occupancy category is then used as one of two components in determining the Seismic Design Category (see Section C11.6) and is a primary factor in setting drift limits for building structures under the design earthquake ground motion (see Section C12.12).

Figure C11.5-1 shows the combined intent of these requirements for design. The vertical scale is the likelihood of the ground motion with the MCE being the rarest considered. The horizontal scale is the level of performance of the structure and attached nonstructural components from collapse prevention at the low end to operational at the high end. (These performance levels are discussed further at other locations in the commentary.) The basic objective of collapse prevention at the MCE for ordinary structures (Occupancy Category II) is shown at the lower right by the solid triangle; protection from life-threatening damage at the design ground motion (defined by the standard as two-thirds of the MCE) is shown by the open triangle. The performance implied for higher occupancy categories is shown by square and circles. The performance anticipated for less severe ground motion is shown by dotted symbols. The three (net) classes and the numerical values assigned are far too coarse to assure the portrayed outcome for all structures, but it is judged to be adequate for the purpose given present limitations of knowledge and tools.

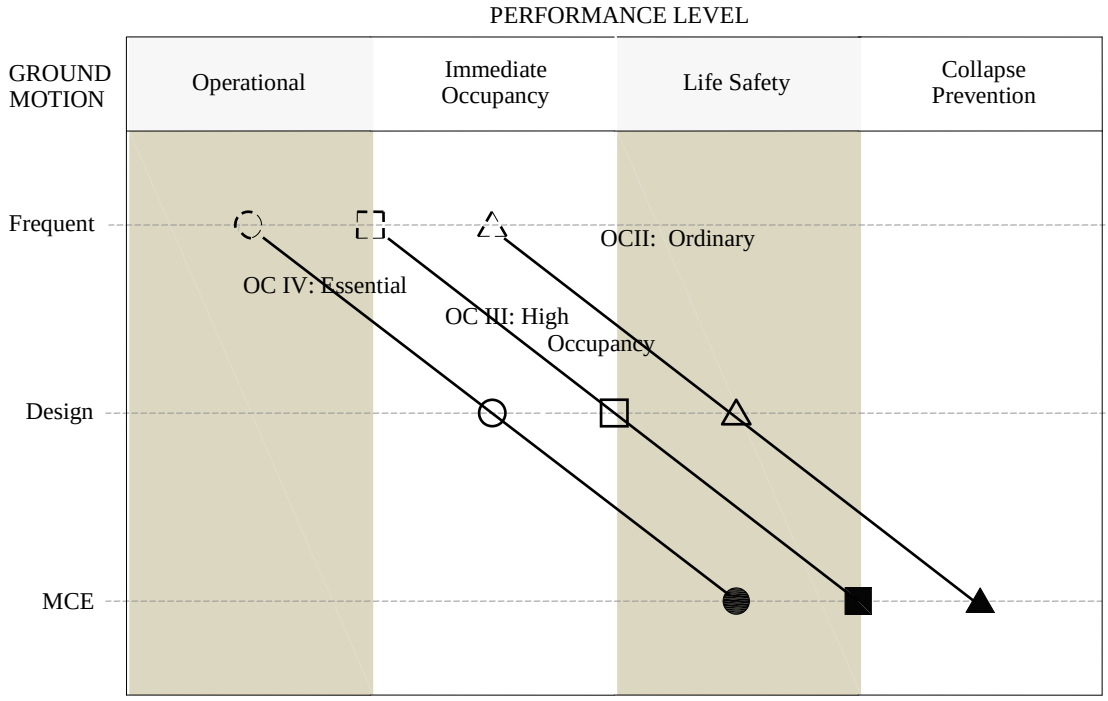

Figure C11.5-1 Expected performance as related to occupancy category (OC) and level of ground motion.

C11.5.1 Importance Factor. The importance factor is used throughout the standard in quantitative criteria for strength. In most of those quantitative criteria, the importance factor is shown as a divisor on the factor R or R_p in order to send a message to designers that the objective is to reduce damage for important structures in addition to preventing collapse in larger ground motions. The R and R_p factors adjust the computed linear elastic response to a value appropriate for design; in many structures, the largest component of that adjustment is ductility (the ability of the structure to undergo repeated cycles of inelastic strain in opposing directions). Inelastic strain damages a structure so, for a given strength demand, reducing the effective R factor (by means of the importance factor) increases the required yield strength, thus reducing ductility demand and related damage.

C11.5.2 Protected Access for Category IV Structures. Those structures considered essential facilities for response and recovery efforts must be accessible to carry out their purpose. For example, if the collapse of a simple canopy at a hospital could block ambulances from the emergency room admittance area, the canopy must meet the same structural standard as the hospital. This requirement must be considered in the siting of essential facilities in densely built urban areas.

C11.6 SEISMIC DESIGN CATEGORIES

Seismic design categories (SDCs) provide a means to step progressively from simple, easily performed design and construction procedures and minimums to more sophisticated, detailed, and costly requirements as both the level of seismic hazard and the consequence of failure escalate. The SDCs are used to trigger requirements that are not scalable; such requirements are either on or off. For example, the basic amplitude of ground motion for design is scalable – the quantity simply increases in a continuous fashion as one moves from a low hazard area to a high hazard area. However, a requirement to avoid weak stories is not particularly scalable. Requirements such as this create step functions. There are many such requirements in the standard, and the SDCs are used systematically to group these step functions. (Further examples include whether seismic anchorage of nonstructural items is required or not, whether particular inspections will be required or not, and height limits applied to various structural systems.)

In this regard, SDCs perform one of the functions of the seismic zones used in earlier U.S. building codes and still in use throughout much of the world. However, SDCs also are dependent on a building's occupancy and, therefore, its desired performance. Further, unlike the traditional implementation of seismic zones, the ground motions used to define the SDCs include the effects of individual site conditions on probable ground-shaking intensity.

In developing the ground-shaking limits for the various Seismic Design Categories and the design requirements for each, the equivalent modified Mercalli intensity (MMI) of various shaking spectra were considered. There are now various correlations of the qualitative MMI with quantitative characterizations of ground. The reader is encouraged to consult any of a great many sources that describe the MMIs. The following list is a very coarse generalization:

MMI V	No real damage
MMI VI	Light nonstructural damage
MMI VII	Hazardous nonstructural damage
MMI VIII	Hazardous damage to susceptible structures
MMI IX	Hazardous damage to robust structures

When the current design philosophy was adopted (the 1997 edition of the *NEHRP Recommended Provisions*, FEMA 302, and *Commentary*, FEMA 303), the upper limit for SDC A was set at roughly one-half of the lower threshold for MMI VII and the lower limit for SDC D was set at roughly the lower threshold for MMI VIII. However, the lower limit for SDC D was more consciously established by equating that design value (two-thirds of the MCE) to one-half of what had been the maximum design value in building codes over the period of 1975 to 1995. As more correlations between MMI and numerical representations of ground motion have been created, it is reasonable to make the following correlation between the MMI at MCE ground motion and the Seismic Design Category (all this discussion is for ordinary occupancies):

MMI V	SDC A
MMI VI	SDC B
MMI VII	SDC C
MMI VIII	SDC D
MMI IX	SDC E

An important change was made to the determination of SDC when the current design philosophy was adopted. Earlier editions of the *Provisions* utilized the peak velocity-related acceleration, A_v, to determine a building's Seismic Performance Category. However, this coefficient does not adequately represent the damage potential of earthquakes on sites with soil conditions other than rock. Consequently, the 1997 *Provisions* adopted the use of response spectral acceleration parameters S_{DS} and S_{D1}, which include site soil effects for this purpose.

Except for the lowest level of hazard (SDC A), the SDC also depends on the occupancy categories. For a given level of ground motion, the SDC is one category higher for Occupancy Category IV structures than for lower-risk structures. This has the effect of increasing the confidence that the design and construction requirements will deliver the intended performance in the extreme event.

Note that the tables in the standard are at the design level, defined as two-thirds of the MCE level. Also recall that the MMIs are qualitative by their nature and that the above correlation will be more or less valid depending on which numerical correlation for MMI is used. The numerical correlations for MMI roughly double with each step so correlation between design earthquake ground motion and MMI is not as simple or convenient.

In sum, at the MCE level, SDC A structures should not see motions that are normally destructive to structural systems, whereas the MCE level motions for SDC D structures can destroy vulnerable structures. The grouping of step function

requirements by SDC is such that there are a few basic structural integrity requirements imposed at SDC A graduating to a suite of requirements at SDC D based upon observed performance in past earthquakes, analysis, and laboratory research.

The nature of ground motions within a few kilometers of a fault can be very different from more distant motions. For example, some near fault motions will have strong velocity pulses, associated with forward rupture directivity, that tend to be highly destructive to irregular structures even if they are well detailed. For ordinary occupancies, the boundary between SDCs D and E is set to define sites likely to be close enough to a fault that these unusual ground motions may be present. Note that this boundary is defined in terms of mapped bedrock outcrop motions affecting response at 1 second, not site adjusted values, in order to better discriminate between sites near and far from faults. Short-period response is not normally as affected as the longer period response. The additional design criteria imposed on structures in SDCs E and F specifically are intended to provide acceptable performance under these very intense near-fault ground motions.

For most buildings, the SDC is determined without consideration of the building's period. Structures are assigned to a SDC based on the more severe condition determined from 1-second acceleration and short-period acceleration. This is done for several reasons. Perhaps the most important of these is that it is often difficult to estimate precisely the period of a structure using default procedures contained in the standard. Consider, for example, the case of rigid wall/flexible diaphragm buildings including low-rise reinforced masonry and concrete tilt-up buildings with either untopped metal deck or wood diaphragms. The formula in the standard for determining the period of vibration of such buildings is based solely on the height of the structure and the length of wall present. These formulas typically indicate very short periods for such structures, often on the order of 0.2 second or less. However, the actual dynamic behavior of these buildings often is dominated by the flexibility of the diaphragm – a factor neglected by the approximate period formula. Large buildings of this type can have actual periods on the order of 1 second or more. In order to avoid misclassifying a building's SDC by inaccurately estimating the structural period, the standard generally requires that the more severe SDC determined on the basis of short- and long-period shaking be used.

Another reason for this requirement is a desire to simplify building regulation by requiring all buildings on a given soil profile in a particular region to be assigned to the same SDC regardless of the structural type. This has the advantage of permitting uniform regulation of structural system selection, inspection and testing requirements, seismic design requirements for nonstructural components, and similar aspects of the design process regulated on the basis of SDC, within a community.

Notwithstanding the above, it is recognized that classification of a building as SDC C instead of B or D can have significant impact on the cost of construction. Therefore, the 2005 edition of the standard includes an exception permitting the classification of buildings that can reliably be classified as having short structural periods on the basis of short-period shaking alone.

Local or regional jurisdictions enforcing building regulations may desire to consider the effect of the maps, typical soil conditions, and Seismic Design Categories on the practices in their jurisdictional areas. For reasons of uniformity of practice or reduction of potential errors, adopting ordinances could stipulate particular values of ground motion, particular site classes, or particular Seismic Design Categories for all or part of the area of their jurisdiction. For example:

1. An area with a historical practice of high seismic zone detailing might mandate a minimum SDC of D regardless of ground motion or site class.
2. A jurisdiction with low variation in ground motion across the area might stipulate particular values of ground motion rather than requiring use of the maps.
3. An area with unusual soils might require use of a particular Site Class unless a geotechnical investigation proves a better Site Class.

C11.7 DESIGN REQUIREMENTS FOR SEISMIC DESIGN CATEGORY A

Seismic Design Category A is assigned when the MCE ground motions are well known to be below those normally associated with hazardous damage. Damaging earthquakes are not unknown or impossible in such regions, however, and ground motions close to such events may be large enough to produce serious damage. Providing a minimum level of resistance reduces both the radius over which the ground motion exceeds structural capacities and resulting damage in such rare events. There are reasons beyond seismic risk for minimum levels of structural integrity.

The requirements for SDC A are all minimum strengths for structural elements stated as forces at the level appropriate for direct use in the strength design load combinations. The two fundamental requirements are a minimum strength for a structural system to resist lateral forces and a minimum strength for connections of structural members.

For many buildings the wind force will control the strength of the lateral-force-resisting system but, for low-rise buildings of heavy construction with large plan aspect ratio, the minimum lateral force specified here may control. Note that the requirement is for strength and not for toughness, energy dissipation capacity, or some measure of ductility. The force level is not tied to any postulated seismic ground motion. The boundary between SDCs A and B is based on a spectral response acceleration of 25 percent of gravity (MCE level) for short-period structures; clearly the 1 percent acceleration level (Equation 11.7-1) is far smaller. For ground motions below the A/B boundary, the spectral displacements generally are on the order of a few inches or less depending on period. Experience has shown that even a minimal strength is beneficial in providing resistance to small ground motions, and it is an easy provision to implement in design. The low probability of motions greater than the MCE is a factor in taking the simple approach without requiring details that would produce a ductile response. Another factor is that larger design forces are specified for connections between main elements of the lateral force load path.

The minimum connection force is specified in three ways: a general minimum horizontal capacity for all connections; a special minimum for horizontal restraint of beams and trusses in line, which also includes the live load on the member; and a special minimum for horizontal restraint of concrete and masonry walls perpendicular to their plane. The 5 percent coefficient used for the first two is a simple and convenient value that provides some margin over the minimum strength of the system as a whole. The value for anchorage of concrete and masonry walls is simply scaled upward from the value of 200 pounds per linear foot traditionally used in past building codes for allowable stress design.

C11.8 GEOLOGIC HAZARDS AND GEOTECHNICAL INVESTIGATION

In addition to this commentary, Part 3 of the 2009 *NEHRP Recommend Provisions* includes additional and more detailed discussion and guidance on evaluation of geologic hazards and determination of seismic lateral pressures.

C11.8.1 Site Limitation for Seismic Design Categories E and F. Because of the difficulty of designing a structure for the direct shearing displacement of fault rupture and the relatively high seismic activity of SDCs E and F, locating a structure on an active fault having the potential to cause rupture of the ground surface at the structure is prohibited.

C11.8.3 Additional Geotechnical Investigation Report Requirements for Seismic Design Categories D through F. The dynamic lateral earth pressure on basement and retaining walls during earthquake ground shaking is considered to be an earthquake load, *E*, for use in design load combinations. This dynamic earth pressure is superimposed on the pre-existing static lateral earth pressure during ground shaking. The pre-existing static lateral earth pressure is considered to be an *H* load.

Liquefaction potential should be evaluated for design earthquake ground motions consistent with peak ground accelerations of $S_{DS}/2.5$. The occurrence and consequences of geologic hazards for MCE ground motions also should be considered when evaluating structural stability and other pertinent performance criteria.

COMMENTARY TO CHAPTER 12, SEISMIC DESIGN REQUIREMENTS FOR BUILDING STRUCTURES

C12.1 STRUCTURAL DESIGN BASIS

The performance expectations for structures designed in accordance with ASCE/SEI 7-05 are described in Sections C11.1 and C11.5. Structures designed in accordance with the standard are likely to have a low probability of collapse but suffer serious damage if subjected to the maximum considered earthquake (MCE) or stronger ground motion. The uncertainty in performance results from variability of both ground motion and structural characteristics.

Earthquakes load structures indirectly. As the ground displaces, a structure follows and vibrates. The vibration produces structural deformations with associated strains and stresses. Computation of dynamic response to earthquake ground shaking is complex. The basic methods of analysis in the standard employ the common simplification of a response spectrum. A response spectrum for a specific earthquake ground motion approximates the maximum value of response to that ground motion for simple structures without reflecting the total time history of response. The design response spectrum specified in Section 11.4 and used in the basic methods of analysis in Chapter 12 is a smoothed and normalized approximation for many different ground motions.

Although the seismic requirements of the standard are stated in terms of forces and loads, there are no external forces applied to the above-ground portion of a structure during an earthquake. The design forces are intended only as approximations to generate internal forces suitable for proportioning the strength of structural elements and for estimating the deformations (when multiplied by the deflection amplification factor, C_d) that would occur in the same structure in the event of design-level (not MCE) ground motion.

C12.1.1 Basic Requirements. Chapter 12 of the standard sets forth a set of coordinated requirements that must be used together. The basic steps in structural design for acceptable seismic resistance are as follows:

1. Select gravity- and seismic-force-resisting systems appropriate to the anticipated intensity of ground shaking. Section 12.2 sets forth limitations depending on the Seismic Design Category.
2. Lay out these systems to produce a continuous, regular, and redundant load path so that the structures act as integral units in responding to ground shaking. Section 12.3 addresses configuration and redundancy issues.
3. Analyze a mathematical model of the structure subjected to lateral seismic motions and gravity forces. Sections 12.6 and 12.7 set forth requirements for the method of analysis and for construction of the mathematical model.
4. Proportion members and connections to have adequate lateral and vertical strength and stiffness. Section 12.4 specifies how the effects of gravity and seismic loads are to be combined to establish required strengths, and Section 12.12 specifies deformation limits for buildings.

One- to three-story structures with shear wall or braced frame systems of simple configuration may be eligible for design under the simplified alternative contained in Section 12.14. Any other deviations from the requirements of Chapter 12 are subject to approval and must be rigorously consistent as specified in Section 11.1.4.

The baseline seismic forces for proportioning structural elements (individual members, connections, and supports) are static horizontal forces derived from a linear elastic response spectrum procedure. A basic requirement is that horizontal motion can come from any direction, with detailed requirements being provided in Section 12.5. For most structures, the effect of vertical ground motions is not analyzed specifically; it is included in an approximate fashion by adjusting the load factors for dead load up and down, as described in Section 12.4. Certain conditions requiring more detailed analysis of vertical response are defined in Chapters 13 and 15 for nonstructural components and nonbuilding structures, respectively.

Higher levels of seismic analysis are permitted (and encouraged) for any structure and are required for some structures (see Section 12.6), but lower limits based on the equivalent lateral force procedures apply. The basic procedure uses response spectra that are representative of, but substantially reduced from, the anticipated ground motions. As a result, at the MCE level of ground shaking, structural elements are expected to yield, buckle, or otherwise behave inelastically.

This approach has substantial historical precedent. In past earthquakes, structures with appropriately ductile, regular, continuous systems designed for reduced forces have performed acceptably. In the standard, such design forces are computed by dividing the forces that would be generated in a structure behaving linearly when subjected to the design ground motion by the response modification coefficient, R, and the design ground motion is taken as two-thirds of the MCE ground motion.

The elastic deformations calculated under these reduced design forces are multiplied by the deflection amplification factor, C_d, to estimate the deformations likely to result from the design ground motion. As set forth in Sections 12.12 and 13, the amplified deformations are used to assess story drifts and to determine seismic demands on elements of the structure that are not part of the seismic-force-resisting system and on nonstructural components within structures. Where C_d is substantially less than R, the system is considered to have damping greater than the nominal 5 percent of critical damping.

The seismic-force-resisting system is expected to reach significant yield for forces in excess of the design forces. Significant yield is the point where complete plastification of the most critical region of the structure (e.g., formation of a first plastic hinge in the structure) occurs, not the point where first yield occurs in any member. Figure C12.1-1 shows the lateral force versus deformation relation for a typical structure. Significant yield is shown as the lowest yield hinge on the force-deformation diagram. With increased lateral loading, additional plastic hinges form and the resistance increases (following the solid curve) until a maximum is reached. The maximum resistance developed along the curve is substantially higher than that at first significant yield, and the margin is referred to as the overstrength capacity.

The provisions of the standard contemplate a seismic-force-resisting system with redundant characteristics wherein significant structural overstrength above the level of significant yield can be obtained by plastification at other points in the structure prior to the formation of a complete mechanism. The overstrength obtained by this continued inelastic action provides the reserve strength necessary for the structure to resist the extreme motions of the actual seismic forces that may be generated by the design ground motion.

The structural overstrength described above results from the development of sequential plastic hinging in a properly designed, redundant structure. Several other sources will further increase structural overstrength. First, material overstrength (i.e., actual material strengths higher than the nominal material strengths specified in the design) may increase the structural overstrength significantly. For example, a recent survey shows that the mean yield strength of A36 steel is about 30 to 40 percent higher than the minimum specified strength used in design calculations. Second, member design strengths usually incorporate a strength reduction (or resistance) factor, Φ, to produce a low probability of failure under design loading. Third, designers themselves introduce additional overstrength by selecting sections or specifying reinforcing patterns that exceed those required by the computations. Similar situations occur where prescriptive minimums of the standard, or of the design standards referenced from it, control the design. Finally, the design of many flexible structural systems (e.g., moment resisting frames) often is controlled by the drift rather than strength limitations of the standard with sections selected to control lateral deformations rather than to provide the specified strength.

The result is that structures typically have a much higher lateral resistance than that specified as a minimum by the standard, and first significant yielding of structures may occur at lateral load levels that are 30 to 100 percent higher than the prescribed design seismic forces. If provided with adequate ductile detailing, redundancy and regularity, full yielding of structures may occur at load levels that are two to four times the prescribed design force levels.

Most structural systems have some components or limit states that cannot provide reliable inelastic response or energy dissipation. Such components or limit states must be designed considering that the actual forces in the structure will be larger than those at first significant yield. The standard specifies an overstrength factor, Ω_0, to amplify the prescribed forces for use in design of such components or limit states. This specified overstrength factor is neither an upper nor a lower bound; it is simply an approximation specified to provide a nominal degree of protection against undesirable behavior.

Figure C12.1-1 illustrates the significance of design parameters contained in the standard including the response modification coefficient, R; the deflection amplification factor, C_d; and the system overstrength factor, Ω_0. These design values, provided in Table 12.2-1, as well as the criteria for story drift and *P*-delta effects, have been established considering the characteristics of typical properly designed structures. The actual structural overstrength, Ω, often will be less than the tabulated factor, Ω_0. This means that the required ductility, R_d, usually will exceed R/Ω_0. If excessive "optimization" of a structural design is performed with lateral resistance provided by only a few elements, the successive yield hinge behavior depicted in Figure C12.1-1 will not be able to form, the actual overstrength (Ω) will be small, and use of the design parameters in the standard may not provide the intended seismic performance.

The response modification coefficient, R, represents the ratio of the forces that would develop under the specified ground motion if the structure had entirely linear-elastic response to the prescribed design forces (see Figure C12.1-1). The structure must be designed so that the level of significant yield exceeds the prescribed design force. The ratio R, expressed as $R = V_E / V_S$, is always larger than 1.0; thus, all structures are designed for forces smaller than those the design ground motion would produce in a structure with completely linear-elastic response. This reduction is possible for a number of reasons. As the structure begins to yield and deform inelastically, the effective period of response of the structure lengthens which, for most structures, results in a reduction in strength demand. Furthermore, the inelastic action results in a significant amount of energy dissipation (hysteretic damping) in addition to other sources of damping present below significant yield. The combined effect, which is also known as the ductility reduction, explains why a properly designed structure with a fully

yielded strength (V_y in Figure C12.1-1) that is significantly lower than the elastic seismic force demand (V_E in Figure C12.1-1) can be capable of providing satisfactory performance under the design ground motion excitations.

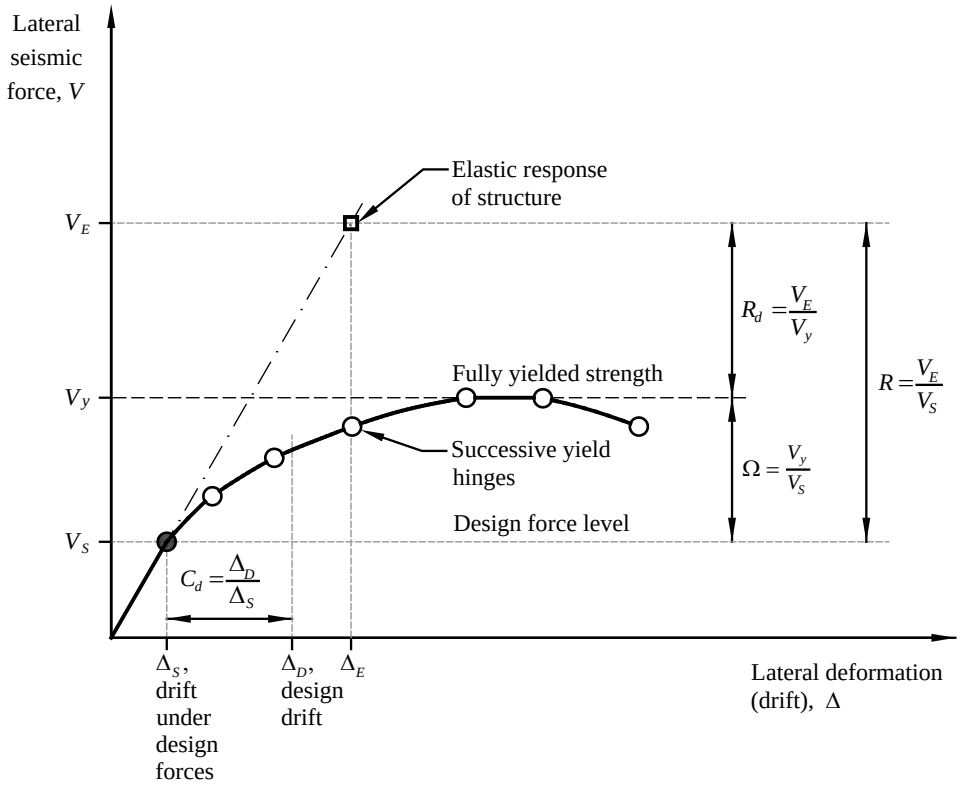

Figure C12.1-1 Inelastic force-deformation curve.

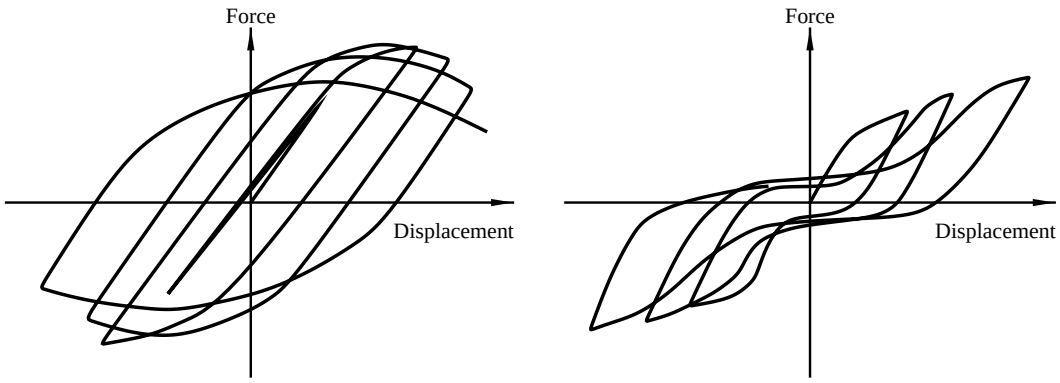
The energy dissipation resulting from hysteretic behavior can be measured as the area enclosed by the force-deformation curve of the structure as it experiences several cycles of excitation. Some structures have far more energy dissipation capacity than others. The extent of energy dissipation capacity available depends largely on the amount of stiffness and strength degradation the structure undergoes as it experiences repeated cycles of inelastic deformation. Figure C12.1-2 shows representative load deformation curves for two simple substructures such as a beam-column assembly in a frame. Hysteretic curve (a) in the figure is representative of the behavior of substructures that have been detailed for ductile behavior. The substructure can maintain nearly all of its strength and stiffness over several large cycles of inelastic deformation. The resulting force-deformation "loops" are quite wide and open, resulting in a large amount of energy dissipation. Hysteretic curve (b) represents the behavior of a substructure that has not been detailed for ductile behavior. It loses stiffness rapidly under inelastic deformation, and the resulting hysteretic loops are quite pinched. Such a substructure has much less energy dissipation than that for the substructure (a) but has a greater change in response period. The structural response is determined by a combination of energy dissipation and period modification.

The *R* values in the standard are based largely on engineering judgment of the performance of the various materials and systems in past earthquakes. The *R* factor for a specific project should be chosen and used with care. For example, lower values should be used for structures possessing a low degree of redundancy wherein all the plastic hinges required for the formation of a mechanism may be formed essentially simultaneously and at a force level close to the specified design strength. This situation can result in considerably more detrimental *P*-delta effects. Since it is difficult for individual designers to judge the extent to which *R* factors should be adjusted based on the inherent redundancy of their designs, Section 12.3.4 provides a coefficient, ρ, that is calculated based on the removal of individual seismic-force-resisting elements.

C12.1.2 Member Design, Connection Design, and Deformation Limit. Given that key elements of the seismic-force-resisting system will likely yield in response to ground motions as discussed in Section C12.1.1, it might be expected that structural connections would be required to develop the strength of connected members. Although that is a logical procedure, it is not a general requirement. The actual requirement varies by system and generally is specified in the standards for design of the various structural materials cited by reference in Section 14. Good seismic design requires careful consideration of this issue.



a. Ductile hysteresis loops b. Pinched hysteresis loops

Figure C12.1-2 Typical hysteretic curves.

C12.1.3 Continuous Load Path and Interconnection. In effect, Section 12.1.3 calls for the seismic design to be complete and in accordance with the principles of structural mechanics. The loads must be transferred rationally from their point of origin to the final point of resistance. This should be obvious, but it often is overlooked by those inexperienced in earthquake engineering. Design consideration should be given to potentially adverse effects where there is a lack of redundancy. Given the many unknowns and uncertainties in the magnitude and characteristics of earthquake loading, in the materials and systems of construction for resisting earthquake loadings and in the methods of analysis, good earthquake engineering practice has been to provide as much redundancy as possible in the seismic-force-resisting system of buildings. Redundancy plays an important role in determining the ability of the building to resist earthquake forces. In a structural system without redundant components, every component must remain operative to preserve the integrity of the building structure. On the other hand, in a highly redundant system, one or more redundant components may fail and still leave a structural system that retains its integrity and can continue to resist lateral forces, albeit with diminished effectiveness.

While a redundancy requirement is included in Section 12.3.4, overall system redundancy can be improved by making all joints of the vertical load-carrying frame moment resisting and incorporating them into the seismic-force-resisting system. These multiple points of resistance can prevent a catastrophic collapse due to distress or failure of a member or joint. (The overstrength characteristics of this type of frame are discussed in Section C12.1.1.) The designer should be particularly aware of the proper selection of R when using only one- or two-bay rigid frames in one direction for resisting seismic loads. A single, one-bay frame or a pair of such frames provides little redundancy so the designer may wish to consider a reduced R to account for a lack of redundancy if the calculated redundancy is considered to be too low. As more one-bay frames are added to the system, however, overall system redundancy increases. The increase in redundancy is a function of frame placement and total number of frames.

The minimum connection forces are not intended to be applied simultaneously to the entire seismic-force-resisting system.

C12.1.4 Connection to Supports. The requirement is the same as given in Section 11.7.4 for Seismic Design Category A. See Section C11.7.

C12.1.5 Foundation Design. Most foundation design criteria are still stated in terms of allowable stresses, and the forces computed in the standard are all based on the strength level of response. When developing strength-based criteria for foundations, all the factors cited in Section 12.1.5 require careful consideration. Section C12.13 provides specific guidance.

C12.1.6 Material Design and Detailing Requirements. The design limit state for resistance to an earthquake is unlike that for any other load within the scope of the standard. The earthquake limit state is based on overall system performance, not member performance, where repeated cycles of inelastic straining are accepted as an energy dissipating mechanism. Provisions that modify customary requirements for proportioning and detailing structural members and systems are provided to produce the desired performance.

C12.2 STRUCTURAL SYSTEM SELECTION

C12.2.1 Selection and Limitations. For purposes of these seismic analyses and design requirements, seismic-force-resisting systems are grouped into categories as shown in Table 12.2-1. These categories are subdivided further for various types of vertical elements used to resist seismic forces. In addition, the sections for detailing requirements are specified.

Specification of *R* factors requires considerable judgment based on knowledge of actual earthquake performance as well as research studies. The factors in Table 12.2-1 continue to be reviewed in light of recent research results. *R* values for the various systems were selected considering observed performance during past earthquakes, the toughness (ability to dissipate energy without serious degradation) of the system, and the amount of damping typically present in the system when it undergoes inelastic response. FEMA P-695, *Quantification of Building Seismic Performance Factors* (Applied Technology Council, 2009) has been developed with the purpose of establishing and documenting a methodology for quantifying building system performance and response parameters for use in seismic design. While the response modification coefficient (*R* factor) is a key parameter being addressed, related design parameters such as the system overstrength factor (Ω_0) and deflection amplification factor (C_d) also are addressed. Collectively, these terms are referred to as "Seismic Performance Factors" (SPFs). Future systems will likely derive their SPFs using this methodology and existing system SPFs also may be reviewed in light of this new procedure.

Building height limits have been specified in codes and standards for over 50 years. The structural system limitations and building height limits specified in Table 12.2-1 evolved from these initial limitations and were further modified by the collective expert judgment of the PUC and the ATC-3 project team (the forerunners of the PUC). They have continued to evolve over the past 30 years based on observations and testing, but the specific values are based on subjective judgment.

In a bearing wall system, major load-carrying columns are omitted and the walls carry a major portion of the gravity (dead and live) loads. The walls supply in-plane lateral stiffness and strength to resist wind and earthquake loads as well as other lateral loads. In some cases, vertical trusses are employed to augment lateral stiffness. In general, this system has comparably lower values of *R* than other systems due to the frequent lack of redundancy for support of vertical and horizontal loads.

In a building frame system, gravity loads are carried primarily by a frame supported on columns rather than by bearing walls. Some portions of the gravity load may be carried on bearing walls, but the amount carried should represent a relatively small percentage of the floor or roof area. Lateral resistance is provided by shear walls or braced frames. Light-framed walls with shear panels are intended for use only with wood and steel building frames. Although gravity-load-resisting systems are not required to provide lateral resistance, most of them do. To the extent that the gravity-load-resisting system provides additional lateral resistance, it will enhance the building's seismic performance capability, so long as it is capable of resisting the resulting stresses and undergoing the associated deformations.

In a moment-resisting frame system, moment-resisting connections between the columns and beams provide lateral resistance. In Table 12.2-1, such frames are classified as ordinary, intermediate, or special. In high Seismic Design Categories, the anticipated ground motions are expected to produce large inelastic demands so special moment frames designed and detailed for ductile response in accordance with Chapter 14 are required. In low Seismic Design Categories, the inherent overstrength in typical structural designs is such that the anticipated inelastic demands are reduced somewhat, and less ductile systems may be employed safely. Since these less ductile ordinary framing systems do not possess as much toughness, lower *R* values are specified.

The *R*, Ω_0, and C_d values for the composite systems in Table 12.2-1 are similar to those for comparable systems of structural steel and reinforced concrete. Use of the tabulated values is allowed only when the design and detailing requirements in Section 14.3 are followed.

In a dual system, a three-dimensional space frame made up of columns and beams provides primary support for gravity loads. Primary lateral resistance is supplied by shear walls or braced frames, and secondary lateral resistance is provided by a moment frame complying with the requirements of Chapter 14.

Where a beam-column frame or slab-column frame lacks special detailing, it cannot act as an effective backup to a shear wall subsystem so there are no dual systems with ordinary moment frames. Instead, Table 12.2-1 permits the use of a shear wall-frame interactive system with ordinary reinforced concrete moment frames and ordinary reinforced concrete shear walls. Use of this defined system, which requires compliance with Section 12.2.5.10, offers a significant advantage over a simple combination of the two constituent ordinary reinforced concrete systems. Where those systems are simply combined, Section 12.2.3.2 would require use of design parameters for an ordinary reinforced concrete moment frame.

In a cantilevered column system, stability of mass at the top is provided by one or more columns with base fixity acting as a single-degree-of-freedom system.

Cantilever column systems are essentially a special class of moment-resisting frame except that they do not possess the redundancy and overstrength that most moment-resisting frames derive from sequential formation of yield or plastic hinges. Where a typical moment-resisting frame must form multiple plastic hinges in members in order to develop a yield mechanism, a cantilever column system develops hinges only at the base of the columns to form a mechanism. As a result, their overstrength is limited to that provided by material overstrength and by design conservatism.

It is permitted to construct cantilever column structures using any of the systems that can be used to develop moment frames including ordinary, intermediate, and special steel and concrete detailing systems as well as timber frames. The system limitations for cantilever column systems reflect the type of moment frame detailing provided but with a height limit of 35 feet.

The R factor for cantilever column systems is derived from moment-resisting frame values where R is divided by Ω_0 but is not taken as less than 1 or greater than 3. This accounts for the lack of sequential yielding in such systems. C_d is taken as equal to R, recognizing that damping is quite low in these systems and inelastic displacement of these systems will not be less than the elastic displacement.

C12.2.2 Combinations of Framing Systems in Different Directions. Different systems can be utilized along each of the two orthogonal directions as long as the respective R, Ω_0, and C_d values are used. Depending on the combination selected, it is possible that one of the two systems will limit the extent of the overall system with regard to use and height. The more restrictive of the limitation systems governs.

C12.2.3 Combinations of Framing Systems in the Same Direction.

C12.2.3.1 R, Ω_0, and C_d Values for Vertical Combinations. The intent of the provision requiring us of the more stringent seismic design parameters (R, Ω_0, and C_d) is to prevent mixed systems that could concentrate inelastic behavior in the lower stories. Exceptions to these requirements exist for conditions that do not affect the dynamic characteristics of the structure or that will not result in concentration of inelastic demand in critical areas.

For the past several decades, building codes have allowed two-stage static analysis for certain structures with a vertical combination of dynamically uncoupled systems. While this approach may be used for any structure that meets the requirements, it is most often used for the design of light-framed construction built on a rigid concrete base. The design process requires that the "flexible" upper structure and "rigid" lower structure be designed separately with the reactions from the upper portion amplified by the ratio of respective R/ρ values. This ratio, which must be taken as no less than 1, produces demands for the "rigid" lower portion that are commensurate with its inelastic capability.

C12.2.3.2 R, Ω_0, and C_d Values for Horizontal Combinations. For nearly all conditions, the least value of R of different structural systems in the same direction must be used in design. This requirement reflects the expectation that the entire system will undergo the same deformation with its behavior controlled by the least ductile system. However, where the listed conditions are met, the R value for each independent line of resistance can be used. This exceptional condition is consistent with light-frame construction that utilizes the ground for parking with residential use above.

C12.2.4 Combination of Framing Detailing Requirements. This requirement is provided so that the higher R value system has the necessary ductile detailing throughout. The intent is that details common to both systems be designed to remain functional throughout the response in order to preserve the integrity of the seismic-force-resisting system.

C12.2.5 System Specific Requirements.

C12.2.5.1 Dual System. The moment frame of a dual system must be capable of resisting at least 25 percent of the design seismic forces; this percentage is based on judgment. The purpose of the 25 percent frame is to provide a secondary lateral system with higher degrees of redundancy and ductility in order to improve the ability of the building to support the service loads (or at least the effect of gravity loads) after strong earthquake shaking. The primary system (walls or bracing) acting together with the moment frame must be capable of resisting all of the design seismic forces. The following analyses are required for dual systems:

1. The moment frame and shear walls or braced frames must resist the design seismic forces considering fully the force and deformation interaction of the walls or braced frames and the moment frames as a single system. This analysis must be made in accordance with the principles of structural mechanics considering the relative rigidities of the elements and torsion in the system. Deformations imposed upon members of the moment frame by their interaction with the shear walls or braced frames must be considered in this analysis.
2. The moment frame must be designed with sufficient strength to resist at least 25 percent of the design seismic forces including torsional effects.

C12.2.5.2 Cantilever Column Systems. Cantilever column systems are singled out for special consideration because of their unique characteristics. These structures often have limited redundancy and overstrength and concentrate inelastic behavior at their bases. As a result, they have substantially less energy dissipation capacity than other systems. A number of apartment buildings incorporating this system experienced very severe damage and, in some cases, collapse in the 1994 Northridge earthquake. Because the ductility of columns having large axial stress is limited, cantilever column systems may not be used where column axial demands exceed 15 percent of their axial strength.

Elements providing restraint at the base of cantilever columns must be designed with overstrength so that the strength of the cantilever columns is developed.

C12.2.5.3 Inverted Pendulum-Type Structures. Inverted pendulum-type structures do not have unique entry in Table 12.2-1 since they can be formed from many structural systems. Inverted pendulum-type structures have more than half of their mass concentrated near the top (producing one degree of freedom in horizontal translation) and rotational compatibility of the mass with the column (producing vertical accelerations acting in opposite directions). Dynamic response amplifies this rotation; hence, the bending moment induced at the top of the column can exceed that computed using the procedures of Section 12.8. The requirement to design for a top moment that is one-half of the base moment calculated in accordance with Section 12.8 is based on analyses of inverted pendulums covering a wide range of practical conditions.

C12.2.5.4 Increased Building Height Limit for Steel Braced Frames and Special Reinforced Concrete Shear Walls. The first criterion for an increased building height limit precludes extreme torsional irregularity since premature failure of one of the single walls or frames could lead to excessive inelastic torsional response. The second criterion, which is similar to the redundancy requirements, is to limit the height of systems that are too strongly dependent on any single line of walls or braced frames. The inherent torsion resulting from the distance between the center or mass and center of stiffness must be included, but accidental torsional effects are neglected for ease of implementation.

C12.2.5.5 Special Moment Frames in Structures Assigned to Seismic Design Categories D through F. Special moment frames, either alone or as part of a dual system, are required to be used in Seismic Design Categories D through F where the building height exceeds 160 feet (or 240 feet for buildings that meet the provisions of Section 12.2.5.4) as indicated in Table 12.2-1. In shorter buildings where special moment frames are not required to be used, the special moment frames may be discontinued and supported on less ductile systems as long as the requirements for system combinations are followed.

For the situation where special moment frames are required, they should be continuous to the foundation. In cases where the foundation is located below the building's base, provisions for discontinuing the moment frames can be made as long as the seismic forces are properly accounted for and transferred to the supporting structure.

C12.2.5.6 Single-Story Steel Ordinary and Intermediate Moment Frames in Structures Assigned to Seismic Design Category D or E. Ordinary and intermediate moment frames are less ductile than special moment frames; consequently, restrictions are placed on their use in higher Seismic Design Categories. The height limit of 65 feet and the limitations on roof and wall dead load are intended to restrict the use of such systems to metal buildings and similar one-story structures, the design of which is often controlled by wind forces, and which have generally evidenced acceptable performance in past seismic events.

C12.2.5.7 Other Steel Ordinary and Intermediate Moment Frames in Structures Assigned to Seismic Design Category D or E. Compared to the limits in Section 12.2.5.6, this section imposes a stricter height limit because higher loads and additional stories are permitted. Low-rise light-frame structures that are commonly used in residential construction generally have evidenced adequate performance in past seismic events due to their light weight, abundance of lateral force-resisting elements, and general resilience.

C12.2.5.8 Single-Story Steel Ordinary and Intermediate Moment Frames in Structures Assigned to Seismic Design Category F. See Section C12.2.5.6.

C12.2.5.9 Other Steel Intermediate Moment Frame Limitations in Structures Assigned to Seismic Design Category F. The intent of this section is to prohibit the use of steel ordinary moment frames in light-frame construction that does not comply with Section 12.2.5.8.

C12.2.5.10 Shear Wall-Frame Interactive Systems. For structures assigned to Seismic Design Category A or B (where seismic hazard is low), it is usual practice to design shear walls and frames of a shear wall-frame structure to resist lateral forces in proportion to their relative rigidities, considering interaction between the two subsystems at all levels. As discussed in Section C12.2.1, this typical approach would require use of a lower R factor than that defined for shear wall-frame interactive systems. Where the special requirements of this section are satisfied, more reliable performance is expected, justifying a higher R factor.

C12.3 DIAPHRAGM FLEXIBILITY, CONFIGURATION IRREGULARITIES, AND REDUNDANCY

C12.3.1 Diaphragm Flexibility. Most seismic-force-resisting systems have two distinct parts: the horizontal system that distributes lateral forces to the vertical elements and the vertical system that transmits lateral forces between the floor levels and the base of the structure.

The horizontal system may consist of diaphragms or a horizontal bracing system. For the majority of buildings, diaphragms offer the most economical and positive method of resisting and distributing seismic forces in the horizontal plane. Typically, diaphragms consist of metal deck (with or without concrete), concrete slabs, and wood sheathing/decking. While most diaphragms are flat, consisting of the floors of buildings, they also may be inclined, curved, warped, or folded configurations, and most diaphragms have openings.

The diaphragm stiffness relative to the stiffness of the supporting vertical seismic-force-resisting system ranges from flexible to rigid and is important to define. Provisions defining diaphragm flexibility are given in Sections 12.3.1.1 through 12.3.1.3. If a diaphragm cannot be idealized as either flexible or rigid, explicit consideration of its stiffness must be included in the analysis.

The diaphragms in most buildings braced by wood light-frame shear walls are semi-rigid. Because semi-rigid diaphragm modeling is beyond the capability of available software for wood light-frame buildings, it is anticipated that this requirement will be met by evaluating force distribution using both rigid and flexible diaphragm models and taking the worst case of the two. While this is in conflict with common design practice, which typically includes only flexible diaphragm force distribution for wood light-frame buildings, it is one method of capturing the effect of the diaphragm stiffness.

Further detailed discussion of diaphragms can be found in Delebi, et al. (1980) and in an Applied Technology Council report on diaphragms (1981).

C12.3.1.2 Rigid Diaphragm Condition. Span length is included in the deemed-to-comply condition as an indirect measure of the flexural contribution to diaphragm stiffness.

C12.3.2 Irregular and Regular Classification. The configuration of a structure can significantly affect its performance during a strong earthquake producing the ground motion contemplated in the standard. Configuration can be divided into two aspects: horizontal and vertical. Most seismic design provisions were derived for buildings having regular configurations, but earthquakes have shown repeatedly that buildings having irregular configurations suffer greater damage. This situation prevails even with good design and construction. There are several reasons for this poor behavior of irregular structures. In a regular structure, the inelastic response produced by strong ground shaking, including energy dissipation and damage, tends to be well distributed throughout the structure. However, in irregular structures, inelastic behavior can be concentrated by irregularities and result in rapid failure of structural elements in these areas. In addition, some irregularities introduce unanticipated demands into the structure, which designers frequently overlook when detailing the structural system. Finally, the elastic analysis methods typically employed in the design of structures often cannot predict the distribution of earthquake demands in an irregular structure very well, leading to inadequate design in the areas associated with the irregularity. For these reasons, the standard encourages regular configurations and prohibits gross irregularity in buildings located on sites close to major active faults where very strong ground motion and extreme inelastic demands are anticipated.

C12.3.2.1 Horizontal Irregularity. A building may have a symmetric geometric shape without re-entrant corners or wings but still be classified as irregular in plan because of its distribution of mass or vertical seismic-force-resisting elements. Torsional effects in earthquakes can occur even where the centers of mass and resistance coincide. For example, ground motion waves acting on a skew with respect to the building axis can cause torsion. Cracking or yielding in an asymmetric fashion also can cause torsion. These effects also can magnify the torsion due to eccentricity between the centers of mass and resistance. Torsional irregularities are defined to address this concern.

A square or rectangular building with minor re-entrant corners would still be considered regular, but large re-entrant corners creating a crucifix form would produce an irregular configuration. The response of the wings of this type of building generally differs from the response of the building as a whole, and this produces higher local forces than would be determined by application of the standard without modification. Other winged plan configurations (e.g., H-shapes) are classified as irregular even if symmetric due to the response of the wings.

Significant differences in stiffness between portions of a diaphragm at a level are classified as irregularities since they may cause a change in the distribution of seismic forces to the vertical components and create torsional forces not accounted for in the distribution normally considered for a regular building. Figure C12.3-1 illustrates plan irregularities.

Where there are discontinuities in the path of lateral force resistance, the structure cannot be considered to be regular. The most critical discontinuity defined is the out-of-plane offset of vertical elements of the seismic-force-resisting system. Such offsets impose vertical and lateral load effects on horizontal elements that are difficult to provide for adequately.

Where vertical elements of the lateral-force-resisting system are not parallel to or symmetric about major orthogonal axes, the equivalent lateral force procedure of the standard cannot be applied appropriately so the structure is considered to be irregular.

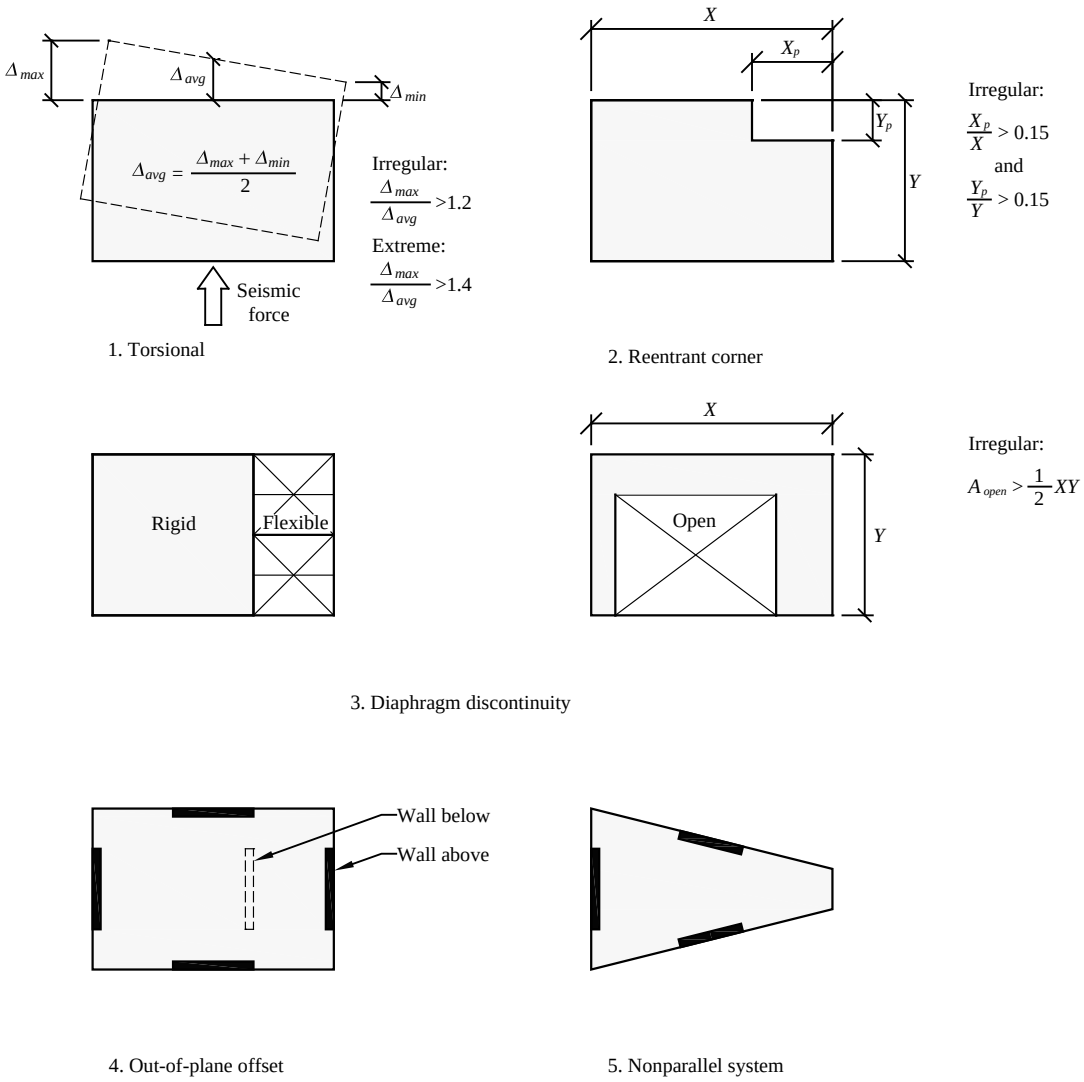


Figure C12.3-1 Building plan irregularities.

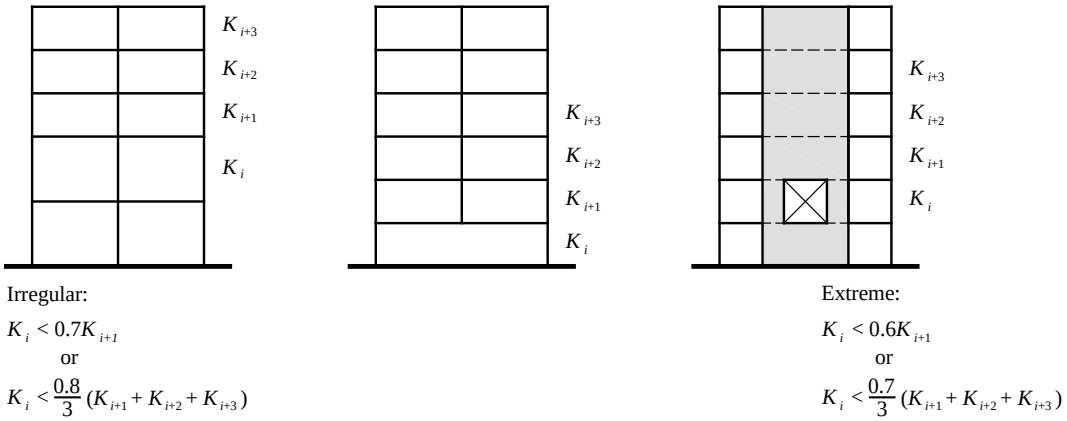
C12.3.2.2 Vertical Irregularity. Vertical configuration irregularities affect the responses at the various levels and induce loads at these levels that differ significantly from the distribution assumed in the equivalent lateral force procedure given in Section 12.8. A moment-resisting frame building might be classified as having a vertical irregularity if one story is much taller than the adjoining stories and the design did not compensate for the resulting decrease in stiffness that normally would occur. Figure C12.3-2 illustrates vertical irregularities.

A building is classified as irregular where the ratio of mass to stiffness in adjacent stories differs significantly. This might occur where a heavy mass (e.g., an interstitial mechanical floor) is placed at one level. Irregularity Type 3 in Table 12.3-2 applies regardless of whether the larger dimension is above or below the smaller one. Buildings with a weak-story irregularity tend to develop all of their inelastic behavior and consequent damage at the weak story, possibly leading to collapse. Section 12.3.3.2 provides an exception for Seismic Design Category B or C structures where essentially elastic response of the weak story is expected.

C12.3.3 Limitations and Additional Requirements for Systems with Structural Irregularities.

C12.3.3.1 Prohibited Horizontal and Vertical Irregularities in Seismic Design Categories D through F. The irregularity prohibitions of this section stem from poor performance in past earthquakes and the potential to concentrate large inelastic demands in certain portions of the structure. Even when such irregularities are permitted, they should be avoided whenever possible in all structures.



Irregular:

$K_i < 0.7K_{i+1}$

or

$K_i < \frac{0.8}{3}(K_{i+1} + K_{i+2} + K_{i+3})$

Extreme:

$K_i < 0.6K_{i+1}$

or

$K_i < \frac{0.7}{3}(K_{i+1} + K_{i+2} + K_{i+3})$

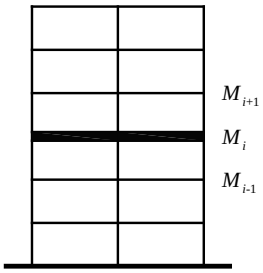
1. Stiffness — Soft Story

Irregular:

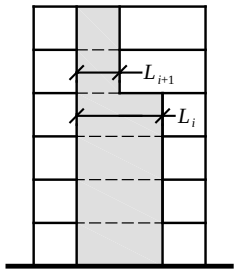
$M_i > 1.5M_{i+1}$

or

$M_i > 1.5M_{i-1}$



2. Weight (Mass)



3. Geometric

Irregular:

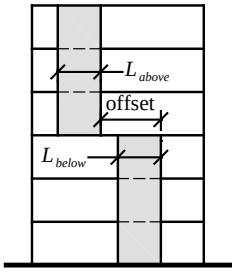
$L_i > 1.3L_{i+1}$

Irregular:

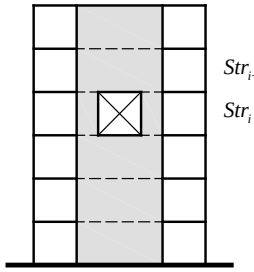
offset > L_{below}

or

offset > L_{above}



4. In-Plane Discontinuity



5. Lateral Strength -- Weak Story

Irregular:

$Str_i < 0.8Str_{i+1}$

Extreme:

$Str_i < 0.65Str_{i+1}$

Figure C12.3-2 Building vertical irregularities.

C12.3.3.2 Extreme Weak Stories. Since extreme weak story irregularities are prohibited for buildings located in Seismic Design Categories D, E and F, the limitations and exceptions in this section apply only to buildings assigned to Seismic Design Category B or C.

C12.3.3.3 Elements Supporting Discontinuous Walls or Frames. The purpose of this requirement is to protect the supporting elements from overload caused by overstrength of a discontinued seismic-force-resisting element. Columns, beams, slabs, or trusses may be subject to such failure so all are included in the design requirement. Overload may result from forces in either the downward or upward direction; therefore, both possibilities must be considered. Such load reversals may be especially problematic for reinforced concrete beams, weaker top laminations of glulam beams, unbraced flanges of steel beams, and steel trusses.

The connection between the discontinuous element and the supporting member must be adequate to transmit the forces for which the discontinuous element is designed. For example, where the discontinuous element must be designed using the load combinations of Section 12.4.3, as is the case for a steel column in a braced frame or moment frame, its connection to the supporting member must be designed using the same load combinations. Since concrete shear walls are not required to be designed using the load combinations of Section 12.4.3, the connection between a discontinuous shear wall and the supporting member may be designed using the loads associated with the shear wall and not the load combinations with overstrength factor.

C12.3.3.4 Increase in Forces Due to Irregularities for Seismic Design Categories D through F. The irregularities listed may result in loads that are distributed differently than assumed in the equivalent lateral force procedure of Section 12.8, especially as related to the interconnection of the diaphragm with vertical elements of the seismic-force-resisting system. The 25 percent increase in force is intended to account for this difference. Where the load combinations with overstrength apply, no further increase is warranted.

C12.3.4 Redundancy. The desirability of redundancy, or multiple lateral-force-resisting load paths, has long been recognized. The redundancy provisions of this section reflect the belief that an excessive loss of story shear strength or development of an extreme torsional irregularity may lead to structural failure. The redundancy factor determined for each direction may differ.

C12.3.4.1 Conditions Where Value of ρ is 1.0. This section provides a convenient list of conditions where ρ is 1.0.

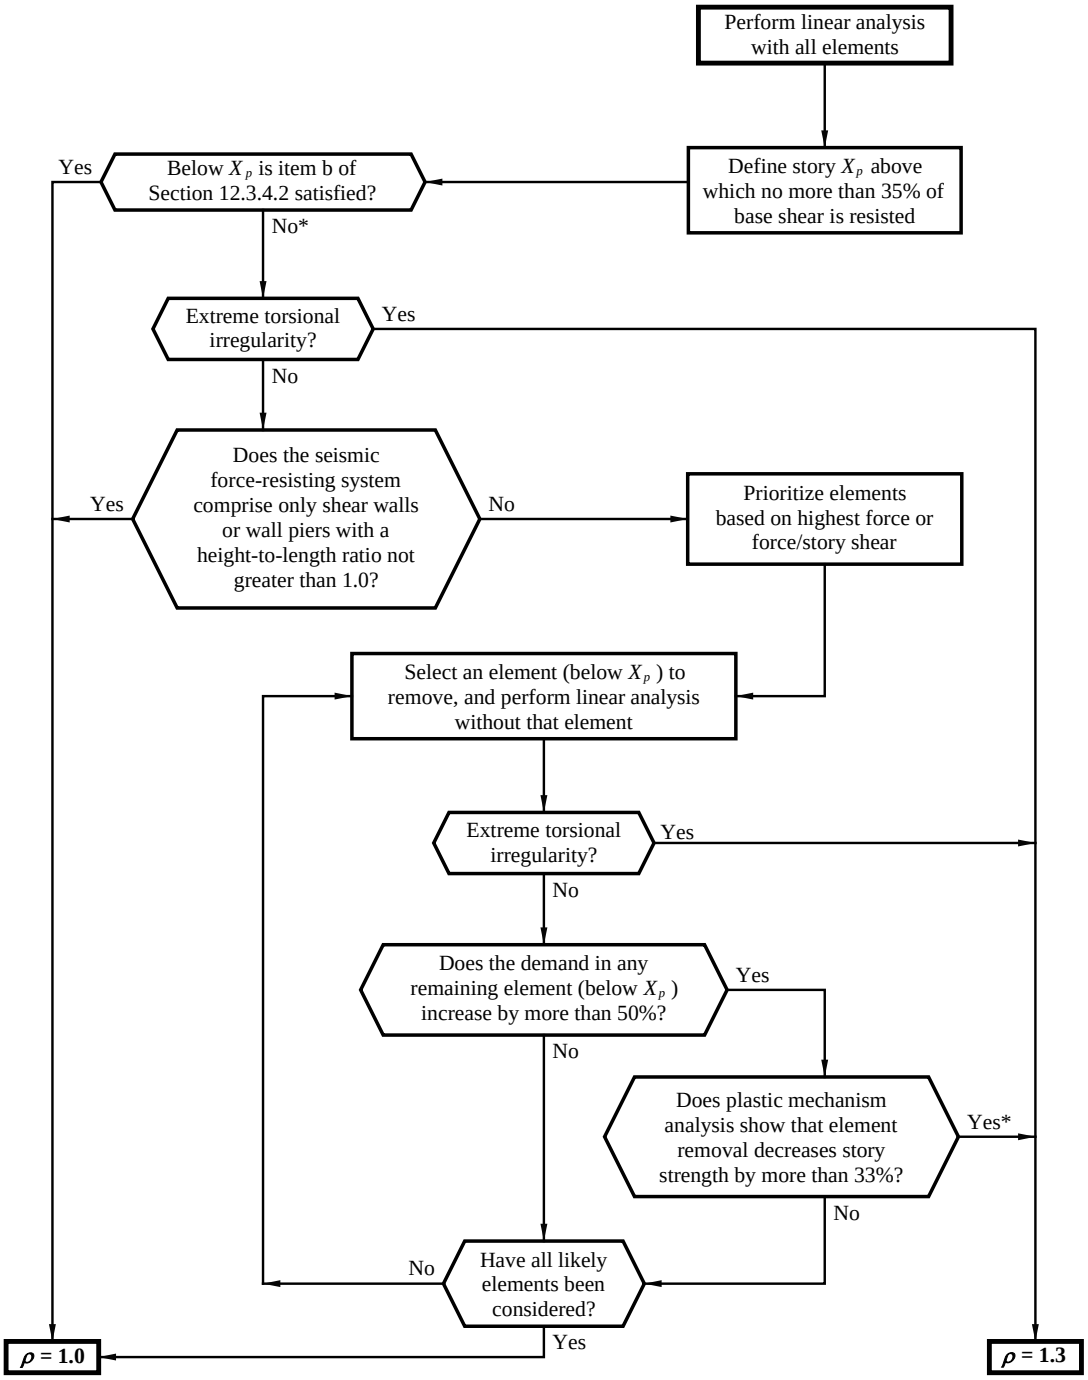
C12.3.4.2 Redundancy Factor, ρ, for Seismic Design Category D through F. There are two approaches to establishing a redundancy factor of 1.0. Where neither condition is satisfied, ρ is taken equal to 1.3. It is permitted to take ρ equal to 1.3 without checking either condition.

The first approach is a check of the elements outlined in Table 12.3-3 for cases where the story shear exceeds 35 percent of the base shear. Parametric studies (conducted by Building Seismic Safety Council Technical Subcommittee 2 but unpublished) were used to select the 35 percent value. Those studies indicated that stories with at least 35 percent of the base shear include all stories of low-rise buildings (buildings up to 5 to 6 stories) and about 87 percent of the stories of tall buildings. The intent of this limit is to exclude penthouses and the uppermost stories from the redundancy requirements.

This approach requires the removal (or loss of moment resistance) of an individual lateral-force-resisting element to determine its effect on the remaining structure. If the removal of elements, one-by-one, does not result in more than a 33 percent reduction in story strength or an extreme torsional irregularity, ρ may be taken as 1.0. For this evaluation, the determination of story strength requires an in-depth calculation. The intent of the check is to use a simple measure (elastic or plastic) to determine whether an individual member has a significant effect on the overall system. If the original structure has an extreme torsional irregularity to begin with, the resulting ρ is 1.3. Figure C12.3-3 presents a flowchart for implementing the redundancy requirements.

As indicated in the table, braced frame, moment frame, shear wall, and cantilever column systems must conform to redundancy requirements. Dual systems also are included but, in most cases, are inherently redundant. Shear walls or wall piers with a height-to-length aspect ratio greater than 1.0 within any story have been included; however, the required design of collector elements and their connections for Ω_0 times the design force may address the key issues. In order to satisfy the collector force requirements, a reasonable number of shear walls usually is required. Regardless, shear wall systems are addressed in this section so that either an adequate number of wall elements is included or the proper redundancy factor is applied. For wall piers, the height is taken as the height of the adjacent opening and generally is less than the story height.

The second approach is a deemed-to-comply condition wherein the structure is regular and has a specified arrangement of seismic-force-resisting elements to qualify for ρ of 1.0. As part of the parametric study, simplified braced frame and moment frame systems were investigated to determine their sensitivity to the analytical redundancy criteria. This simple deemed-to-comply condition is consistent with the results of the study.



* or not considered

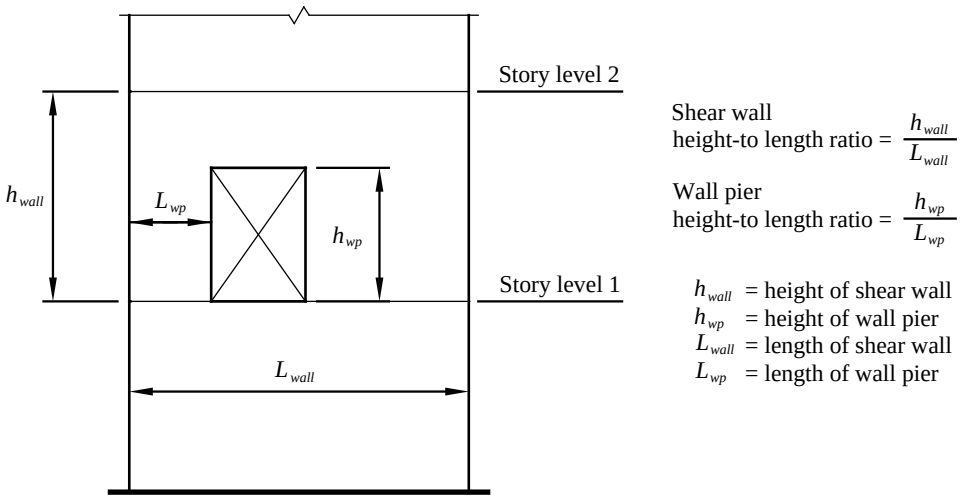

Figure C12.3-4 Shear wall and wall pier height-to-length ratios.

C12.4 SEISMIC LOAD EFFECTS AND COMBINATIONS

C12.4.1 Applicability. Structural elements designated by the engineer as part of the seismic-force-resisting system typically are designed directly for seismic load effects. None of the seismic forces associated with the design base shear are formally assigned to structural elements that are not designated as part of the seismic-force-resisting system, but such elements must be designed using the load conditions of Section 12.4 and must accommodate the deformations resulting from application of seismic loads.

C12.4.2 Seismic Load Effect. Section 12.4 presents the required combinations of seismic forces with other loads. The load combinations are taken from the basic load combinations of Chapter 2 of the standard with further elaboration of the seismic load effect, E. The seismic load effect includes horizontal and vertical components. For strength design, the effect of vertical seismic forces, E_v, is based on an assumed effective vertical acceleration of $0.2S_{DS}$ times gravity.

It may be helpful to recognize that the quantities E_h and E_v are the effects of loads, not the loads themselves. They can be tension or compression axial forces, shear, bending moments, or torsional moments. For a one-story shear wall, application of the horizontal seismic forces from V causes overturning moment and shear in the wall, both of which are E_h effects. The factor $0.2\ S_{DS}$ times gravity dead load corresponds to an E_v load effect that increases or decreases the axial force in the wall. In this simple example, an E_h force or moment is never added directly to an E_v force or moment because the former affects only moment and shear, while the latter affects only axial force.

While the shear and moment are independent of the axial force, the capacity check of the wall may need to include all three terms (or certainly moment and axial force) simultaneously.

For a diagonal brace that carries earthquake and gravity load, application of the horizontal seismic forces from V causes a brace force that has both horizontal and vertical components, and the factor $0.2\ S_{DS}$ times dead load produces a load effect that also affects both the horizontal and vertical components of axial force. In this case the brace force is based on $E_h \pm E_v$. Section 12.4.2.3 presents the load combinations written using the separate horizontal and vertical load effects that constitute E.

The $0.2S_{DS}$ vertical acceleration effect is required to be considered in the design of all members of a structure—even those that are not part of the seismic-force-resisting system. For example, design of a gravity load-resisting prestressed concrete girder may be governed by the dead and earthquake condition, where $0.2S_{DS}D$ is subtracted from the dead load. This could be the controlling condition for tension at the top of the girder.

C12.4.3 Seismic Load Effect Including Overstrength Factor. Certain structural elements or actions, such as collectors in Seismic Design Categories C through F or columns supporting discontinuous walls, are required to be designed for seismic load combinations with overstrength. In such cases the seismic load effect, E_m, has its horizontal component multiplied by the overstrength factor Ω_0, as indicated in Section 12.4.3.

C12.4.4 Minimum Upward Force for Horizontal Cantilevers for Seismic Design Categories D through F. In Seismic Design Categories D, E, and F, horizontal cantilevers are designed for an upward force that results from an effective vertical

acceleration of 1.2 times gravity. This is to provide some minimum strength in the upward direction and to account for possible dynamic amplification of vertical ground motions resulting from the vertical flexibility of the cantilever. The requirement is not applied to downward forces on cantilevers, for which the typical load combinations are used.

C12.5 DIRECTION OF LOADING

Seismic forces are delivered to a building through ground accelerations that may approach from any direction relative to the orthogonal directions of the building; therefore, seismic effects are expected to develop in both directions simultaneously. The standard requires structures to be designed for the most critical loading effects from seismic forces applied in any direction, and the procedures outlined in this section are deemed to satisfy that requirement.

The orthogonal combination procedure combines the effects from 100 percent of the seismic load applied in one direction with 30 percent of the seismic load applied in the perpendicular direction. Combining effects for seismic loads in each direction and accidental torsion results in 16 load combinations as follows:

Orthogonal load combinations	where :
$Q_E = +/- Q_{E_X+AT} +/- 0.3Q_{E_Y}$	Q_{E_Y} = effect of Y-direction load at the center of mass (Section 12.8.4.2)
$Q_E = +/- Q_{E_X-AT} +/- 0.3Q_{E_Y}$	Q_{E_X} = effect of X-direction load at the center of mass (Section 12.8.4.2)
$Q_E = +/- Q_{E_Y+AT} +/- 0.3Q_{E_X}$	AT = accidental torsion computed in accordance with Section 12.8.4.2
$Q_E = +/- Q_{E_Y-AT} +/- 0.3Q_{E_X}$	

For horizontal structural elements such as beams and slabs, orthogonal effects may be minimal; however, for vertical elements of the seismic-force-resisting system that participate in both orthogonal directions, the design likely will be governed by these combinations.

Orthogonal combinations should not be confused with modal combinations such as the square root of the sum of the squares (SRSS) or complete quadratic combination (CQC) technique.

The maximum effect of seismic forces, Q_E, from orthogonal load combinations must be modified by the redundancy factor, ρ, or the overstrength factor, Ω_0, and consider the effects of vertical seismic forces, E_V, in accordance with Section 12.4, to obtain the seismic load effect, E.

C12.6 ANALYSIS SELECTION PROCEDURE

Table 12.6-1 applies only to buildings without seismic isolation (Chapter 17) or passive energy devices (Chapter 18).

The procedures addressed in Table 12.6-1 are equivalent lateral force (ELF) analysis (Section 12.8), modal response spectrum (MRS) analysis (Section 12.9), linear response history (LRH) analysis, and nonlinear response history (NRH) analysis. Requirements for performing response history analysis are provided in Chapter 16. Nonlinear static (pushover) analysis is not addressed in the standard.

The value of T_s (= S_{D1}/S_{DS}) depends on the site class because S_{DS} and S_{D1} include such effects. Where ELF is not allowed, analysis must be performed using modal response spectrum or response history analysis.

ELF is not allowed for buildings with the listed irregularities because it assumes a gradually varying distribution of mass and stiffness along the height and negligible torsional response. The $3.5T_s$ limit recognizes that higher modes are more significant in taller buildings (Lopez and Cruz, 1996; Chopra, 2007) such that the ELF method may underestimate the design base shear and may not predict correctly the vertical distribution of seismic forces.

C12.7 MODELING CRITERIA

C12.7.1 Foundation Modeling. Structural systems consist of three interacting components: the structural framing (girders, columns, walls, diaphragms), the foundation (footings, piles, caissons), and the supporting soil. The ground motion that a structure experiences, as well as the response to that ground motion, depends on the complex interaction between these components.

Those aspects of ground motion that are affected by site characteristics are assumed to be independent of the structure-foundation system as these effects would occur in the free-field in the absence of the structure. Hence, site effects are considered separately (Sections 11.4.2 through 11.4.4 and Chapters 20 and 21).

Given a site-specific ground motion or response spectrum, the dynamic response of the structure will depend on the foundation system and on the characteristics of the soil that support the system. The dependence of the response on the structure-foundation-soil system is referred to as soil-structure interaction. Such interactions will usually, but not always, result in a reduction of base shear. This reduction in shear is due to the flexibility of the foundation-soil system and an associated lengthening of the period of vibration of the structure. In addition, the soil system may provide an additional source of damping. However, that total displacement typically increases with soil-structure interaction.

If the foundation is considered to be rigid, the computed base shears usually will be conservative, and it is for this reason that rigid foundation analysis is allowed. The designer may ignore soil-structure interaction or may consider it explicitly in accordance with Section 12.13.3 or implicitly in accordance with Chapter 19.

C12.7.2 Effective Seismic Weight. During an earthquake, the structure accelerates laterally, and these accelerations of the structural mass produce inertial forces. These inertial forces, accumulated over the height of the structure, produce the design base shear.

When a building vibrates during an earthquake, only that portion of the mass or weight that is physically tied to the structure needs to be considered as effective. Hence, live loads (e.g., loose furniture, loose equipment, and human occupants) need not be included. However, certain types of live loads such as storage loads may develop inertial forces, particularly where they are densely packed.

Also considered as effective weight is all permanently attached equipment (e.g., air conditioners, elevator equipment, and mechanical systems), movable partitions (a minimum of 10 psf is required), and 20 percent of significant roof snow load. The full snow load need not be considered because maximum snow load and maximum earthquake load are unlikely to occur simultaneously and loose snow does not move with the roof.

C12.7.3 Structural Modeling. The development of a mathematical model of a structure is always required because the story drifts and the design forces in the structure cannot be computed without such a model. In some cases, the mathematical model can be as simple as a free-body diagram as long that model can appropriately capture the strength and stiffness of the structure.

The most realistic analytical model is three-dimensional, includes all sources of stiffness (and flexibility) of the structure and the soil-foundation system as well as P-delta effects, and allows for nonlinear inelastic behavior in all parts of the structure-foundation-soil system. Development of such an analytical model is very time consuming, and such analysis is rarely warranted for typical building designs performed in accordance with the standard. Instead of performing a nonlinear analysis, inelastic effects are accounted for indirectly in the linear analysis methods by means of the response modification factor, R, and the deflection amplification factor, C_d.

Using modern software, it often is more difficult to decompose a structure into planar models than it is to develop a full three-dimensional model so three-dimensional models now are commonplace. Increased computational efficiency has reduced the motivation to model rigid diaphragms, allowing for easy and efficient modeling of diaphragm flexibility. Three-dimensional models are required where the structure has torsional irregularities, out-of-plane offset irregularities, or nonparallel system irregularities.

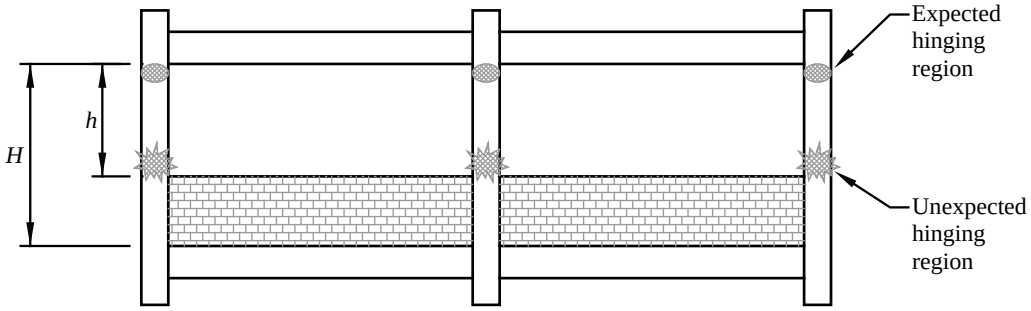
In general, the same three-dimensional model may be utilized for equivalent lateral force, modal response spectrum, and linear response history analysis. The response spectrum and linear response history models require a realistic modeling of structural mass, and the response history method also requires an explicit representation of inherent damping. Five percent critical damping is automatically included in the modal response spectrum approach. See Chapter 16 and the related commentary for additional information on linear and nonlinear response history analysis.

It is well known that deformations in the panel zones of the beam-column joints of steel moment frames are a significant source of flexibility. Two different mechanical models for including such deformations are summarized in Charney and Marshall (2006). These methods apply to both elastic and inelastic systems. For elastic structures, centerline analysis provides reasonable, but not always conservative, estimates of frame flexibility. Fully rigid end zones should not be used, as this will always result in an overestimation of lateral stiffness in steel moment-resisting frames. Partially rigid end zones may be justified in certain cases such as where doubler plates are used to reinforce the panel zone.

Including the effect of composite slabs on the stiffness of beams and girders may be warranted in some circumstances. Where composite behavior is included, due consideration should be paid to the reduction in effective composite stiffness for portions of the slab in tension (Schaffhausen and Wegmuller, 1977; Liew, et al., 2001)

For reinforced concrete buildings, it is important to address the effects of axial, flexural, and shear cracking in modeling the effective stiffness of the structural components. Determining appropriate effective stiffness of the structural components should take into consideration the anticipated demands on the components, their geometry, and the complexity of the model. Recommendations for computing cracked section properties may be found in Paulay and Priestley (1992) and similar texts.

C12.7.4 Interaction Effects. The interaction requirements are intended to prevent unexpected failures in members of moment-resisting frames. Figure C12.7-1 illustrates a typical situation where masonry infill is used, and this masonry is fitted tightly against reinforced concrete columns. Since the masonry is much stiffer than the columns, column hinges form at the top of column and at the top of the masonry rather than at the top and bottom of the column. If the column flexural capacity is M_p, the shear in the columns increases by the factor H/h, and this may cause an unexpected nonductile shear failure in the columns. Many building collapses have been attributed to this effect.



Expected plastic hinge capacity = M_p

Expected column shear = $2M_p/H$

Actual column shear = $2M_p/h$

Figure C12.7-1 Undesired interaction effects.

C12.8 EQUIVALENT LATERAL FORCE PROCEDURE

The equivalent lateral force (ELF) procedure provides a simple way to incorporate the effects of inelastic dynamic response into a linear static analysis. This procedure is useful in preliminary design of all structures and is allowed for final design of the vast majority of structures. The procedure is valid only for structures without significant discontinuities in mass and stiffness along the height, where the dominant response to ground motions is in the horizontal direction without significant torsion.

The ELF procedure has three basic steps:

1. Determine the seismic base shear,
2. Distribute the shear vertically along the height of the structure, and
3. Distribute the shear horizontally across the width and breadth of the structure.

Each of these steps is based on a number of simplifying assumptions. A broader understanding of these assumptions may be obtained from any structural dynamics textbook that emphasizes seismic applications.

C12.8.1 Seismic Base Shear

C12.8.1.1 Calculation of Seismic Response Coefficient. Equation 12.8-1 simply expresses the base shear as the product of the effective seismic weight, W, and a response coefficient, C_s. The response coefficient is a spectral pseudoacceleration, in g units, which has been modified by R and I to account for inelastic behavior and to provide for improved performance for high occupancy or essential structures.

There are five equations for determining the response coefficient C_s; the first three are plotted in Figure C12.8-1.

Equation 12.8-2, representing the constant acceleration part of the spectrum, controls where $0.0 < T < T_s$. As shown in Table C12.6-1 (which provides values of $3.5T_s$), T_s is a function of seismicity and site. It may be as low as 0.2 seconds for low hazard regions on Site Class B or as high as 0.9 seconds in high hazard regions on Site Class E.

The true pseudoacceleration response spectrum transitions to the peak ground acceleration as the period approaches zero. This transition is not used in the ELF method. One reason is that simple reduction of the response spectrum by (1/*R*) in the very short period region would exaggerate inelastic effects.

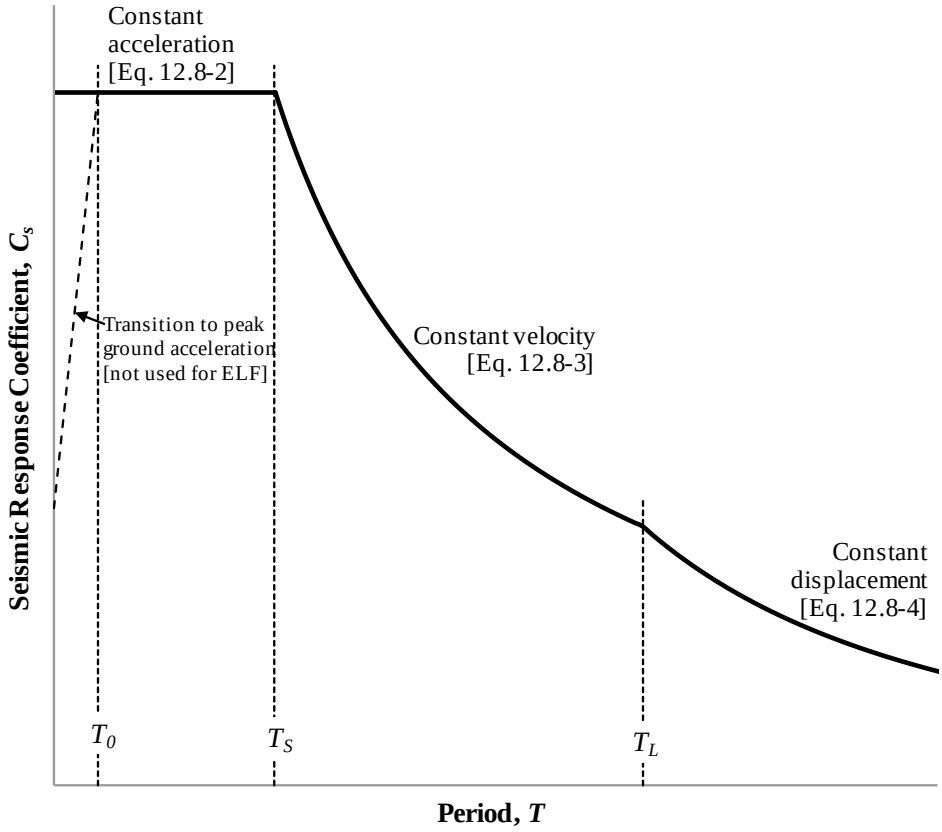


Figure C12.8-1 Seismic response coefficient versus period.

Equation 12.8-3, representing the constant velocity part of the spectrum, controls where $T_s < T < T_L$. In this region, the seismic response coefficient is inversely proportional to period, and the pseudovelocity (pseudoacceleration divided by circular frequency, ω, is constant. $T_{L,}$ the long-period transition period, is provided in Figures 22-15 through 22-20. T_L ranges from 4 seconds in in the northcentral conterminous states and western Hawaii to 16 seconds in the Pacific Northwest and in western Alaska.

Equation 12.8-4, representing the constant displacement part of the spectrum, controls where $T > T_L$. Given the current mapped values of T_L, this equation only affects tall and flexible structures.

Equation 12.8-5 is the minimum base shear and provides a (working stress) strength of approximately 3 percent of the weight of the structure (Seismology Committee, Structural Engineers Association of California, 1996). This minimum base shear was originally enacted in 1933 by the state of California's Riley Act.

Equation 12.8-6 applies to sites near major active faults (as reflected by values of S_1) where pulse effects can increase long-period demands.

C12.8.1.2 Soil-Structure Interaction Reduction. Soil-structure interaction, which can influence significantly the dynamic response of structures to earthquakes, is addressed in Chapter 19.

C12.8.1.3 Maximum S_s Value in Determination of C_s. The maximum value of S_s was created as hazard maps were revised in 1997. The cap on S_s reflects engineering judgment about performance of code-complying buildings in past earthquakes so the height, period, and regularity conditions required for use of the limit are very important qualifiers.

C12.8.2 Period Determination. The fundamental period of the structure, *T*, is used to determine the design base shear as well as the exponent *k* that establishes the distribution of the shear along the height of the structure. Equation 12.8-7 is an

empirical relationship determined through statistical analysis of the measured response of buildings in California. Figure C12.8-2 illustrates such data for various structures with steel moment resisting frames.

Since the empirical expression is based on the lower bound of the data, it produces a lower bound for the period of a building of given height. This lower bound period, used in Equations 12.8-3 and 12.8-4, provides a conservative estimate of base shear.

The fundamental period determined from a rational analysis may be used in design unless it exceeds the approximate period times the coefficient provided in Table 12.8-1. This period limit prevents the use of unusually low ELF base shear for design of buildings (or computational models) that are overly flexible. The coefficients in the table have two effects. First, the conservatism of lower bound empirical formulas for T_a is removed. Second, the period is increased in regions of lower seismicity as buildings in such areas generally are more flexible (and, hence, have longer periods) than buildings in regions of higher seismicity.

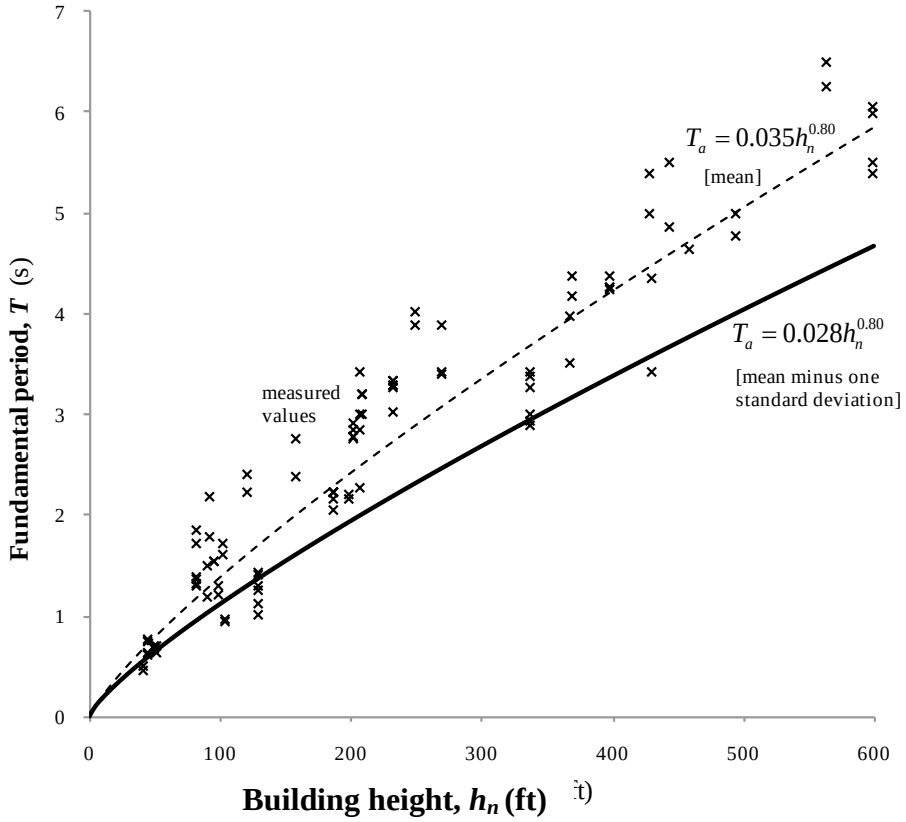

Figure C12.8-2 Variation of fundamental period with building height.

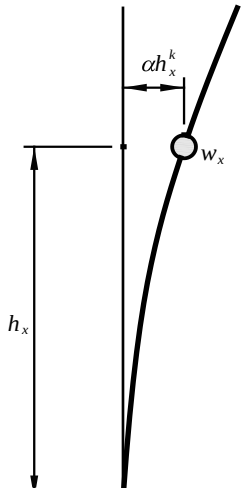
C12.8.3 Vertical Distribution of Seismic Force. Equation 12.8-12 is based on the simplified first mode shape shown in Figure C12.8-3. In the figure, F_x is the inertial force at level x, which is simply the total acceleration at level x times the mass at level x. The base shear is the sum of these inertial forces, and Equation 12.8 simply gives the ratio of the force at level x to the total base shear.

The deformed shape of the structure of Figure C12.8-3 is a function of the exponent k, which is related to the fundamental period of vibration of the structure. The variation of k with T is illustrated in Figure C12.8-4. The exponent k is intended to approximate the effect of higher modes, which are generally more dominant in structures with a longer fundamental period of vibration. Lopez and Cruz (1996) discuss the factors that influence higher modes of response. Although the actual first mode shape for a structure is also a function of the type of seismic-force-resisting system, that effect is not reflected in these equations.

The horizontal forces computed using Equation 12.8-12 do not reflect the actual inertial forces imparted on a structure at any particular time. Instead, they are intended to provide design story shears that are consistent with enveloped results from more accurate analysis (Chopra and Newmark, 1980).



$$F_x = \omega^2 \alpha h_x^k \frac{w_x}{g}$$

$$V_b = \sum_{i=1}^{n} \omega^2 \alpha h_i^k \frac{w_i}{g}$$

$$C_{vx} = \frac{F_x}{V_b} = \frac{w_x h_x^k}{\sum^{n} w_i h_i^k}$$

Figure C12.8-3 Basis of Equation 12.8-12.

C12.8.4 Horizontal Distribution of Forces. Within the context of an elastic ELF analysis, the distribution of lateral forces to various seismic-force-resisting elements depends on the type, geometric arrangement, and vertical extents of the resisting elements and on the shape and flexibility of the floor diaphragms. Because seismic-force-resisting elements are expected to respond inelastically to design ground motions, the distribution of forces to the various elements also depends on the strength of the elements and their sequence of yielding. Clearly, such effects cannot be captured accurately by a linear elastic static analysis (Paulay, 1997). Nonlinear dynamic analysis is too cumbersome to be applied to the design of most buildings so other approximate methods are used.

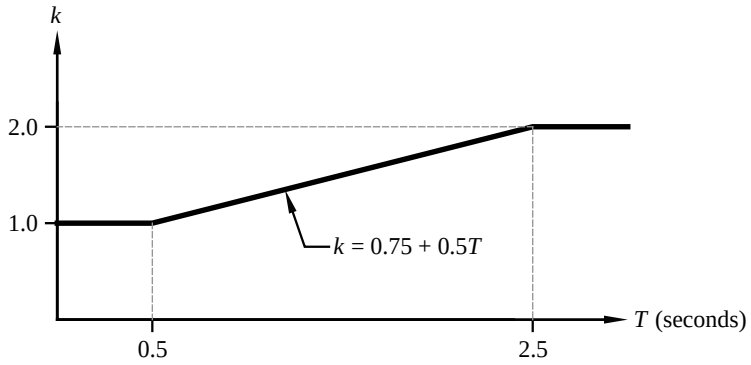


Figure C12.8-4 Variation of exponent *k* with period *T*.

Of particular concern is the torsional response of the structure during the earthquake. This response has been observed in structures that are designed to be nearly symmetric in plan and layout of seismic-force-resisting systems (De La Liera and Chopra, 1994). This torsional response is due to a variety of "accidental" eccentricities that exist due to uncertainties in quantifying the mass and stiffness distribution of the structure, as well as torsional components of ground motion that are not included explicitly in code-based designs (Newmark and Rosenbleuth, 1971).

C12.8.4.1 Inherent Torsion. When lateral forces in a particular direction are applied statically at each story of a building with rigid diaphragms, torsional displacement (twisting about the vertical axis) occurs if the centers of stiffness and mass of each story are not perfectly coincident in plan. When three-dimensional analysis is used, this inherent torsion is included automatically. When planar analysis is used, the centers of mass and rigidity for each story must be determined explicitly. Unfortunately, it is difficult to determine the center of rigidity for a multistory building to compute the inherent torsion; the center of rigidity for a particular story depends on the configuration of the seismic-force-resisting elements above and below that story and may be load dependent (Chopra and Goel, 1991).

For buildings with fully flexible diaphragms (as defined in Section 12.3), vertical elements are assumed to resist inertial forces from the mass that is tributary to the elements, but with no explicitly computed torsion. No diaphragm is perfectly flexible, so some torsional forces always develop even when they are ignored.

C12.8.4.2 Accidental Torsion. Even for perfectly symmetric buildings, the true locations of the centers of mass and rigidity are uncertain. As discussed in Section C12.8.4, other effects also may produce torsion. The requirement to consider accidental torsion is intended to address this concern.

Accidental and inherent torsions result in forces that must be combined with those obtained from the application of the lateral story forces; all components must be designed for the maximum effects determined considering positive accidental torsion, negative accidental torsion, and no accidental torsion.

C12.8.4.3 Amplification of Accidental Torsion. Equation 12.8-14 was developed by the SEAOC "seismology committee to encourage buildings with good torsional stiffness" (Structural Engineers Association of California, 1999).

In calculating the torsional amplification factor, A_x, the applied loads include inherent and accidental torsion, but with no further amplification; the calculation is not iterative.

Figure C12.8-5 illustrates the effect of Equation 12.8-14 for a symmetric rectangular building with various aspect ratios (L/B) where the seismic-force-resisting elements are positioned at a variable distance (defined by α) from the center of mass in each direction. Each element is assumed to have the same stiffness. The structure is loaded parallel to the short direction with an eccentricity of $0.05L$.

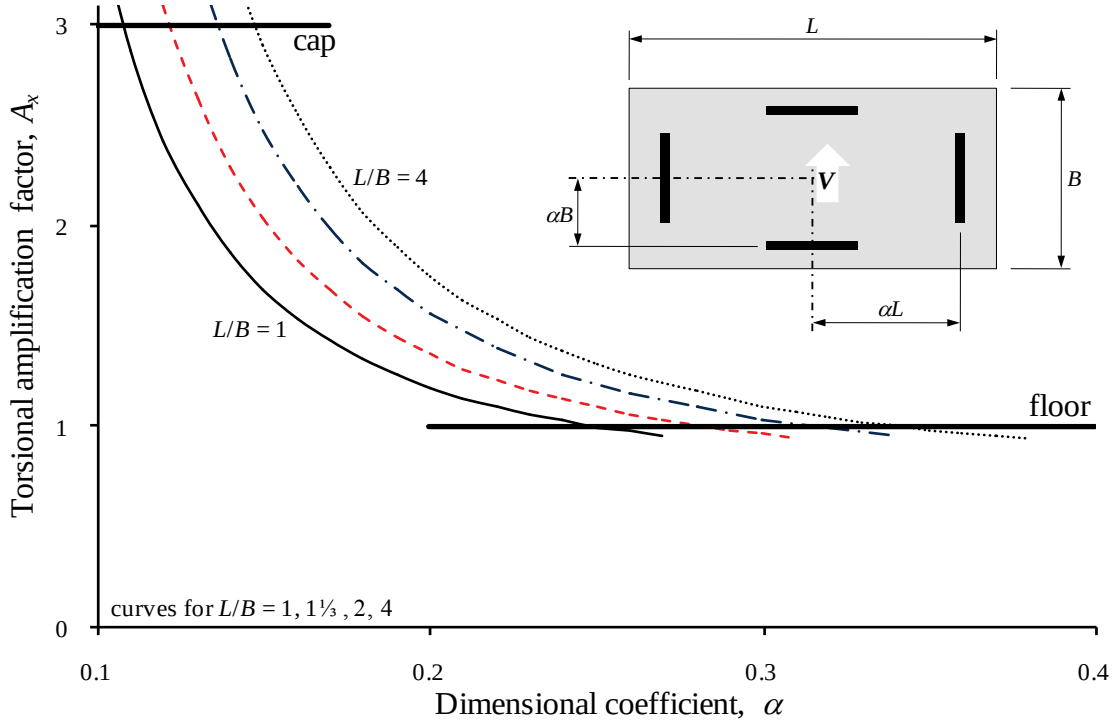

Figure C12.8-5 Amplification factor for symmetric rectangular buildings.

For α equal to 0.5, these elements are at the perimeter of the buildings, and for α equal to 0.0, they are at the center (providing no torsional resistance). For a square building ($L/B = 1.00$), the torsional amplification factor is greater than 1.0 where α is less than 0.25 and increases to the maximum of 3.0 where α is equal to 0.11. For a rectangular building with L/B equal to 4.00, the amplification factor is greater than 1.0 where α is less than 0.34 and increases to 3.0 where α is equal to 0.15. For the range of aspect ratios investigated, A_x is equal to 1.0 where α is greater than 0.34 and A_x reaches its maximum value of 3.0 where ($\alpha < 0.11$ to 0.15).

C12.8.6 Story Drift Determination. Equation 12.8-15 is used to estimate inelastic deflections, which are then used to calculate design story drifts. These story drifts must be less than the allowable story drifts of Table 12.12-1. For buildings without torsional irregularity, computations are performed using deflections at the centers of mass of adjacent stories. For Seismic Design Category C, D, E, or F structures that are torsionally irregular, Section 12.12.1 requires that drifts be computed along the edges of the structure.

The term C_d in Equation 12.8-15 amplifies the displacements from elastic analysis at design level forces, which are reduced by *R*.

Figure C12.8-6 illustrates the relationships between elastic response; response to reduced design-level forces; and the expected inelastic response. If the structure remained elastic during an earthquake, the force would be V_E, and the corresponding displacement would be δ_E. Note that V_E does not include the reduction factor, *R*, which accounts primarily for ductility and overstrength. According to the equal displacement "rule" of seismic design, the maximum displacement of an inelastic system is approximately equal to that of an elastic system with the same initial stiffness. This condition has been observed for structures idealized with bilinear inelastic response and a fundamental period greater than T_s. For shorter period structures, peak displacement of an inelastic system tends to exceed that of the corresponding elastic system. Since the forces used for design include the response modification coefficient, *R*, the resulting displacements are too small and must be amplified.

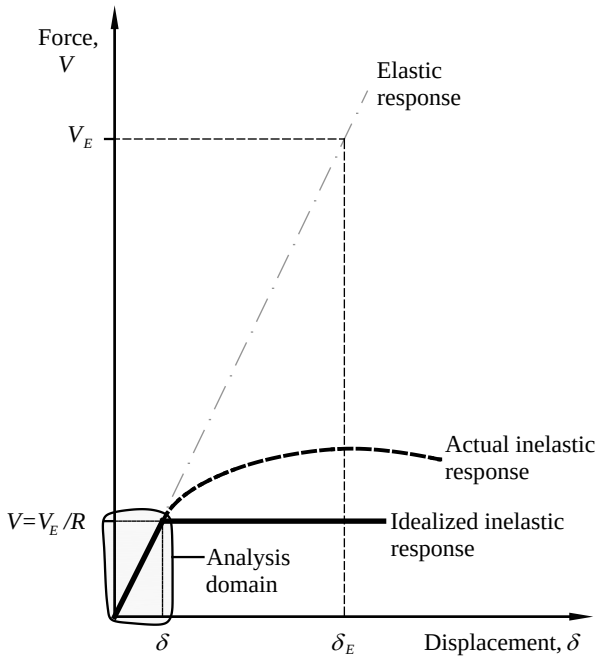

Figure C12.8-6 Displacements used to compute drift.

This analysis domain is shown in Figure C12.8-6. Because of overstrength and associated stiffness increases, the actual inelastic response differs from the idealized inelastic response; the actual displacement of the system may be less than *R* times δ. The standard accounts for this difference by multiplying the fictitious (design-level) elastic displacements δ by the factor C_d, which is usually less than *R*.

The design forces used to compute δ_{xe} include the importance factor, *I*, so Equation 12.8-15 includes *I* in the denominator. This is appropriate since the allowable story drifts (except for masonry shear wall structures) in Table 12.12-1 are more stringent for higher occupancy categories.

C12.8.6.1 Minimum Base Shear for Computing Drift. Except for period limits (as described in Section C12.8.6.2), all of the requirements of Section 12.8 (including minimum base shears and force distributions) must be satisfied where computing drift for ELF analysis.

C12.8.6.2 Period for Computing Drift. Where the response spectrum of Section 11.4.5 or the corresponding equations of Section 12.8.1 are used and the structural period is less than TL, displacements increase with increasing period (even though forces may decrease). Section 12.8.2 applies a period limit so that design forces are not too low, but if the lateral forces used to compute drifts are inconsistent with the forces corresponding to the computed period, displacements will be overestimated. Therefore, the standard allows the determination of drift using forces that are consistent with the computed period of vibration of the structure.

Computed periods greater than $C_u T_a$ are common, particularly for moment frames. In such cases the seismic design forces used to proportion strength may produce displacements that violate drift limits, whereas displacements based on the computed period will satisfy drift limits.

The more flexible the structure, the more likely it is that P-delta effects will ultimately control the design. Computed periods that are significantly greater than (perhaps more than 1.5 times) $C_u T_a$ may indicate a modeling error.

C12.8.7 P-delta Effects. P-delta effects influence both the stiffness and strength of structures. Figure C12.8-7 shows idealized static force-displacement responses for a simple, one-story structure (such as a cantilevered column). The stiffness and strength of the structure without considering P-delta effects (condition 0) are represented by K_0 and V_0. When P-delta effects are considered (condition 1), the related quantities are K_1 and V_1. Since the two model conditions are for the same structure, inherent capacity of the structure is the same in either condition, the yield displacement is the same ($\delta_{0y} = \delta_{1y} = \delta_y$).

The geometric stiffness of the structure, K_G, is equal to P/h, where P is the total gravity load and h is the story height. K_G is negative where gravity loads cause compression in the story.

The stability coefficient, θ, is defined as the absolute value of the geometric stiffness divided by the elastic stiffness. From Figure C12.8-7, $K_0 = V_{0y} / \delta_{0y}$. Hence,

$$\theta = \frac{|K_G|}{K_0} = \left| \frac{P\delta_{0y}}{V_{0y}h} \right| \qquad \text{C12.8-1}$$

Given the above, and the geometric relationships shown in Figure C12.8-7, it can be shown that the force producing yield in condition 1 (with P-delta effects) is

$$V_{1y} = V_{0y}(1-\theta) \qquad \text{C12.8-2}$$

and that for an applied force, V, less than or equal to V_{1y}

$$\delta_1 = \frac{\delta_0}{1-\theta} \qquad \text{C12.8-3}$$

As θ approaches 1.0, δ_1 approaches infinity and V_1 approaches zero, defining a state of static instability.

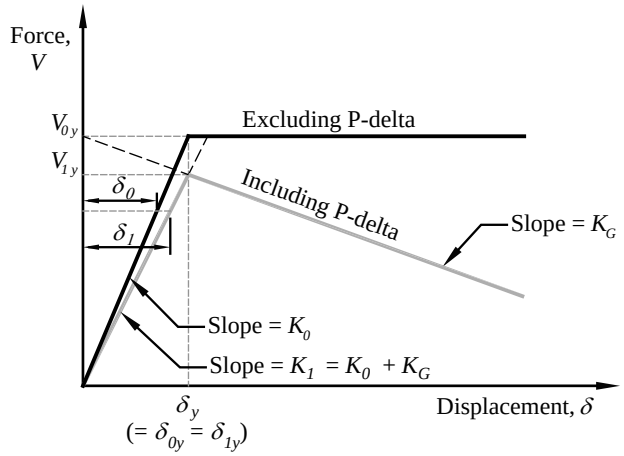

Figure C12.8-7 P-delta effect on a simple structure.

The intent of Section 12.8.7 is to determine whether P-delta effects are significant, and if so, to modify the strength and stiffness of the structure to account for such effects. Also, maximum permitted values of θ are established.

Equation 12.8-16 is used to determine the stability coefficient of each story of a structure. Where the stability coefficient exceeds 0.1, P-delta effects must be considered using one of two approaches. Displacements and member forces are either multiplied by $1/(1-\theta)$ to reflect the conditions shown in Figure C12.8-7 in accordance with the equal displacement rule or determined by rational analysis. Two types of rational analysis are envisioned. First, a nonlinear static (pushover) analysis could be performed to show that the post-yield slope of the pushover curve is continuously positive up to the target displacement. Second, a nonlinear dynamic response history analysis could be repeated with and without P-delta effects to determine if the behavior including P-delta meets all performance criteria.

Although the P-delta procedures in the standard reflect the simple static idealization shown in Figure C12.8-7, the real issue is one of dynamic stability. For that reason, nonlinear response history analysis is appealing. Such analysis should reflect variability of ground motions and system properties, including initial stiffness, strain hardening stiffness, initial strength, hysteretic behavior, and magnitude of gravity load. Unfortunately, the dynamic response of structures is highly sensitive to such parameters, causing considerable dispersion to appear in the results (Vamvatsikos, 2002). This dispersion, which increases dramatically with stability coefficient θ, is due primarily to the incrementally increasing residual deformations (ratcheting) that occur during the response. Residual deformations may be controlled by increasing either the initial strength or the secondary stiffness. See Gupta and Krawinkler (2000) for additional information.

Equation 12.8-17 establishes the maximum stability coefficient permitted. The intent of this requirement is to protect structures from the possibility of stability failures triggered by post-earthquake residual deformation.

C12.9 MODAL RESPONSE SPECTRUM ANALYSIS

In the modal response spectrum analysis method, the structure is decomposed into a number of single-degree-of-freedom systems, each having its own mode shape and natural period of vibration. The number of modes available is equal to the number of mass degrees of freedom of the structure, so the number of modes can be reduced by eliminating mass degrees of freedom. For example, rigid diaphragm constraints may be used to reduce the number of mass degrees of freedom to one per story for planar models, and to three per story (two translations and rotation about the vertical axis) for three-dimensional structures. However, where the vertical elements of the seismic-force-resisting system have significant differences in lateral stiffness, rigid diaphragm models should be used with caution as relatively small in-plane diaphragm deformations can have a significant effect on the distribution of forces.

For a given direction of loading, the displacement in each mode is determined from the corresponding spectral acceleration, modal participation, and mode shape. Because the sign (positive or negative) and the time of occurrence of the maximum acceleration are lost in creating a response spectrum, there is no way to recombine modal responses exactly. However, statistical combination of modal responses produces reasonably accurate estimates of displacements and component forces. The loss of signs for computed quantities leads to problems in interpreting force results where seismic effects are combined with gravity effects, produces forces that are not in equilibrium, and makes it impossible to plot deflected shapes of the structure.

C12.9.1 Number of Modes. The key motivation to perform modal response spectrum analysis is to determine how the actual distribution of mass and stiffness of a structure affects the elastic displacements and component forces. Where at least 90 percent of the model mass participates in the response, the distribution of forces and displacements is sufficient for design. The scaling required by Section 12.9.4 controls the overall magnitude of design values so that incomplete mass participation does not produce unconservative results.

The number of modes required to achieve 90 percent modal mass participation is usually a small fraction of the total number of modes. See Lopez and Cruz (1996) for further discussion of the number of modes to use for modal response spectrum analysis.

C12.9.2 Modal Response Parameters. The design response spectrum (whether the general spectrum from Section 11.4.5 or a site-specific spectrum determined in accordance with Section 21.2) is representative of linear elastic structures. Division of the spectral ordinates by R accounts for inelastic behavior, and multiplication of spectral ordinates by I provides the additional strength needed to improve the performance of important structures. The displacements that are computed using the response spectrum that has been modified by R and I (for strength) must be amplified by C_d and reduced by I to produce the expected inelastic displacements. (See Section C12.8.6.)

C12.9.3 Combined Response Parameters. Most computer programs provide for either the SRSS or the CQC method (Wilson, et al., 1981) of modal combination. The two methods are identical where applied to planar structures, or where zero damping is specified for the computation of the cross-modal coefficients in the CQC method. The modal damping specified in each mode for the CQC method should be equal to the damping level that was used in the development of the response spectrum. For the spectrum in Section 11.4.5, the damping ratio is 0.05.

The SRSS or CQC method is applied to loading in one direction at a time. Where Section 12.5 requires explicit consideration of orthogonal loading effects, the results from one direction of loading may be added to 30 percent of the results from loading in an orthogonal direction. Wilson (2000) suggests that a more accurate approach is to use the SRSS method to combine 100 percent of the results from each of two orthogonal directions where the individual directional results have been combined by SRSS or CQC, as appropriate.

C12.9.4 Scaling Design Values of Combined Response. The modal base shear, V_t, may be less than the ELF base shear, V, because: (a) the calculated fundamental period may be longer than that used in computing V, (b) the response is not characterized by a single mode, and (c) the ELF base shear assumes 100 percent mass participation in the first mode, which is always an overestimate. The scaling required by Section 12.9.4 provides, in effect, a minimum base shear for design. This minimum base shear is provided because the computed period of vibration may be the result of an overly flexible (incorrect) analytical model. The possible 15 percent reduction in design base shear may be considered as an incentive for using a modal response spectrum analysis in lieu of the equivalent lateral force procedure.

Displacements from the modal response spectrum are not scaled because the use of an overly flexible model will result in conservative estimates of displacement that need not be further scaled.

C12.9.5 Horizontal Shear Distribution. Accidental torsion must be included in the analysis as specified in Section 12.8.7. For modal analysis there are two basic approaches to include accidental torsion.

The first approach is to perform static analyses with accidental torsions applied at each level of the structure, and then add these results to those obtained from the modal response spectrum analysis. Where this approach is used, torsional amplification in accordance with Section 12.8.4.3 is required.

The second approach, which applies only to three-dimensional analysis, is to offset the centers of mass of each story 5 percent in each direction, thus requiring four separate models. The advantage of this method is that the effects of direct loading and accidental torsion are combined automatically. A practical disadvantage is the increased bookkeeping for multiple analyses.

Where this approach is used, further amplification of accidental torsion is not required because repositioning the center of mass in a dynamic analysis changes the natural mode shapes and frequencies, producing torsions larger than the static accidental torsion.

C12.9.6 P-delta Effects. The requirements of Section 12.8.7, including the stability coefficient limit, θ_{max}, apply to modal response spectrum analysis.

Amplification of displacements and member forces as a result of P-delta effects may be accomplished through use of the geometric stiffness. For the purpose of dynamic analysis, the linearized geometric stiffness, which includes the story-wise P-Δ effect, is usually sufficient. Using the consistent geometric stiffness (P-δ effect), which is associated with the deflected shape of the individual elements of the structure, slightly improves accuracy. Including P-delta effects directly in dynamic analysis lengthens of the periods of vibration of each mode of response and increases lateral displacements.

C12.10 DIAPHRAGMS, CHORDS, AND COLLECTORS

C12.10.1 Diaphragm Design. Diaphragms are generally treated as horizontal deep beams or trusses that distribute lateral forces to the vertical elements of the seismic-force-resisting system. As deep beams, diaphragms must be designed to resist the resultant shear and bending stresses. Diaphragms are commonly compared to girders, with the roof or floor deck analogous to the girder web in resisting shear, and the boundary elements (chords) analogous to the flanges of the girder in resisting flexural tension and compression. As in girder design, the chord members (flanges) must be sufficiently connected to the body of the diaphragm (web) to prevent separation and to force the diaphragm to work as single unit.

Diaphragms may be considered flexible, semi-rigid, or rigid. The flexibility or rigidity of the diaphragm determines how lateral forces will be distributed to the vertical elements of the seismic-force-resisting system. See Section C12.3.1. Once the distribution of lateral forces is determined, shear and moment diagrams are used to compute the diaphragm shear and chord forces. Where diaphragms are not flexible, inherent and accidental torsion must be considered in accordance with Section 12.8.4.

Diaphragm openings may require additional localized reinforcement (sub-chords and collectors) to resist the subdiaphragm chord forces above and below the opening and to collect shear forces where the diaphragm depth is reduced. (See Figure C12.10-1.) Collectors on each side of the opening drag shear into the subdiaphragms above and below the opening. The subchord and collector reinforcement must extend far enough into the adjacent diaphragm to develop the axial force through shear transfer. The required development length is determined by dividing the axial force in the sub-chord by the shear capacity (in force/unit length) of the main diaphragm.

Chord reinforcement at reentrant corners must extend far enough into the main diaphragm to develop the chord force through shear transfer. (See Figure C12.10-2.) Continuity of the chord members also must be considered where the depth of the diaphragm is not constant.

In wood and metal deck diaphragm design, framing members are often used as continuity elements, serving as sub-chords and collector elements at discontinuities. These continuity members also are often used to transfer wall out-of-plane forces to the main diaphragm, where the diaphragm itself does not have the capacity to resist the anchorage force directly. For additional discussion, see Section C12.11.2.2.3.

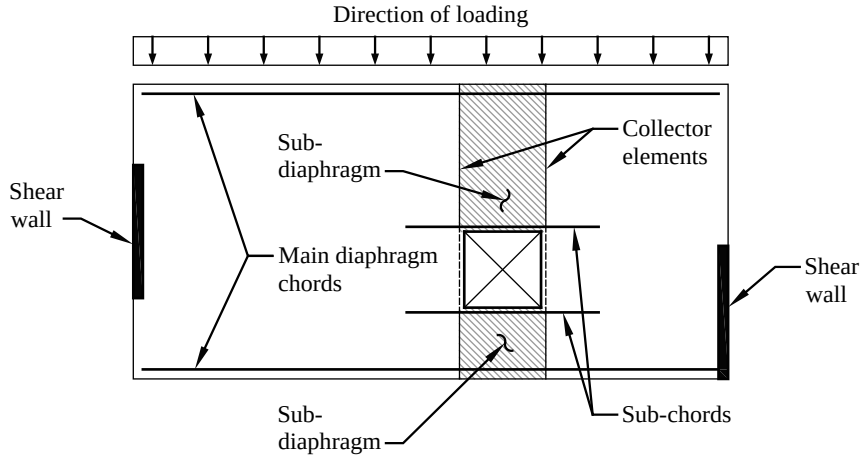

Figure C12.10-1 Diaphragm components.

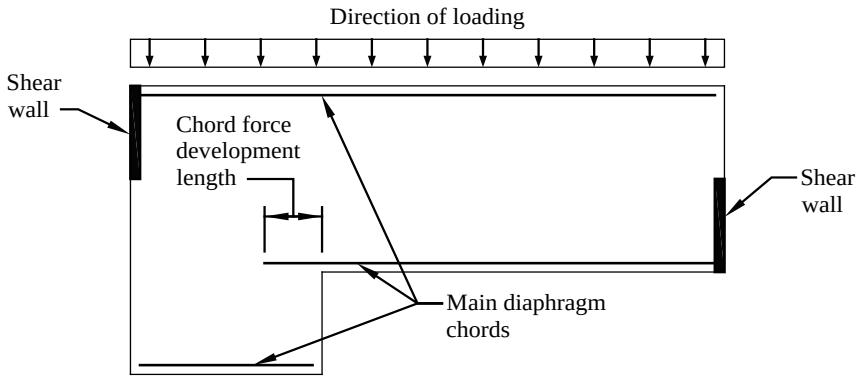

Figure C12.10-2 Diaphragm with a re-entrant corner.

C12.10.1.1 Diaphragm Design Forces. Diaphragms must be designed to resist inertial forces, as specified in Equation 12.10-1, and to transfer design seismic forces due to horizontal offsets or changes in stiffness of the vertical resisting elements. Inertial forces are those seismic forces that originate at the specified diaphragm level, while the transfer forces originate above the specified diaphragm level. The redundancy factor, ρ, used for design of the seismic-force-resisting elements also applies to diaphragm transfer forces, thus completing the load path.

C12.10.2.1 Collector Elements Requiring Load Combinations with Overstrength Factor for Seismic Design Categories C through F. The overstrength requirement of this section is intended to keep inelastic behavior in the ductile elements of the seismic-force-resisting system (consistent with the *R* factor) rather than in collector elements.

C12.11 STRUCTURAL WALLS AND THEIR ANCHORAGE

As discussed in Section C11.7, structural integrity is important not only in earthquake-resistant design but also in resisting high winds, floods, explosion, progressive failure, and even such ordinary hazards as foundation settlement. The detailed requirements of this section address wall-to-diaphragm integrity.

C12.11.1 Design for Out-of-Plane Forces. Because they are often subjected to local deformations caused by material shrinkage, temperature changes, and foundation movements, wall connections require some degree of ductility in order to accommodate slight movements while providing the required strength.

Although nonstructural walls are not subject to this requirement, they must be designed in accordance with Chapter 13.

C12.11.2 Anchorage of Concrete or Masonry Structural Walls. One major hazard in past earthquakes is the separation of heavy masonry or concrete walls from floors or roofs. The forces defined in this section apply only to the anchorage or connection of the wall to the structure, and not to overall wall design. The anchorage force should be considered both for tension (out-of-plane) and sliding (in-plane) directions.

Where the lateral spacing of connections used to resist the wall anchorage force are spaced further apart than 4 feet (1219 mm) as measured along the length of the wall, the section of wall that spans between the anchors must be designed to resist the local out-of-plane bending caused by this force.

C12.11.2.1 Anchorage of Concrete or Masonry Structural Walls to Flexible Diaphragms. Diaphragm flexibility can amplify out-of-plane accelerations so the wall anchorage forces in this condition are twice those defined in Section 12.11.1.

C12.11.2.2 Additional Requirements for Diaphragms in Structures Assigned to Seismic Design Categories C through F.

C12.11.2.2.1 Transfer of Anchorage Forces into Diaphragm. This requirement, which aims to prevent the diaphragm from tearing apart during strong shaking by requiring transfer of anchorage forces across the complete depth of the diaphragm, was prompted by failures of connections between tilt up concrete walls and wood panelized roof systems in the 1971 San Fernando earthquake. An exception is provided for modestly proportioned diaphragms of light-frame construction, which have not performed poorly.

Depending upon diaphragm shape and member spacing, numerous suitable combinations of subdiaphragms and continuous tie elements and smaller sub-subdiaphragms connecting to larger subdiaphragm and continuous tie elements are possible. The configuration of each subdiaphragm (or sub-subdiaphragm) provided must comply with the simple 2.5-to-1 length-to-width ratio, and the continuous ties must have adequate member and connection strength to carry the accumulated wall anchorage forces.

C12.11.2.2.2 Steel Elements of Structural Wall Anchorage System. A multiplier of 1.4 has been specified for strength design of steel elements in order to obtain a fracture strength of almost 2 times the specified design force (where φ_t is 0.75 for tensile rupture).

C12.11.2.2.3 Wood Diaphragms. Material standards for wood structural panel diaphragms permit the sheathing to resist shear forces only; use to resist direct tension or compression forces is not permitted. Therefore, seismic anchorage forces from walls must be transferred into framing members (such as beams, purlins, or subpurlins) using suitable straps or anchors. For wood diaphragms, it is common to use local framing and sheathing elements as subdiaphragms to transfer the uniform lateral wall forces into more concentrated lines of drag or continuity framing that carry the forces across the diaphragm and hold the building together. Figure C12.11-1 shows a schematic plan of typical roof framing using subdiaphragms.

Fasteners to wood framing are intended to transfer shear forces only along the wood framing; any forces acting transverse to the framing tend to induce splitting (due to cross-grain tension). Fasteners into wood ledgers attached to concrete or masonry walls are designed to resist shear forces only; separate straps or anchors generally are provided to transfer out-of-plane wall forces into perpendicular framing members.

C12.11.2.2.4 Metal Deck Diaphragms. In addition to transferring shear forces, metal deck diaphragms often can resist direct axial forces in at least one direction. However, corrugated metal decks cannot transfer axial forces in the direction perpendicular to the corrugations and are prone to buckling if the unbraced length of the deck as a compression element is large. To manage diaphragm forces perpendicular to the deck corrugations, it is common that metal decks are supported at 8- to 10-foot intervals by joists that are connected to walls in a manner suitable to resist the full wall anchorage design force and to carry that force across the diaphragm. In the direction parallel to the deck corrugations, subdiaphragm systems are considered near the walls; if the compression forces in the deck become large relative to the joist spacing, small compression reinforcing elements are provided to transfer the forces into the subdiaphragms.

C12.11.2.2.6 Eccentrically Loaded Anchorage System. Wall anchors often are loaded eccentrically, either because the anchorage mechanism allows eccentricity, or because of anchor bolt or strap misalignment. This eccentricity reduces the anchorage connection capacity and hence must be considered explicitly in design of the anchorage. Figure C12.11-2 shows a one-sided roof-to-wall anchor that is subjected to severe eccentricity due to a misplaced anchor rod. If the detail were designed as a concentric two-sided connection, this condition would be easier to correct.

C12.11.2.2.7 Walls with Pilasters. The anchorage force at pilasters must be calculated considering two-way bending in wall panels. It is customary to anchor the walls to the diaphragms assuming one-way bending and simple supports at the top and bottom of the wall. However, where pilasters are present in the walls, their stiffening effect must be taken into account. Each panel between pilasters is supported on four sides. The reaction at the pilaster top is the result of two-way action of the

panel and is applied directly to the beam or girder anchorage at the top of the pilaster. The anchor load at the pilaster generally is larger than the typical uniformly distributed anchor load between pilasters. Figure C12.11-3 shows the tributary area typically used to determine the anchorage force for a pilaster.

Anchor points adjacent to the pilaster must be designed for the full tributary loading, conservatively ignoring the effect of the adjacent pilaster.

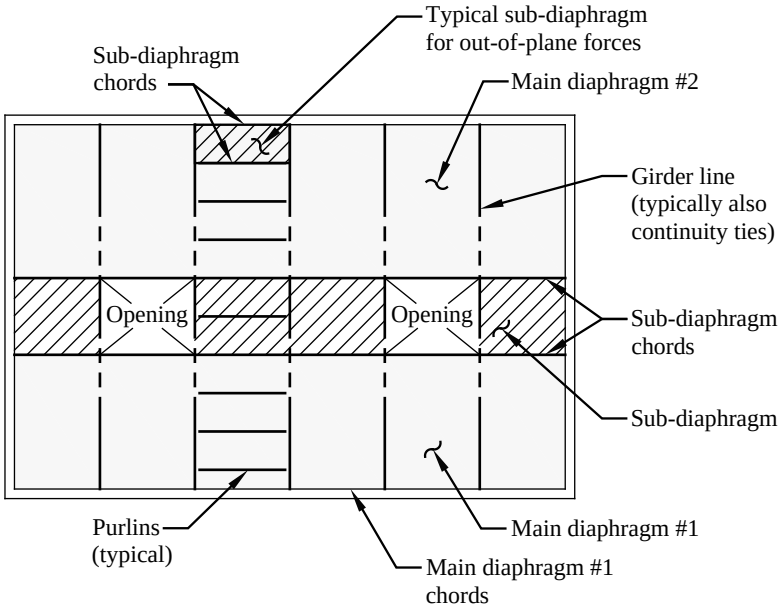

Figure C12.11-1 Typical subdiaphragm framing.

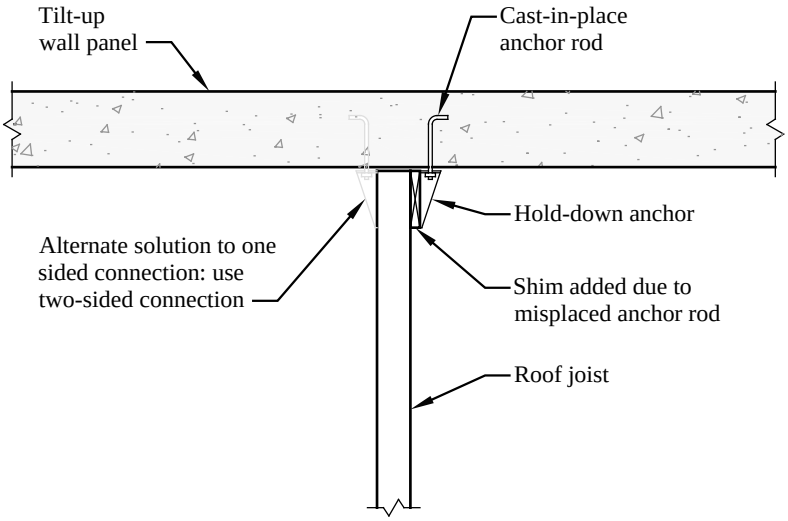

Figure C12.11-2 Plan view of wall anchor with misplaced anchor rod.

C12.12 DRIFT AND DEFORMATION

As used in the standard, deflection is the absolute lateral displacement of any point in a structure relative to its base, and story drift is the difference in deflection across a story (i.e., the deflection of a floor relative to that of the floor below).

The drifts and deflections are checked for the design earthquake ground motion, which is two-thirds of the maximum considered earthquake (MCE) ground motion.

There are many reasons to control drift; the most significant are to address the structural performance concerns of member inelastic strain and system stability and to limit damage of nonstructural components, which can be life-threatening. Drifts provide a direct but imprecise measure of member strain and structural stability. Under small lateral deformations, secondary stresses due to the P-delta effect are normally within tolerable limits. (See Section C12.8.7.) The drift limits provide indirect control of structural performance.

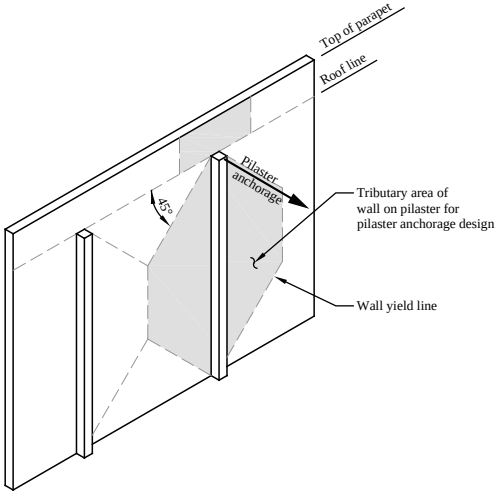

Figure 12.11-3 Tributary area used to determine anchorage force at pilaster.

Buildings subjected to earthquakes need drift control to restrict damage of partitions, shaft and stair enclosures, glass, and other fragile nonstructural elements. The drift limits have been established without regard to economic considerations such as a comparison of present worth of future repairs with additional structural costs to limit drift. These are matters for building owners and designers to address.

The drift limits of Table 12.12-1 reflect consensus judgment taking into account life safety and damage control objectives described above. Since the displacements induced in a structure include inelastic effects, structural damage in the design-level earthquake is likely. This may be seen from the seismic drift limits stated in Table 12.12-1. For ordinary structures (Occupancy Category I or II), the drift limit is $0.02h_{sx}$, which is about ten times the drift ordinarily allowed under wind loads. If deformations well in excess of the seismic drift limits were to occur repeatedly, structural components could lose so much stiffness or strength that they compromise the safety and stability of the structure.

To provide better performance for Occupancy Category IV essential facilities, their drift limits generally are more stringent than those for Occupancy Categories II and III. However, those limits are still greater than the damage thresholds for most nonstructural components. Therefore, while the performance of Occupancy Category IV buildings should be better than that of lower Occupancy Category buildings, there still can be considerable damage in the design earthquake.

The drift limits for low-rise structures are relaxed somewhat, provided that the interior walls, partitions, ceilings, and exterior wall systems have been designed to accommodate story drifts. The type of steel building envisioned by the exception to the table would be similar to a prefabricated steel structure with metal skin.

The limits set forth in Table 12.12-1 are for story drifts and apply to each and every story. For some structures, satisfying strength requirements may produce a system with adequate drift control. However, the design of moment-resisting frames and of tall, narrow shear walls or braced frames often is governed by drift considerations. Where design spectral response accelerations are large, seismic drift considerations are expected to control the design of midrise buildings. Where design spectral response accelerations are small or the building is very tall, design for wind generally will control.

C12.12.3 Building Separation. The intent of this section is to address separations (also called seismic joints) between adjacent structures or portions of the same structure (with or without frangible closures) for the purpose of permitting independent response to earthquake ground motion. For irregular structures that cannot be expected to act reliably as a unit, seismic joints should be used to produce separate units whose independent response to earthquake ground motion can be predicted.

The standard does not give a precise formulation for the separations, but it does require that the distance be "sufficient to avoid damaging contact under total deflection." It is recommended that the distance be no less than the square root of the sum of the squares of the lateral deflections, which represent the anticipated maximum inelastic deformations including torsion, of the two units assumed to deflect toward each other (thus increasing with height). If the effects of impact can be shown not to be detrimental, these distances can be reduced. For very rigid shear wall structures with rigid diaphragms whose lateral deflections cannot be reasonably estimated, it is suggested that older code requirements for structural separations of at least 1 inch (25 mm) plus 1/2 inch (13 mm) for each 10 feet (3 m) of height above 20 feet (6 m) be followed.

C12.12.4 Deformation Compatibility For Seismic Design Categories D Through F. The purpose of this section is to require that the seismic-force-resisting system provide adequate deformation control to protect elements of the structure that are not part of the seismic-force-resisting system. In regions of high seismicity, many designers apply ductile detailing requirements to elements that are intended to resist seismic forces but neglect such practices in nonstructural elements or elements intended to resist only gravity forces. Even where elements of the structure are not intended to resist seismic forces and are not detailed for such resistance, they can participate in the response and suffer severe damage as a result.

In the 1994 Northridge earthquake, such participation was a cause of several failures. A preliminary reconnaissance report of that earthquake (EERI, 1994) states:

> Of much significance is the observation that six of the seven partial collapses (in modern precast concrete parking structures) seem to have been precipitated by damage to the gravity load system. Possibly, the combination of large lateral deformation and vertical load caused crushing in poorly confined columns that were not detailed to be part of the lateral load resisting system. . . . Punching shear failures were observed in some structures at slab-to-column connections such as at the Four Seasons building in Sherman Oaks. The primary lateral load resisting system was a perimeter ductile frame that performed quite well. However, the interior slab-column system was incapable of undergoing the same lateral deflections and experienced punching failures.

This section addresses such concerns. Rather than relying on designers to assume appropriate levels of stiffness, this section explicitly requires that the stiffening effects of adjoining rigid structural and nonstructural elements be considered and that a rational value of member and restraint stiffness be used for the design of components that are not part of the seismic-force-resisting system.

This section also includes a requirement to address shears that can be induced in structural components that are not part of the seismic-force-resisting system, since sudden shear failures have been catastrophic in past earthquakes.

The exception in Section 12.12.4 is intended to encourage the use of intermediate or special detailing in beams and columns that are not part of the seismic-force-resisting system. In return for better detailing, such beams and columns are permitted to be designed to resist moments and shears from unamplified deflections. This reflects observations and experimental evidence that well-detailed components can accommodate large drifts by responding inelastically without losing significant vertical load-carrying capacity.

C12.13 FOUNDATION DESIGN

C12.13.3 Foundation Load-Deformation Characteristics. This section of the standard provides guidance on modeling load-deformation characteristics of the foundation-soil system (foundation stiffness) for linear analysis procedures. The further guidance contained herein addresses both linear and nonlinear analysis methods. Where linear analysis procedures are used with the methodology given below, the earthquake forces should not be reduced by R.

Modeling of the load-deformation characteristics of foundations should be in accordance with ASCE/SEI 41. For nonlinear analysis of piles that may form plastic hinges, the lateral load-deformation characteristics of piles may be taken from Song, et al. (2005).

For load combinations including seismic load effects, the vertical, lateral, and rocking load capacities of foundations as limited by the soil should be sufficient to resist loads with acceptable deformations, considering the short duration of loading, the dynamic properties of the soil, and the ultimate load capacities, Q_{us}, of the foundations.

Ultimate foundation load capacities should be determined by a qualified geotechnical engineer based on geotechnical site investigations that include field and laboratory testing to determine soil classification and soil strength parameters or on in-situ testing of prototype foundations. For competent soils that do not undergo strength degradation under seismic loading, strength parameters for static loading conditions may be used to compute ultimate load capacities for seismic design. For sensitive cohesive soils or saturated cohesionless soils, the potential for earthquake-induced strength degradation should be considered.

Ultimate foundation load capacities, Q_{us}, under vertical, lateral, and rocking loading should be determined using accepted foundation design procedures and principles of plastic analysis. Calculated ultimate load capacities, Q_{us}, should be best-estimated values using soil properties that are representative average values for individual foundations. Best-estimated values of Q_{us} should be reduced by resistance factors (ϕ) to reflect uncertainties in site conditions and in the reliability of analysis methods. The factored foundation load capacity, ϕQ_{us}, should be used both to check acceptance criteria and as the foundation capacity in nonlinear load-deformation models.

If ultimate foundation load capacities are determined based on geotechnical site investigations including laboratory or in-situ tests, ϕ factors equal to 0.8 for cohesive soils and 0.7 for cohesionless soils should be used for vertical, lateral, and rocking resistance for all foundation types. If ultimate foundation load capacities are determined based on full-scale field-testing of prototype foundations, ϕ factors equal to 1.0 for cohesive soils and 0.9 for cohesionless soils are recommended.

For both linear and nonlinear analysis procedures, a model incorporating a combined superstructure and foundation system is necessary to assess the effect of foundation deformations on the superstructure elements.

For linear analysis methods, the linear load-deformation behavior of foundations should be represented by an equivalent linear (secant) stiffness using soil properties that are compatible with the soil strain levels associated with the design earthquake motion. The strain-compatible shear modulus, G, and the associated strain-compatible shear wave velocity, v_s, needed for the evaluation of equivalent linear stiffness are specified in Chapter 19 of the standard or can be based on a site-specific study. ASCE/SEI 41 is an acceptable alternative to that contained in the standard and may provide more realistic results.

For nonlinear analysis procedures, the nonlinear load-deformation behavior of the foundation-soil system may be represented by a bilinear or multilinear curve having an initial equivalent linear stiffness and a limiting foundation capacity. The initial equivalent linear stiffness should be determined as described above for linear analysis methods. The limiting foundation capacity should be taken as the factored foundation load capacity, ϕQ_{us}. Parametric variations in analyses should include: (a) a reduction in stiffness of 50 percent combined with a limiting foundation capacity, $\phi Q_{us,}$ and (b) an increase in stiffness of 50 percent combined with a limiting foundation capacity equal to Q_{us} multiplied by $1/\phi$.

For linear analysis procedures, factored foundation load capacities, ϕQ_{us}, should not be exceeded for load combinations that include seismic load effects.

For the nonlinear analysis procedures, if the factored foundation load capacity, ϕQ_{us}, is reached during seismic loading, the potential significance of associated transient and permanent foundation displacements should be evaluated. Foundation displacements are acceptable if they do not impair the continuing function of Occupancy Category IV structures or the life safety of any structure.

C12.13.4 Reduction of Foundation Overturning. Since the vertical distribution of forces prescribed for use with the equivalent lateral force procedure is intended to envelope story shears, overturning moments are exaggerated. (See Section C12.13.3.) Such moments will be lower where multiple modes respond, so a 25 percent reduction is permitted for design (strength and stability) of the foundation using this procedure. This reduction is not permitted for inverted pendulum or cantilevered column type structures, which typically have a single mode of response.

Since the modal response spectrum analysis procedure more accurately reflects the actual distribution of shears and overturning moments, the permitted reduction is only 10 percent.

C12.13.5 Requirements for Structures Assigned to Seismic Design Category C.

C12.13.5.1 Pole-Type Structures. The high contact pressures that develop between pole and soil as a result of lateral loads make pole-type structures sensitive to earthquake motions. Bending in the poles and soil lateral capacity and deformation are key considerations in the design. For further discussion of pole-soil interaction, see Section C12.13.6.7.

C12.13.5.2 Foundation Ties. One important aspect of adequate seismic performance is that the foundation acts as a unit, not permitting one column or wall to move appreciably with respect to another. To attain this performance, it is common to provide ties between footings and pile caps. This is especially important where the use of deep foundations is driven by the existence of soft surface soils.

Multistory buildings often have major columns that run the full height of the building adjacent to smaller columns that support only one level; the calculated tie force is based on the heavier column load.

The standard permits alternate methods of tying foundations together. Lateral soil pressure on pile caps is not a recommended method because motion is imparted from soil to structure and during displacement under dynamic conditions.

C12.13.5.3 Pile Anchorage Requirements. The pile anchorage requirements are intended to prevent brittle failures of the connection to the pile cap under moderate ground motions. Moderate ground motions can result in pile tension forces or bending moments that could compromise shallow anchorage embedment. Loss of pile anchorage could result in increased structural displacements from rocking, overturning instability, and loss of shearing resistance at the ground surface. A concrete bond to a bare steel pile section usually is unreliable, but connection by means of deformed bars properly developed from the pile cap into concrete confined by a circular pile section is permitted.

C12.13.6 Requirements for Structures Assigned to Seismic Design Categories D through F.

C12.13.6.1 Pole-Type Structures. See Section C12.13.5.1.

C12.13.6.2 Foundation Ties. See Section C12.13.5.2. For Seismic Design Categories D through F, the requirement is extended to spread footings on soft soils.

C12.13.6.3 General Pile Design Requirements. Design of piles is based on the same *R* factor used in design of the superstructure; since inelastic behavior will result, piles should be designed with ductility similar to that of the superstructure. When strong ground motions occur, inertial structure pile-soil interaction may produce plastic hinging in piles near the bottom of the pile cap, and kinematic soil-pile interaction will result in bending moments and shearing forces throughout the length of the pile, being higher at interfaces between stiff and soft soil strata. These effects are particularly severe in soft soils and liquefiable soils so Section 14.2.3.2.1 requires special detailing in areas of concern.

The shears and curvatures in piles caused by inertial and kinematic interaction may exceed the bending capacity of conventionally designed piles, resulting in severe damage. Analysis techniques to evaluate pile bending are discussed by Margason and Holloway (1977) and Mylonakis (2001), and these effects on concrete piles are further discussed by Shepard (1983). For homogeneous, elastic media and assuming the pile follows the soil, the free-field curvature (soil strains without a pile present) can be estimated by dividing the peak ground acceleration by the square of the shear wave velocity of the soil; considerable judgment is necessary in using this simple relationship for a layered, inelastic profile with pile-soil interaction effects. Norris (1994) discusses methods to assess pile-soil interaction.

Where determining the extent of special detailing, the designer must consider variation in soil conditions and driven pile lengths, so that adequate ductility is provided at potential high curvature interfaces. Confinement of concrete piles to provide ductility and to maintain functionality of the confined core pile during and after the earthquake may be obtained by use of heavy spiral reinforcement or use of exterior steel liners.

C12.13.6.4 Batter Piles. Partially embedded batter piles have a history of poor performance in strong ground shaking, as shown by Gerwick and Fotinos (1992). Failure of battered piles has been attributed to design that neglect loading on the piles from ground deformation or that assumes that lateral loads are resisted by axial response of piles without regard to moments induced in the pile at the pile cap (Lam and Bertero, 1990). Because batter piles are considered to have limited ductility, they must be designed using the load combinations with overstrength. Moment-resisting connections between pile and pile cap must resolve the eccentricities inherent in batter pile configurations. This concept is illustrated clearly by EQE Engineering (1991).

C12.13.6.5 Pile Anchorage Requirements. Piles should be anchored to the pile cap to permit energy dissipating mechanisms, such as pile slip at the pile-soil interface, while maintaining a competent connection. This section of the standard sets forth a capacity design approach to achieve that objective. Anchorages occurring at pile cap corners and edges should be reinforced to preclude local failure of plain concrete sections due to pile shears, axial loads, and moments.

C12.13.6.6 Splices of Pile Segments. A capacity design approach, similar to that for pile anchorage, is applied to pile splices.

C12.13.6.7 Pile Soil Interaction. Short piles and long slender piles embedded in the earth behave differently when subject to lateral forces and displacements. The response of a long slender pile depends on its interaction with the soil considering the nonlinear response of the soil. Numerous design aid curves and computer programs are available for this type of analysis, which is necessary to obtain realistic pile moments, forces, and deflections and is common in practice (Ensoft, 2004). More sophisticated models, which also consider inelastic behavior of the pile itself, can be analyzed using general-purpose nonlinear analysis computer programs or closely approximated using the pile-soil limit state methodology and procedure given by Song, et al. (2005).

Short piles (with length-to-diameter ratios no more than 6) can be treated as a rigid body simplifying the analysis. A method assuming a rigid body and linear soil response for lateral bearing is given in the current building codes. A more accurate and comprehensive approach using this method is given in a study by Czerniak (1957).

C12.13.6.8 Pile Group Effects. The effects of groups of piles, where closely spaced, must be taken into account for vertical and horizontal response. As groups of closely spaced piles move laterally, failure zones for individual piles overlap, and horizontal strength and stiffness response of the pile-soil system is reduced. Reduction factors or "*p*-multipliers" are used to account for these groups of closely spaced piles. For a pile center-to-center spacing of three pile diameters, reduction factors of 0.6 for the leading pile row and 0.4 for the trailing pile rows are recommended by Rollins, et al. (1999). Computer programs are available to analyze group effects assuming a nonlinear soil and elastic piles (Ensoft, 2004a).

C12.14 SIMPLIFIED ALTERNATIVE STRUCTURAL DESIGN CRITERIA FOR SIMPLE BEARING WALL OR BUILDING FRAME SYSTEMS

C12.14.1 General. In recent years, engineers and building officials have become concerned that the seismic design requirements in codes and standards, while intended to make structures perform more reliably, have become so complex and difficult to understand and to implement that they may be counterproductive. Since the response of buildings to earthquake ground shaking is very complex (especially for irregular structural systems), realistically accounting for these effects can lead to complex requirements. There is a concern that the typical designers of small, simple structures, which may represent more than 90 percent of construction in the United States, have difficulty understanding and applying the general seismic requirements of the standard.

The simplified procedure presented in this section of the standard applies to low-rise, stiff structures. The procedure, which was refined and tested over a five-year period, was developed to be used for a defined set of structures deemed to be sufficiently regular in configuration to allow a reduction of prescriptive requirements. For some design elements, such as foundations and anchorage of nonstructural systems, other sections of the standard must be followed, as referenced within Section 12.14.

C12.14.1.1 Simplified Design Procedure. Reasons for the limitations of the simplified design procedure of Section 12.14 are as follows:

1. The procedure was developed to address adequate seismic performance for standard occupancies. Since it was not developed for higher levels of performance associated with Occupancy Category III and IV structures, no importance factor (I) is employed.
2. Site Class E and F soils require specialized procedures that are beyond the scope of the procedure.
3. The procedure was developed for stiff, low-rise buildings, where higher-mode effects are negligible.
4. Only stiff systems, where drift is not a controlling design criterion, may employ the procedure. Because of this limitation, drifts are not computed. The response modification coefficient, R, and the associated system limitations are consistent with those found in the general Chapter 12 requirements.
5. In order to achieve a balanced design and to achieve a reasonable level of redundancy, two lines of resistance are required in each of the two major axis directions. Because of this stipulation, no redundancy factor (ρ) is applied.
6. To reduce the potential for dominant torsional response, at least one line of resistance must be placed on each side of the center of mass.
7. Large overhangs for flexible diaphragm buildings can produce response that is inconsistent with the assumptions associated with the procedure.
8. A system that satisfies these layout and proportioning requirements avoids torsional irregularity, so calculation of accidental torsional moments is not required.
9. An essentially orthogonal orientation of lines of resistance effectively uncouples response along the two major axis directions, so orthogonal effects may be neglected.
10. Where the simplified design procedure is chosen, it must be used for the entire design, in both major axis directions.
11. Since in-plane and out-of-plane offsets generally create large diaphragm, collector, and discontinuous element demands that are not addressed by the procedure, these irregularities are prohibited.
12. Buildings that exhibit weak-story behavior violate the assumptions used to develop the procedure.

C12.14.3 Seismic Load Effects and Combinations. The seismic load effect and combination equations for the simplified design procedure are consistent with those for the general procedure, with one notable exception: the overstrength factor (corresponding to Ω_0 in the general procedure) is set at 2.5 for all systems as indicated in Section 12.14.3.2.1. Given the limited systems that can use the simplified design procedure, specifying unique overstrength factors was deemed unnecessary.

C12.14.7 Design and Detailing Requirements. The design and detailing requirements outlined in this section are similar to those for the general procedure. The few differences include the following:

1. Forces used to connect smaller portions of a structure to the remainder of the structures are taken as 0.20 times the short-period design spectral response acceleration, S_{DS}, rather than the general procedure value of 0.133 (Section 12.14.7.1).
2. Anchorage forces for concrete or masonry structural walls for structures with diaphragms that are not flexible are computed using the requirements for nonstructural walls.

C12.14.8 Simplified Lateral Force Analysis Procedure

C12.14.8.1 Seismic Base Shear. The seismic base shear in the simplified design procedure, as given by Equation 12.14-11, is a function of the short-period design spectral response acceleration, S_{DS}. The value for F in the base shear equation addresses changes in dynamic response for two- and three-story buildings. As in the general procedure (Section 12.8.1.3), S_{DS} may be computed for short, regular structures with S_S taken no greater than 1.5.

C12.14.8.2 Vertical Distribution. The seismic forces for multistory buildings are distributed vertically in proportion to the weight of the respective floor. Given the slightly amplified base shear for multi-story buildings, this assumption, along with the three-story height limit, produces results consistent with the more traditional triangular distribution without introducing that more sophisticated approach.

C12.14.8.5 Drift Limits and Building Separation. For the simplified design procedure, which is restricted to stiff wall and braced frame structures, drift need not be calculated. Where drifts are required (such as for structural separations and cladding design) a conservative drift value of 1 percent is specified.

COMMENTARY CHAPTER 13, SEISMIC DESIGN REQUIREMENTS FOR NONSTRUCTURAL COMPONENTS

C13.1 GENERAL

Chapter 13 defines minimum design criteria for architectural, mechanical, electrical, and other nonstructural systems and components recognizing structure use, occupant load, the need for operational continuity, and the interrelation of structural and architectural, mechanical, electrical, and other nonstructural components. Nonstructural components are designed for design earthquake ground motions as defined in Section 11.2 and determined in Section 11.4.4 of the standard. In contrast to structures, which are implicitly designed for a low probability of collapse when subjected to the maximum considered earthquake (MCE) ground motions, there are no implicit performance goals associated with the MCE for nonstructural components. Performance goals associated with the design earthquake are discussed in Section C13.1.3.

Suspended or attached nonstructural components that could detach either in full or in part from the structure during an earthquake are referred to as falling hazards and may represent a serious threat to property and life safety. Critical attributes that influence the hazards posed by these components include their weight, their attachment to the structure, their failure or breakage characteristics (e.g., certain types of glass), and their location relative to occupied areas (e.g., over an entry or exit, a public walkway, an atrium, or a lower adjacent structure). Architectural components that pose potential falling hazards include parapets, cornices, canopies, marquees, glass, large ornamental elements (e.g., chandeliers), and building cladding. In addition, suspended mechanical and electrical components (e.g., mixing boxes, piping, and ductwork) may represent serious falling hazards. Figures C13.1-1 through C13.1-4 show damage to nonstructural components in past earthquakes.

Figure C13.1-1 Hospital imaging equipment that fell from overhead mounts.

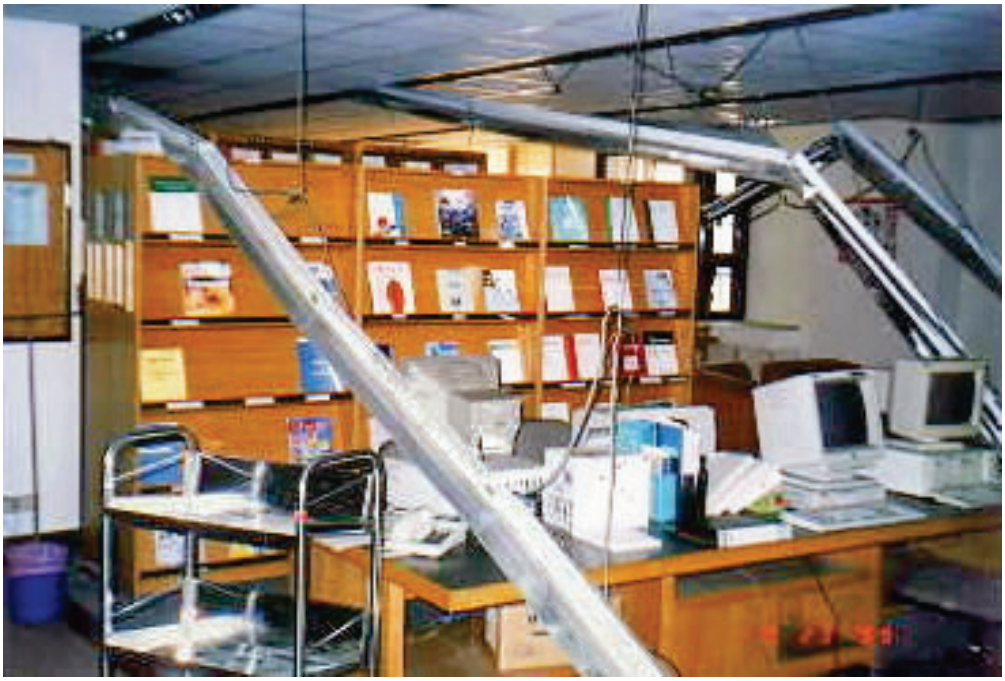

Figure C13.1-2 Collapsed light fixtures.

Figure C13.1-3 Collapsed duct and HVAC diffuser.

Figure C13.1-4 Damaged ceiling system.

Components whose collapse during an earthquake could result in blockage of the means of egress deserve special consideration. The term "means of egress" is used commonly in building codes with respect to fire hazard. Consideration of egress may include intervening aisles, doors, doorways, gates, corridors, exterior exit balconies, ramps, stairways, pressurized enclosures, horizontal exits, exit passageways, exit courts, and yards. Items whose failure could jeopardize the means of egress include walls around stairs and corridors, veneers, cornices, canopies, heavy partition systems, ceilings, architectural soffits, light fixtures, and other ornaments above building exits or near fire escapes. Examples of components that generally do not pose a significant falling hazard include fabric awnings and canopies. Architectural, mechanical, and electrical components that, if separated from the structure, will fall in areas that are not accessible to the public (e.g., into a mechanical shaft or light well) also pose little risk to egress routes.

For some architectural components such as exterior cladding elements, wind design forces may exceed the calculated seismic design forces. Nevertheless, seismic detailing requirements may still govern the overall structural design. Where this is a possibility, it must be investigated early in the structural design process.

The seismic design of nonstructural components may involve consideration of nonseismic requirements that are affected by seismic bracing. For example, accommodation of thermal expansion in pressure piping systems often is a critical design consideration and seismic bracing for these systems must be arranged in a manner that accommodates thermal movements. Particularly in the case of mechanical and electrical systems, the design for seismic loads should not compromise the functionality, durability, or safety of the overall design; this requires collaboration between the various disciplines of the design and construction team.

For various reasons (e.g., business continuity), it may be desirable to consider higher performance than that required by the building code. For example, to achieve continued operability of a piping system, it is necessary to prevent unintended operation of valves or other inline components in addition to preventing collapse and providing leak tightness. Higher performance also is required for components containing substantial quantities of hazardous contents (as defined in Section 11.2). These components must be designed to prevent uncontrolled release of those materials.

The requirements of Chapter 13 are intended to apply to new construction and tenant improvements installed at any time during the life of the structure, provided they are listed in Table 13.5-1 or 13.6-1. Further, they are intended to reduce (not eliminate) the risk to occupants and to improve the likelihood that essential facilities remain functional. While property protection (in the sense of investment preservation) is a possible consequence of implementation of the standard, it is not currently a stated or implied goal; a higher level of protection may be advisable if such protection is desired or required.

C13.1.1 Scope. The requirements for seismic design of nonstructural components apply to the nonstructural component as well as to its supports and attachments to the main structure. In some cases as defined in Section 13.2, it is necessary to consider explicitly the performance characteristics of the component. The requirements are intended to apply only to

permanently attached components – not to furnishings, temporary items, or mobile units. Furnishings such as tables, chairs, and desks may shift during strong ground shaking but generally pose minimal hazards provided they do not obstruct emergency egress routes. Storage cabinets, tall bookshelves, and other items of significant mass do not fall into this category and should be anchored or braced in accordance with this chapter.

Figure C13.1-5 Toppled storage cabinets.

Temporary items are those that remain in place for short periods of time (months, not years). Components that, while movable or relocatable, are expected to remain in place for periods of a year or longer should be considered permanent for the purposes of this section. Modular office systems are considered permanent since they ordinarily remain in place for long periods. In addition, they often include storage units of significant capacity which may topple in an earthquake. They are subject to the provisions of Section 13.5.8 for partitions if they exceed 6 feet in height. Mobile units include components that are moved from one point in the structure to another during ordinary use. Examples include desktop computers, office equipment, and other components that are not permanently attached to the building utility systems (Figure C13.1-5). Components that are mounted on wheels to facilitate periodic maintenance or cleaning but that otherwise remain in the same location (e.g., server racks) are not considered moveable for the purposes of anchorage and bracing. Likewise, skid-mounted components (as shown in Figure C13.1-6) as well as the skids themselves are considered permanent equipment.

In all cases, equipment must be anchored if it is permanently attached to utility services (electricity, gas, and water). For the purposes of this requirement, "permanently attached" should be understood to include all electrical connections except NEMA 5-15 and 5-20 straight-blade connectors (duplex receptacles).

C13.1.2 Seismic Design Category. The requirements for nonstructural components are based in part on the Seismic Design Category to which they are assigned. As the Seismic Design Category is established considering factors not unique to specific nonstructural components, all nonstructural components occupying or attached to a structure are assigned to the same Seismic Design Category as the structure.

C13.1.3 Component Importance Factor. Performance expectations for nonstructural components often are defined in terms of the functional requirements of the structure to which the components are attached. While specific performance goals for nonstructural components have yet to be defined in building codes, the component importance factor (I_p) implies performance levels for specific cases. For noncritical nonstructural components (those with an importance factor, I_p, of 1.0) the following behaviors are anticipated for shaking having different levels of intensity:

1. Minor earthquake ground motions – minimal damage; not likely to affect functionality
2. Moderate earthquake ground motions – some damage that may affect functionality
3. Design earthquake ground motions – major damage but significant falling hazards are avoided; likely loss of functionality.

Figure C13.1-6 Skid-mounted components.

Components with importance factors greater than 1.0 are expected to remain in place, sustain limited damage, and, when necessary, function following an earthquake (see Section C13.2.2). These components can be located in structures that are not assigned to Occupancy Category IV. For example, fire sprinkler piping systems have an importance factor, I_p, of 1.5 in all structures since these essential systems should function following an earthquake.

The component importance factor is intended to represent the greater of the life-safety importance of the component and the hazard-exposure importance of the structure. It indirectly influences the survivability of the component via required design forces and displacement levels as well as component attachments and detailing. While this approach provides some degree of confidence in the seismic performance of a component, it may not be sufficient in all cases. For example, individual ceiling tiles may fall from a ceiling grid that has been designed for larger forces. This may not represent a serious falling hazard if the ceiling tiles are made of lightweight materials, but it may lead to blockage of critical egress paths or disruption of the facility function. When higher levels of confidence in performance are required, the component is classified as a designated seismic system (Section 11.2), and, in certain cases, seismic qualification of the component or system is necessary. Seismic qualification approaches are provided in Sections 13.2.5 and 13.2.6. In addition, seismic qualification approaches presently in use by the Department of Energy (DOE) can be applied.

Occupancy Category IV structures are intended to be functional following a design earthquake; critical nonstructural components and equipment in such structures are designed with I_p equal to 1.5. This requirement applies to most components and equipment since damage to vulnerable unbraced systems or equipment may disrupt operations following an earthquake even if they are not directly classified as essential to life safety. The nonessential/nonhazardous components themselves are not assessed, and requirements focus solely on the supports and attachments. UFC 3-310-04 has additional guidance for improved performance.

C13.1.4 Exemptions. Some nonstructural components either possess inherent strength and stability, are subject to low-level earthquake demands (accelerations and relative displacements), or both. Since these nonstructural components and systems are expected to achieve the performance goals described earlier in this commentary without explicitly satisfying additional requirements, they are exempt from the requirements of Chapter 13.

Chapter 13 does not apply to Seismic Design Category A due to its very low level of seismic hazard. (See Section C11.7.) With the exception of parapets supported by bearing walls or shear walls, all components in Seismic Design Category B are exempt due to the minimal level of seismic risk. Parapets are not exempt because experience has shown these items can fail and pose a significant falling hazard even at low shaking levels.

Mechanical and electrical components in Seismic Design Category C with an importance factor (I_p) equal to 1.0 are exempt because they are subject to low levels of seismic hazard, they do not contain hazardous substances, and their function is not required to maintain life safety following an earthquake. Small components with I_p equal to 1.0 in Seismic Design Categories D, E, and F also are exempt since they do not contain hazardous substances and are not large enough to pose a life-safety hazard if they fall, slide, or topple. Failures of unbraced distribution systems at or near the point of connection to nonstructural components have been observed in past earthquakes. For this reason, flexible connections such as expansion loops, braided hose, or expansion joints are required to allow for the larger relative displacements associated with unbraced components. Note that the stiffness of flexible connections may be sensitive to internal pressure and length of the connection.

C13.1.5 Applicability of Nonstructural Component and Requirements. At times, a nonstructural component should be treated as a nonbuilding structure. When the physical characteristics associated with a given class of nonstructural components vary widely, judgment is needed to select the appropriate design procedure and coefficients. For example, cooling towers vary from small packaged units with an operating weight of 2,000 pounds or less to structures the size of buildings. Consequently, design coefficients for the design of "cooling towers" are found both in Table 13.6-1 and Table 15.4-2. Small cooling towers are best designed as nonstructural components using the provisions of Chapter 13 while large ones are clearly nonbuilding structures that are more appropriately designed using the provisions of Chapter 15. Similar issues arise for other classes of nonstructural component (e.g., boilers and bins). Guidance on determining whether an item should be treated as a nonbuilding structure or nonstructural component for the purpose of seismic design is provided in Bachman and Dowty (2008).

There are practical limits on the size of a component that can be qualified via shake table testing. Components too large to be qualified by shake table testing need to be qualified by a combination of structural analysis and qualification testing or empirical evaluation through a subsystem approach. Subsystems of a large, complex component (e.g., a very large chiller) can be qualified individually and the overall structural frame of the component evaluated by structural analysis

Premanufactured modular mechanical units are considered nonbuilding structures supporting nonstructural components. The entire system (all modules assembled) can be shake table qualified or qualified separately as subsystems. Modular mechanical units house various nonstructural components that are subject to all the design requirements of Chapter 13.

The specified weight limit for nonstructural components (25 percent relative to the combined weight of the structure and component) relates to the condition at which dynamic interaction between the component and the supporting structural system is potentially significant. Section 15.3.2 contains requirements for addressing this interaction in design.

C13.1.6 Reference Documents. Professional and trade organizations have developed nationally recognized codes and standards for the design and construction of specific mechanical and electrical components. These documents provide design guidance for normal and upset (abnormal) operating conditions and for various environmental conditions. Some of these documents include earthquake design requirements in the context of the overall mechanical or electrical design. It is the intent of the standard that seismic requirements in referenced documents be used. The developers of these documents are familiar with the expected performance and failure modes of the components; however, the documents may be based on design considerations not immediately obvious to a structural design professional. For example, in the design of industrial piping, stresses due to seismic inertia forces typically are not added to those due to thermal expansion.

There is a potential for misunderstanding and misapplication of reference documents for the design of mechanical and electrical systems. A registered design professional familiar with both the standard and the reference documents used should be involved in the review and acceptance of the seismic design.

Even when reference documents for nonstructural components lack specific earthquake design requirements, mechanical and electrical equipment constructed in accordance with industry-standard reference documents have performed well historically when properly anchored. Nevertheless, it is expected that manufacturers of mechanical and electrical equipment will consider seismic loads in the design of the equipment itself even when not explicitly required by this chapter.

While some reference documents provide requirements for seismic capacity appropriate to the component being designed, the seismic demands used in design may not be less than those specified in the standard.

Specific guidance for selected mechanical and electrical components and conditions is provided in Section 13.6.

C13.1.7 Reference Documents Using Allowable Stress Design. Many nonstructural components are designed using specifically developed reference documents that are based on allowable stress loads and load combinations and permit increases in allowable stresses for seismic loading. Although Section 2.4.1 of the standard does not permit increases in allowable stresses, Section 13.1.7 explicitly defines the conditions for their use in the design of nonstructural components.

C13.2 GENERAL DESIGN REQUIREMENTS

C13.2.1 Applicable Requirements for Architectural, Mechanical, and Electrical Components, Supports, and Attachments. Compliance with the requirements of Chapter 13 may be accomplished by project-specific design or by a manufacturer's certification of seismic qualification of a system or component. In each case, the evidence of compliance is submitted to the authority having jurisdiction. When compliance is by manufacturer's certification, the items must be installed in accordance with the manufacturer's requirements.

Components addressed by the standard include individual simple units and assemblies of simple units for which reference documents establish seismic analysis or qualification requirements. Also addressed by the standard are complex architectural, mechanical, and electrical systems for which reference documents either do not exist or exist for only elements of the system. In the design and analysis of both simple components and complex systems, the concepts of flexibility and ruggedness often can assist the designer in determining the necessity for analysis and, when analysis is necessary, the extent and methods by which seismic adequacy may be determined. These concepts are discussed in Section C13.6.1.

C13.2.2 Special Certification Requirements for Designated Seismic Systems. While the goal of design for most nonstructural components is to prevent detachment or toppling that would pose a hazard to life safety, designated seismic systems (with $I_p = 1.5$) are intended to meet higher performance goals. In some cases, failure of mechanical or electrical equipment itself poses a significant hazard. This section addresses the design and certification of designated seismic system components and their supports and attachments. The goals of this section are to improve survivability and achieve a high level of confidence in post-earthquake functionality, and they require additional considerations.

Examples of designated seismic systems include fire protection piping, uninterruptible power supplies for hospitals, and certain vessels or piping that contain highly toxic or explosive substances.

Using an importance factor, I_p, equal to 1.5 to increase design forces can reduce the possibility of detachment or toppling, but this directly affects only structural integrity and stability; function and operability of mechanical and electrical components may be affected only indirectly by increasing design forces. For complex components, testing or experience may be the only reasonable way to improve the confidence of function and operability. For many types of equipment, past earthquake experience has shown that maintaining structural integrity and stability provides post-earthquake function and operability. On the other hand, mechanical joints in containment components (e.g., tanks, vessels, and piping) may not remain leak-tight in an earthquake. Avoiding this condition may require a design that is more conservative than that required by the standard.

Evaluating post-earthquake operational performance by analysis is impractical for active mechanical and electrical equipment with components that rotate or otherwise move mechanically during operation. Active equipment includes pumps and electric motors. In many cases, such equipment is inherently rugged, and an evaluation of experience data together with analysis of the component anchorage is adequate to demonstrate compliance (see Section 13.6). In other cases (e.g., motor control centers and switching equipment), shake table testing may be required. Components that contain hazardous materials (e.g., tanks, piping, and vessels) typically are qualified by analysis, but it may be necessary to qualify certain operational valving or mechanical equipment within the system by other means.

C13.2.3 Consequential Damage. Although the components identified in Tables 13.5-1 and 13.6-1 are listed separately, significant interrelationships exist and must be considered. Consequential damage occurs due to interaction between components and systems. Even "braced" components displace and the displacement between lateral supports can be significant in the case of distributed systems such as piping systems, cable and conduit systems and other linear systems. It is the intent of the standard that the seismic displacements considered include both relative displacement between multiple points of support (addressed in Section 13.3.2) and, for mechanical and electrical components, displacement within the component assemblies. Impact of components must be avoided unless the components are fabricated of ductile materials that have been shown to be capable of accommodating the expected impact loads. With protective coverings, ductile mechanical and electrical components and many more fragile components are expected to survive all but the most severe impact loads. Flexibility and ductility of the connections between distribution systems and the equipment to which they attach is essential to the seismic performance of the system.

The determination of the displacements that generate these interactions are not addressed explicitly in Section 13.3.2.1. That section concerns relative displacement of support points. Consequential damage may occur due to displacement of components and systems between support points. For example, in older suspended ceiling installations, excessive lateral displacement of a ceiling system may fracture sprinkler heads that project through the ceiling. A similar situation may arise if sprinkler heads projecting from a small diameter branch line pass through a rigid ceiling system. While the branch line may be properly restrained, it may still displace sufficiently between lateral support points, to impact other components or systems. Similar interactions occur where a relatively flexible distributed system connects to a braced or rigid component.

The potential for impact between components that are in contact with or in close proximity to other structural or nonstructural components must be considered. However, where considering these potential interactions, the designer must determine if the potential interaction is both credible and significant. For example, the fall of a ceiling panel located above a motor control center is a credible interaction because the falling panel in older suspended ceiling installations can reach and impact the motor control center. An interaction is significant if it can result in damage to the target. Impact of a ceiling panel on a motor control center may not be significant, due to the light weight of the ceiling panel. Special design consideration is appropriate where the failure of a nonstructural element could adversely influence the performance of an adjacent critical nonstructural component, such as an emergency generator.

C13.2.4 Flexibility. In many cases, flexibility is more important than strength in the performance of distributed systems, such as piping and ductwork. A good understanding of the displacement demand on the system as well as its displacement capacity is required. Components or their supports and attachments must be flexible enough to accommodate the full range of expected differential movements; some localized inelasticity is permitted in accommodating the movements. Relative movements in all directions must be considered. For example, even a braced branch line of a piping system will displace, so it needs to be connected to other braced or rigid components in a manner that will accommodate the displacements without failure (see Figure C13.2-1). For another example, cladding units (such as precast concrete wall units) while often very rigid in-plane, if supported at more than one level, require connections capable of accommodating story drift. (See Section C13.5.3 for an illustration.)

If component analysis assumes rigid anchors or supports, the predicted loads and local stresses can be unrealistically large, so it may be necessary to consider anchor and/or support stiffness.

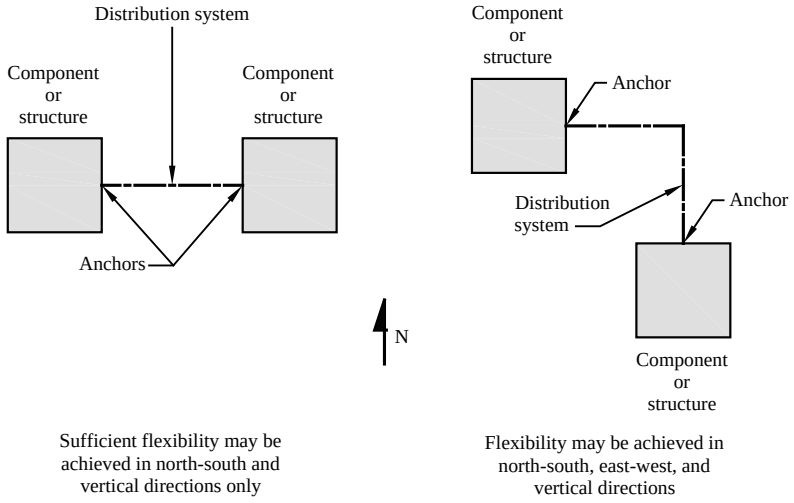

Figure C13.2-1 Schematic plans illustrating branch line flexibility.

C13.2.5 Testing Alternative for Seismic Capacity Determination. Testing is a well established alternative method of seismic qualification for small- to medium-size equipment. Several national reference documents have testing requirements adaptable for seismic qualification. One such reference document, ICC-ES AC156 (2007), is a shake-table testing protocol that has been adopted by the ICC Evaluation Service. It was developed specifically to be consistent with acceleration demands (that is, force requirements) of the standard.

The development or selection of testing and qualification protocols should at a minimum include the following:

1. Description of how the protocol meets the intent for the project-specific requirements and relevant interpretations of the standard.
2. Definition of a test input motion with a response spectrum that meets or exceeds the Design Earthquake spectrum for the site.
3. Accounting for dynamic amplification due to above-grade equipment installations. Consideration of the actual dynamic characteristics of the primary support structure is permitted, but not required.
4. Definition of how shake-table input demands were derived.
5. Definition and establishment of a verifiable pass/fail acceptance criterion for the seismic qualification based upon the equipment importance factor and consistent with the building code and project-specific design intent.

6. Development of criteria that can be used to rationalize test unit configuration requirements for highly variable equipment product lines.

To aid the design professional in assessing the adequacy of the manufacturer's certificate of compliance it is recommended that certificates of compliance include:

1. Product family or group covered
2. Building code(s) and standard(s) for which compliance was evaluated
3. Testing standard used
4. Performance objective and corresponding importance factor (I_p = 1.0 or I_p = 1.5)
5. Seismic demand for which the component is certified, including code and/or standard design parameters used to calculate seismic demand (such as values used for a_p, R_p, and site class)
6. Installation restrictions, if any (grade, floor, or roof level)

Without a test protocol recognized by the building code, qualification testing is inconsistent and difficult to verify. The use of ICC-ES AC156 simplifies the task of compliance verification since it was developed to address directly the testing alternative for nonstructural components, as specified in the standard. It also sets forth minimum test plan and report deliverables.

Use of other standards or ad-hoc protocols to verify compliance of nonstructural components with the requirement of the standard should be considered carefully and used only where project-specific requirements cannot be met otherwise.

Where other qualification test standards will be used, in whole or in part, it is necessary to verify compliance with this standard. For example, IEEE 693 indicates that it is to be used for the sole purpose of qualifying electrical equipment (specifically listed in the standard) for use in utility substations. Where equipment testing has been conducted to other standards (for instance, testing done in compliance with IEEE 693), a straightforward approach would be to permit evaluation, by the manufacturer, of the test plan and data to validate compliance with the requirements of ICC-ES AC156, because it was developed specifically to comply with the seismic demands of this standard.

The qualification of mechanical and electrical components for seismic loads alone may not be sufficient to achieve high performance objectives. Establishing a high confidence that performance goals will be met requires consideration of the performance of structures, systems (fluid, mechanical, electrical, instrumentation, etc.), and their interactions (for example interaction of seismic and other loads) as well as compliance with installation requirements.

C13.2.6 Experience Data Alternative for Seismic Capacity Determination. An established method of seismic qualification for certain types of nonstructural components is the assessment of data for the performance of similar components in past earthquakes. The seismic capacity of the component in question is extrapolated based on estimates of the demands (force, displacement) to which the components in the database were subjected. Procedures for such qualification have been developed for use in nuclear facility applications by the Seismic Qualification Utility Group (SQUG) of the Electric Power Research Institute.

The SQUG rules for implementing the use of experience data are described in a proprietary Generic Implementation Procedure (GIP) database. It is a collection of findings from detailed engineering studies by experts for equipment from a variety of utility and industrial facilities.

Valid use of experience data requires satisfaction of rules that address physical characteristics, manufacturer's classification and standards, and findings from testing, analysis, and expert consensus opinion.

Four criteria are used to establish seismic qualification by experience, as follows:

1. Seismic capacity versus demand (a comparison with a bounding spectrum)
2. Earthquake experience database cautions and inclusion rules
3. Evaluation of anchorage
4. Evaluation of seismic interaction

Experience data should be used with care, since the design and manufacture of components may have changed considerably in the intervening years. The use of this procedure is also limited by the relative rarity of strong motion instrument records associated with corresponding equipment experience data.

C13.2.7 Construction Documents. Where the standard requires seismic design of components or their supports and attachments, appropriate construction documents defining the required construction and installation must be prepared. This facilitates the special inspection and testing needed to provide a reasonable level of quality assurance. Of particular concern are large nonstructural components (such as rooftop chillers) whose manufacture and installation involves multiple trades and

suppliers, and which impose significant loads on the supporting structure. In these cases, it is important that the construction documents used by the various trades and suppliers to satisfy the seismic design requirements are prepared by a registered design professional.

The information required to prepare construction documents for component installation includes the dimensions of the component, the locations of attachment points, the operating weight, and the location of the center of mass. For instance, if an anchorage angle will be attached to the side of a metal chassis, the gage and material of the chassis must be known so that the number and size of required fasteners can be determined. Or, when a piece of equipment has a base plate that will be anchored to a concrete slab with expansion anchors, the drawings must show the base plate's material and thickness, the diameter of the bolt holes in the plate, and the size and depth of embedment of the anchor bolts. If the plate will be elevated above the slab for leveling, the construction documents must also show the maximum gap permitted between the plate and the slab.

C13.3 SEISMIC DEMANDS ON NONSTRUCTURAL COMPONENTS

The seismic demands on nonstructural components, as defined in this section, are acceleration demands and relative displacement demands. Acceleration demands are represented by equivalent static forces. Relative displacement demands are provided directly and are based on either the actual displacements computed for the structure or the maximum allowable drifts that are permitted for the structure.

C13.3.1 Seismic Design Force. The seismic design force for a component depends on the weight of the component, the component importance factor, the component response modification factor, the component amplification factor, and the component acceleration at a point of attachment to the structure. The forces prescribed in this section of the standard reflect the dynamic and structural characteristics of nonstructural components. As a result of these characteristics, forces used for verification of component integrity and design of connections to the supporting structure typically are larger than those used for design of the overall seismic-force-resisting system.

Certain nonstructural components lack the desirable attributes of structures (such as ductility, toughness, and redundancy) that permit the use of greatly reduced lateral design forces. Thus values for the response modification factor, R_p, in Tables 13.5-1 and 13.6-1 generally are smaller than R values for structures. These R_p values, used to represent the energy absorption capability of a component and its attachments, depend on both overstrength and deformability. At present these potentially separate considerations are combined in a single factor. The tabulated values are based on the collective judgment of the responsible committee.

The 2005 edition of the standard includes significant adjustments to tabulated R_p values for certain mechanical and electrical systems. For example, the value of R_p for welded steel piping systems is increased from 3.5 to 9. The a_p value increased from 1.0 to 2.5, so while it might appear that forces on such piping systems have been reduced greatly, the net change is negligible, as R_p/a_p changes from 3.5 to 3.6. The minimum seismic design force of Equation 13.3-3, which governs in many cases, is unchanged.

The component amplification factor (a_p) represents the dynamic amplification of component responses as a function of the fundamental periods of the structure (T) and component (T_p). When components are designed or selected, the structural fundamental period is not always defined or readily available. The component fundamental period (T_p) is usually only accurately obtained by shake-table or pull-back tests and is not available for the majority of components. Tabulated a_p values are based on component behavior that is assumed to be either rigid or flexible. Where the fundamental period of the component is less than 0.06 seconds, dynamic amplification is not expected, and the component is considered rigid. The tabulation of assumed a_p values is not meant to preclude more precise determination of the component amplification factor where the fundamental periods of both structure and component are available. The NCEER formulation shown in Figure C13.3-1 may be used to compute a_p as a function of T_p/T.

Dynamic amplification occurs where the period of a nonstructural component closely matches that of any mode of the supporting structure, although this effect may not be significant depending on the ground motion. For most buildings, the primary mode of vibration in each direction will have the most influence on the dynamic amplification for nonstructural components. For long-period structures (such as tall buildings), where the period of vibration of the fundamental mode is greater than 3.5 times T_s, higher modes of vibration may have periods that more closely match the period of nonstructural components. For this case, it is recommended that amplification be considered using such higher mode periods in lieu of the higher fundamental period. This approach may be generalized by computing floor response spectra for various levels that reflect the dynamic characteristics of the supporting structure to determine how amplification will vary as a function of component period. Calculation of floor response spectra can be complex, but simplified procedures are presented in Kehoe and Hachem (2003). Consideration of nonlinear behavior of the structure greatly complicates the analysis.

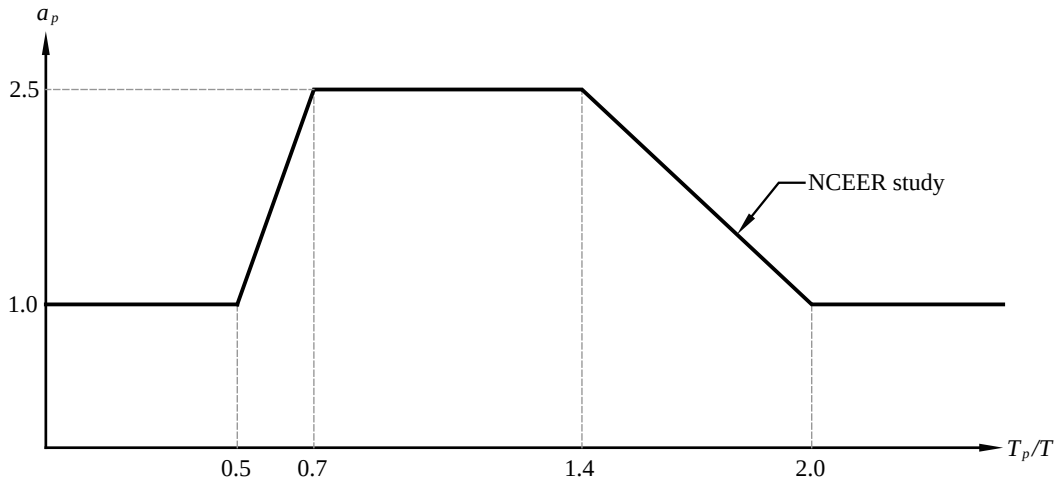

Figure C13.3-1 NCEER formulation for a_p as function of structural and component periods.

Equation 13.3-1 represents a trapezoidal distribution of floor accelerations within a structure, varying linearly from the acceleration at the ground (taken as $0.4S_{DS}$) to the acceleration at the roof (taken as $1.2S_{DS}$). The ground acceleration ($0.4S_{DS}$) is intended to be the same acceleration used as design input for the structure itself, including site effects. The roof acceleration is established as three times the input ground acceleration based on examination of recorded in-structure acceleration data for short and moderate height structures in response to large California earthquakes. Work by Miranda and Singh suggest that, for taller structures, the amplification with height may vary significantly due to higher mode effects. Where more information is available, Equation 13.3-4 permits an alternate determination of the component design forces based on the dynamic properties of the structure.

Equation 13.3-3 establishes a minimum seismic design force, F_p, that is consistent with current practice. Equation 13.3-2 provides a simple maximum value of F_p that prevents multiplication of the individual factors from producing a design force that would be unreasonably high, considering the expected nonlinear response of support and component. Figure C13.3-2 illustrates the distribution of the specified lateral design forces.

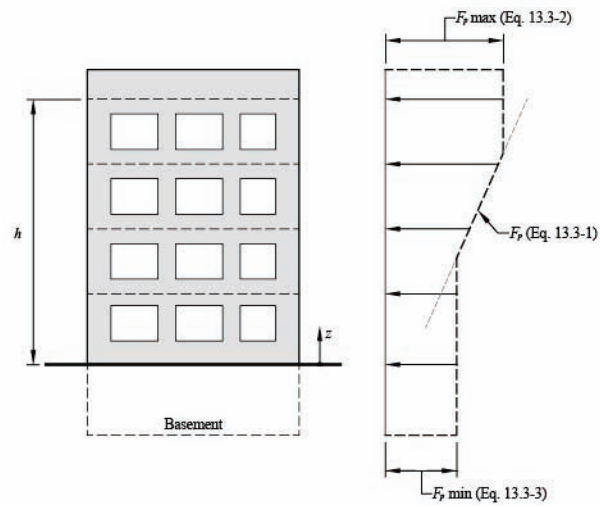

Figure C13.3-2 Lateral force magnitude over height.

For elements with points of attachment at more than one height, it is recommended that design be based on the average of values of F_p determined individually at each point of attachment (but with the entire component weight, W_p) using Equations 13.3-1 through 13.3-3.

Alternatively, for each point of attachment a force F_p may be determined using Equations 13.3-1 through 13.3-3, with the portion of the component weight, W_p, tributary to the point of attachment. For design of the component, the attachment force F_p must be distributed relative to the component's mass distribution over the area used to establish the tributary weight. To

illustrate these options, consider a solid exterior nonstructural wall panel, supported top and bottom, for a one-story building with a rigid diaphragm. The values of F_p computed, respectively, for the top and bottom attachments using Equations 13.3-1 through 13.3-3 are $0.48S_{DS}I_pW_p$ and $0.30S_{DS}I_pW_p$. In the recommended method, a uniform load is applied to the entire panel based on $0.39S_{DS}I_pW_p$. In the alternative method, a trapezoidal load varying from $0.48S_{DS}I_pW_p$ at the top to $0.30S_{DS}I_pW_p$ at the bottom is applied. Each anchorage force is then determined considering static equilibrium of the complete component subject to all the distributed loads.

Cantilever parapets that are part of a continuous element should be checked separately for parapet forces. The seismic force on any component must be applied at the center of gravity of the component and must be assumed to act in any horizontal direction. Vertical forces on nonstructural components equal to $\pm 0.2S_{DS}W_p$ are specified in Section 13.3.1 and are intended to be applied to all nonstructural components and not just cantilevered elements. Nonstructural concrete or masonry walls laterally supported by flexible diaphragms must be anchored out-of-plane in accordance with Section 12.11.2.

C13.3.2 Seismic Relative Displacements. The equations of this section are for use in design of cladding, stairways, windows, piping systems, sprinkler components, and other components connected to one structure at multiple levels or to multiple structures. Two equations are given for each situation. Equations 13.3-5 and 13.3-7 produce structural displacements as determined by elastic analysis, unreduced by the structural response modification factor (R). Since the actual displacements may not be known when a component is designed or procured, Equations 13.3-6 and 13.3-8 provide upper-bound displacements based on structural drift limits. Use of upper-bound equations may facilitate timely design and procurement of components, but may also result in costly added conservatism.

The standard does not provide explicit acceptance criteria for the effects of seismic relative displacements, except for glazing. Damage to nonstructural components due to relative displacement is acceptable, provided the performance goals defined elsewhere in the chapter are achieved.

C13.3.2.1 Displacements within Structures. Seismic relative displacements can subject components or systems to unacceptable stresses. Nonstructural components designed with no intended structural function, such as infill walls, may interact with structural framing elements as a result of building deformation. The resulting stresses may exceed acceptable limits for the nonstructural components, the structural elements, or both. Consideration of this interrelationship is likely to govern the clearance between such components and the ductility and strength of their supports and attachments.

Where nonstructural components are supported between, rather than at, structural levels, as frequently occurs for glazing systems, partitions, stairs, veneers, and mechanical and electrical distributed systems, the height over which the displacement demand, D_p, must be accommodated may be less than the story height, h_{sx}, and should be considered carefully. For example, consider the glazing system supported by rigid precast concrete spandrels shown in Figure C13.3-3. The glazing system will be subjected to full story drift, D_p, although its height ($h_x - h_y$) is only a fraction of the story height. The design drift must be accommodated by anchorage of the glazing unit, the joint between the precast spandrel and the glazing unit, or some combination of the two. Similar displacement demands arise where pipes, ducts, or conduit that are braced to the floor or roof above are connected to the top of a tall, rigid, floor-mounted component.

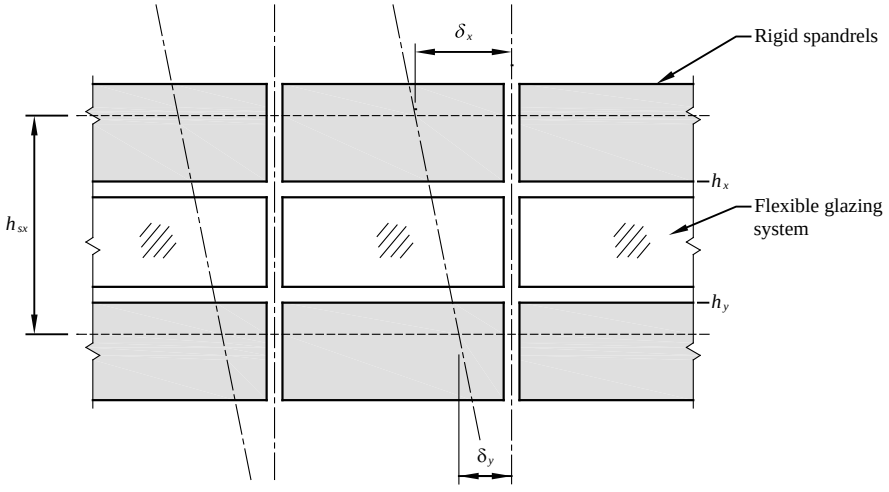

Figure C13.3-3 Displacements over less than story height.

For ductile components, such as steel piping fabricated with welded connections, the relative seismic displacements between support points can be more significant than inertial forces. Ductile piping can accommodate relative displacements by local

yielding with strain accumulations well below failure levels. However, for components fabricated using less ductile materials, where local yielding must be avoided to prevent unacceptable failure consequences, relative displacements must be accommodated by flexible connections.

C13.3.2.2 Displacements between Structures. A component or system connected to two structures must accommodate horizontal movements in any direction, as illustrated in Figure C13.3-4.

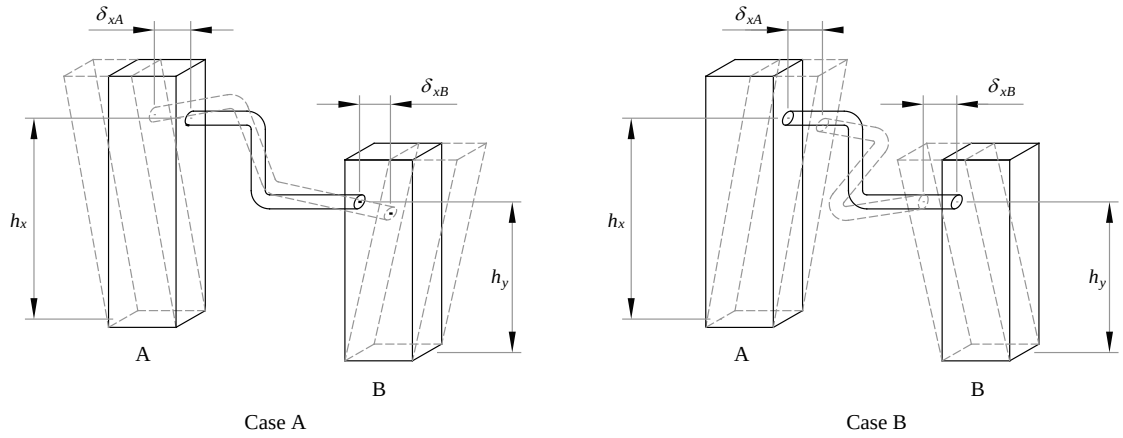

Figure C13.3-4 Displacements between structures.

C13.4 NONSTRUCTURAL COMPONENT ANCHORAGE

Unless exempted in Section 13.1.4, components must be anchored to the structure, and all required supports and attachments must be detailed in the construction documents. To satisfy the load path requirement of this section, the detailed information described in Section C13.2.7 must be communicated, during the design phase, to the registered design professional responsible for the design of the supporting structure.

Unanchored components often rock or slide when subjected to earthquake motions. Since this behavior may have serious consequences, is difficult to predict, and is exacerbated by vertical ground motions, positive restraint must be provided for each component.

The effective seismic weight used in design of the seismic force-resisting system must include the weight of supported components. To satisfy the load path requirements of this section, localized component demand must also be considered. This may be accomplished by checking the capacity of the first structural element in the load path (for example, a floor beam directly under a component) for combined dead, live, operating, and seismic loads, using the horizontal and vertical loads from Section 13.3.1 for the seismic demand, and repeating this procedure for each structural element or connection in the load path until the load case including horizontal and vertical loads from Section 13.3.1 no longer governs design of the element. The load path includes housekeeping slabs and curbs, which must be adequately reinforced and positively fastened to the supporting structure.

Since the exact magnitude and location of loads imposed on the structure may not be known until nonstructural components are ordered, the initial design of supporting structural elements should be based on conservative assumptions. The design of the supporting structural elements must be verified once the final magnitude and location of the design loads have been established.

Tests have shown there are consistent shear ductility variations between bolts installed in drilled or punched plates with nuts and connections using welded shear studs. The need for reductions in allowable loads for particular anchor types to account for loss of stiffness and strength may be determined through appropriate dynamic testing. Although comprehensive design recommendations are not available at present, this issue should be considered for critical connections subject to dynamic or seismic loading.

C13.4.2 Anchors in Concrete or Masonry. Design capacity for anchors in concrete must be determined in accordance with ACI 318 Appendix D. Design capacity for anchors in masonry is determined in accordance with ACI 530. Anchors must be designed to have ductile behavior or to provide a specified degree of excess strength. In either case, design forces are

multiplied by 1.3 or based on the capacity of the component or its supports. The anchorage criteria provided in Chapter 13 specifically address the issue of non-ductile response and force amplification. Since the capacity of anchors in masonry is rarely governed by steel capacity, and failure in the masonry is non-ductile, an R_p of 1.5 should be used for design. Depending on the specifics of the design condition, ductile design of anchors in concrete may satisfy one or more of the following objectives:

1. Adequate load redistribution between anchors in a group
2. Allowance for anchor overload without brittle failure
3. Energy dissipation

Achieving deformable, energy-absorbing behavior in the anchor itself is often difficult. Unless the design specifically addresses the conditions influencing desirable hysteretic response (adequate gauge length, anchor spacing, edge distance, steel properties, etc.), anchors cannot be relied upon for energy dissipation. Simple geometric rules, such as restrictions on the ratio of anchor embedment length to depth, are not adequate to produce reliable ductile behavior. For example, a single anchor with sufficient embedment to force ductile tension failure in the steel body of the anchor bolt may still experience concrete fracture (a non-ductile failure mode) if the edge distance is small, the anchor is placed in a group of tension-loaded anchors with reduced spacing, or the anchor is loaded in shear instead of tension. In the common case where anchors are subject primarily to shear, response governed by the steel element may be non-ductile if the deformation of the anchor is constrained by rigid elements on either side of the joint. Designing the attachment so that its response is governed by a deformable link in the load path to the anchor is encouraged. This approach provides ductility and overstrength in the connection while protecting the anchor from overload. Ductile bolts should only be relied upon as the primary ductile mechanism of a system if the bolts are designed to have adequate gauge length (unbonded strained length of the bolt) to accommodate the anticipated nonlinear displacements of the system at the design earthquake. Guidance for determining the gauge length can be found in Part 3 of the *Provisions.*

Post-installed expansion and undercut anchors must be qualified in accordance with ACI 355.2-04, *Qualification of Post-Installed Mechanical Anchors in Concrete*. The ICC-ES acceptance criteria AC193 and AC308, which include specific provisions for screw anchors and adhesive anchors, also reference ACI 355.2. Reference to adhesives (such as in Section 13.5.7.2) apply, not to adhesive anchors, but to steel plates and other structural elements bonded or glued to the surface of another structural component with adhesive; such connections are generally non-ductile.

Anchors used to support towers, masts, and equipment are often provided with double nuts for leveling during installation. Where baseplate grout is specified at anchors with double nuts, it should not be relied upon to carry loads since it can shrink and crack or be omitted altogether. The design should include the corresponding tension, compression, shear, and flexure loads.

C13.4.3 Installation Conditions. Prying forces on anchors, which result from a lack of rotational stiffness in the connected part, can be critical for anchor design and must be considered explicitly.

For anchorage configurations that do not provide a direct mechanism to transfer compression loads (for example, a base plate that does not bear directly on a slab or deck but is supported on a threaded rod), the design for overturning must reflect the actual stiffness of baseplates, equipment, housing, and other elements in the load path when computing the location of the compression centroid and the distribution of uplift loads to the anchors.

C13.4.4 Multiple Attachments. While the standard does not prohibit the use of single anchor connections, it is good practice to use at least two anchors in any load-carrying connection whose failure might lead to collapse, partial collapse, or disruption of a critical load path.

C13.4.5 Power Actuated Fasteners. The capacity of power actuated fasteners in concrete often varies more than that of drilled post-installed anchors. The shallow embedment, small diameter, and friction mechanism of these fasteners make them particularly susceptible to the effects of concrete cracking. The suitability of power actuated fasteners to resist tension in concrete should be demonstrated by simulated seismic testing in cracked concrete.

Where properly installed in steel, power actuated fasteners typically exhibit reliable cyclic performance. Nevertheless, they should not be used singly to support suspended elements. Where used to attach cladding and metal decking, subassembly testing may be used to establish design capacities since the interaction between the decking, the sub-frame, and the fastener can only be estimated crudely by currently available analysis methods.

C13.4.6 Friction Clips. Friction clips, such as beam clamps, may loosen under cyclic loading, resulting in slippage or loss of connection capacity. Where friction clips are used, they may not be relied upon for seismic resistance. Fasteners that provide a positive mechanical connection have more reliable seismic performance. Clips that provide marginal mechanical

connection, such as beam clamps that "dimple" the flange of the steel support may still rely chiefly on friction. These may not provide adequate cyclic capacity and should be qualified by seismic testing.

C13.5 ARCHITECTURAL COMPONENTS

For structures in Occupancy Category I through III, the requirements of Section 13.5 are intended to reduce property damage and life-safety hazards posed by architectural components due to loss of stability or integrity. When subjected to seismic motion, components may pose a direct falling hazard to building occupants or to people outside the building (as in the case of parapets, exterior cladding, and glazing). Failure or displacement of interior components (such as partitions and ceiling systems in exits and stairwells) may block egress.

For structures in Occupancy Category IV, the potential disruption of essential function due to component failure must also be considered.

Architectural component failures in earthquakes can be caused by deficient design or construction of the component, interrelationship with another component that fails, interaction with the structure, or inadequate attachment or anchorage. For architectural components, attachment and anchorage are typically the most critical concerns related to their seismic performance. Concerns regarding loss of function are most often associated with mechanical and electrical components. Architectural damage, unless very severe, can be accommodated temporarily. Very severe architectural damage is often accompanied by significant structural damage.

C13.5.1 General. Suspended architectural components are not required to satisfy the force and displacement requirements of Chapter 13, where prescriptive requirements are met. The requirements were relaxed in the 2005 edition of the standard to better reflect the consequences of the expected behavior. For example, impact of a suspended architectural ornament with a sheet metal duct may only dent the duct without causing a credible danger (assuming the ornament remains intact). The reference to Section 13.2.3 allows the designer to consider such consequences in establishing the design approach.

C13.5.2 Forces and Displacements. Partitions and interior and exterior glazing must accommodate story drift without failure that will cause a life-safety hazard. Design judgment must be used to assess potential life-safety hazards and the likelihood of life-threatening damage. Special detailing to accommodate drift for typical gypsum board or demountable partitions is unlikely to be cost-effective, and damage to these components poses a low hazard to life safety. Damage in these partitions occurs at low drift levels, but is inexpensive to repair.

If they must remain intact following strong ground motion, nonstructural fire-resistant enclosures and fire-rated partitions require special detailing that provides isolation from the adjacent or enclosing structure for deformation equivalent to the calculated drift (relative displacement). In-plane differential movement between structure and wall is permitted. Provision must be made for out-of-plane restraint. These requirements are particularly important in steel or concrete moment frame structures, which experience larger drifts. The problem is less likely to be encountered in stiff structures, such as those with shear walls.

Differential vertical movement between horizontal cantilevers in adjacent stories (such as cantilevered floor slabs) has occurred in past earthquakes. The possibility of such effects should be considered in the design of exterior walls.

C13.5.3 Exterior Nonstructural Wall Elements and Connections. Nonbearing wall panels that are attached to and enclose the structure must be designed to resist seismic (inertial) forces, wind forces, and gravity forces and to accommodate movements of the structure resulting from lateral forces and temperature change. The connections must allow wall panel movements due to thermal and moisture changes, and be designed so as to prevent the loss of load-carrying capacity in the event of significant yielding. Where wind loads govern, common practice is to design connectors and panels to allow for not less than two times the story drift caused by wind loads determined using a return period appropriate to the site location.

Design to accommodate seismic relative displacements often presents a greater challenge than design for strength. Story drifts can amount to 2 inches (50 mm) or more. Separations between adjacent panels are intended to limit contact and resulting panel misalignment or damage under all but extreme building response. Section 13.5.3(a) calls for a minimum separation of 1/2 inch (13 mm). For practical joint detailing and acceptable appearance, separations typically are limited to about 3/4 inch (19 mm). Manufacturing and construction tolerances for both wall elements and the supporting structure must be considered in establishing design joint dimensions and connection details.

Cladding elements, which are often very stiff in-plane, must be isolated so that they do not restrain and are not loaded by drift of the supporting structure. Slotted connections can provide isolation, but connections with long rods that flex achieve the desired behavior without requiring precise installation. Such rods must be designed to resist tension and compression in addition to induced flexural stresses, brittle, low-cycle fatigue failure.

Full-story wall panels are usually rigidly attached to and move with the floor structure nearest the panel bottom and isolated at the upper attachments. Panels also can be vertically supported at the top connections with isolation connections at the bottom. An advantage of this configuration is that failure of an isolation connection is less likely to result in complete detachment of the panel, since it will tend to rotate into the structure rather than away from it.

To minimize the effects of thermal movements and shrinkage on architectural cladding panels, connection systems are generally detailed to be statically determinate. Since the resulting support systems often lack redundancy, exacerbating the consequences of a single connection failure, fasteners must be designed for amplified forces and connecting members must be ductile. The intent is to keep inelastic behavior in the connecting members while the more brittle fasteners remain essentially elastic. To achieve this intent, the tabulated a_p and R_p values produce fastener design forces that are about 3 times those for the connecting members.

Limited deformability curtain walls, such as aluminum systems, are generally light and can undergo large deformations without separating from the structure. However, care must be taken in design of these elements so that low deformability components(as defined in Section 11.2) that may be part of the system, such as glazing panels, are detailed to accommodate the expected deformations without failure.

In Table 13.5-1, veneers are classified as either limited or low deformability elements. Veneers with limited deformability, such as vinyl siding, pose little risk. Veneers with low deformability, such as brick and ceramic tile, are highly sensitive to the performance of the supporting substrate. Significant distortion of the substrate results in veneer damage, possibly including separation from the structure. The resulting risk depends on the size and weight of fragments likely to be dislodged and on the height from which the fragments would fall. Detachment of large portions of the veneer can pose a significant risk to life. Such damage can be reduced by isolating veneer from displacements of the supporting structure. For structures with flexible lateral force-resisting systems, such as moment frames and buckling-restrained braced frames, approaches used to design non-bearing wall panels to accommodate story drift should be applied to veneers.

C13.5.5 Out-of-Plane Bending. The effects of out-of-plane application of seismic forces (defined in Section 13.3.1) on nonstructural walls, including the resulting deformations, must be considered. Where weak or brittle materials are employed, conventional deflection limits are expressed as a proportion of the span. The intent is to preclude out-of-plane failure of heavy materials (such as brick or block) or applied finishes (such as stone or tile).

C13.5.6 Suspended Ceilings. Suspended ceiling systems are fabricated using a wide range of building materials with differing characteristics. Some systems (such as lath and plaster or gypsum board, screwed or nailed to suspended members) are fairly homogeneous and should be designed as light-frame diaphragm assemblies, using the forces of Section 13.3 and the applicable material-specific design provisions of Chapter 14. Others comprise discrete elements laid into a suspension system and are the subject of this section.

Seismic performance of ceiling systems with lay-in or acoustical panels depends on support of the grid and individual panels at walls and expansion joints, integrity of the grid/panel assembly, interaction with other systems (such as fire sprinklers), and support for other nonstructural components (such as light fixtures and HVAC systems). Observed performance problems include dislodgement of tiles due to impact with walls and water damage (sometimes leading to loss of occupancy) due to interaction with fire sprinklers. Extensive shake table testing performed at the State University of New York at Buffalo addresses seismic performance of suspended ceiling systems at various ground motion levels. That work is reported by Yao (2000) and by Bidillo, et al. (2003, 2006, and 2007).

The performance of ceiling systems is affected by the placement of seismic bracing and the layout of light fixtures and other supported loads. Dynamic testing has demonstrated that splayed wires, even with vertical compression struts, may not adequately limit lateral motion of the ceiling system due to straightening of the end loops. Construction problems include slack installation or omission of bracing wires due to obstructions. Other testing has shown that unbraced systems may perform well where the system can accommodate the expected displacements, by providing both sufficient clearance at penetrations and wide closure members which are now required by the standard.

C13.5.6.1 Seismic Forces. Where the weight of the ceiling system is distributed non-uniformly, that condition should be considered in the design, since the typical T-bar ceiling grid has limited ability to redistribute lateral loads.

C13.5.6.2 Industry Standard Construction. Industry standard construction relies on ceiling contact with the perimeter wall for restraint. The key to good seismic performance is sufficiently wide closure angles at the perimeter to accommodate relative ceiling motion and adequate clearance at penetrating components (such as columns and piping) to avoid concentrating restraining loads on the ceiling system.

C13.5.6.2.1 Seismic Design Category C. While there is no direct equivalency between Seismic Design Categories and seismic zones, application of CISCA requirements for Seismic Zones 0 to 2 produces reasonable results for Seismic Design

Category C. ASTM E580 is currently being revised for consistency with the IBC and ASCE/SEI 7-05. When updated, it is expected to replace the CISCA requirements.

C13.5.6.2.2 Seismic Design Categories D through F. Where certain prescriptive requirements are met, lateral restraints may be omitted for small areas of suspended ceiling. The behavior of an unbraced ceiling system is similar to that of a pendulum; therefore, the lateral displacement is a function of the level of ground motion and the square root of the suspension length. The default displacement limit is based on anticipated damping and energy absorption of the suspended ceiling system without significant impact with the perimeter wall.

The requirements set forth in this section of the standard for Seismic Design Categories D through F are in addition to the CISCA requirements for Seismic Zones 3 and 4. Therefore, seismic requirements for ceilings are triggered where ceiling areas exceed 256 square feet, and additional requirements apply where ceiling areas exceed 1,000 square feet and 2,500 square feet. The alternative to provide swing joint connections or flexible devices (such as hoses) for sprinkler drops is included in the latest edition of NFPA 13.

C13.5.6.3 Integral Construction. Ceiling systems utilizing integral construction are constructed of modular pre-engineered components, which integrate lights, ventilation components, fire-sprinklers, and seismic bracing into a complete system. They may include aluminum, steel, and PVC components and may be designed using integral construction of ceiling and wall. They often use rigid grid and bracing systems, which provide lateral support for all the ceiling components, including sprinkler drops. This reduces the potential for adverse interactions between components, and eliminates the need to provide clearances for differential movement.

C13.5.7 Access Floors

C13.5.7.1 General. In past earthquakes and in cyclic load tests, some typical raised access floor systems behaved in a brittle manner and exhibited little reserve capacity beyond initial yielding or failure of critical connections. Testing shows that unrestrained individual floor panels may pop out of the supporting grid unless mechanically fastened to supporting pedestals or stringers. This may be a concern, particularly in egress pathways.

For systems with floor stringers, it is accepted practice to calculate the seismic force, F_p, for the entire access floor system within a partitioned space and then distribute the total force to the individual braces or pedestals. For stringerless systems, the seismic load path should be established explicitly.

Overturning effects subject individual pedestals to vertical loads well in excess of the weight, W_p, used in determining the seismic force, F_p. It is unconservative to use the design vertical load simultaneously with the design seismic force for design of anchor bolts, pedestal bending, and pedestal welds to base plates. "Slip on" heads that are not mechanically fastened to the pedestal shaft and thus cannot transfer tension are likely unable to transfer to the pedestal the overturning moments generated by equipment attached to adjacent floor panels.

To preclude brittle failure, each element in the seismic load path must have energy absorbing capacity. Buckling failure modes should be prevented. Lower seismic force demands are allowed for special access floors that are designed to preclude brittle and buckling failure modes.

C13.5.7.2 Special Access Floors. An access floor can be a "special access floor" if the registered design professional opts to comply with the requirements of Section 13.5.7.2. Special access floors include construction features that improve the performance and reliability of the floor system under seismic loading. The provisions focus on providing a reliable load path for seismic shear and overturning forces. Special access floors are designed for smaller lateral forces, and their use is encouraged at facilities with higher nonstructural performance objectives.

C13.5.8 Partitions. Partitions subject to these requirements must have independent lateral support bracing from the top of the partition to the building structure or to a substructure attached to the building structure. Some partitions are designed to span vertically from the floor to a suspended ceiling system. The ceiling system must be designed to provide lateral support for the top of the partition. An exception to this condition is provided to exempt bracing of light (gypsum board) partitions where the load does not exceed the minimum partition lateral load. Experience has shown that partitions subjected to the minimum load can be braced to the ceiling without failure.

C13.5.9 Glass in Glazed Curtain Walls, Glazed Storefronts, and Glazed Partitions. The performance of glass in earthquakes falls into one of four categories:

1. The glass remains unbroken in its frame or anchorage.
2. The glass cracks but remains in its frame or anchorage while continuing to provide a weather barrier, and to be otherwise serviceable.
3. The glass shatters but remains in its frame or anchorage in a precarious condition, likely to fall out at any time.

4. The glass falls out of its frame or anchorage, either in shards or as whole panels.

Categories 1 and 2 satisfy both immediate-occupancy and life-safety performance objectives. Although the glass is cracked in Category 2, immediate replacement is not required. Categories 3 and 4 cannot provide for immediate occupancy, and their provision of life safety depends on the post-breakage characteristics of the glass and the height from which it can fall. Tempered glass shatters into multiple, pebble-size fragments that fall from the frame or anchorage in clusters. These broken glass clusters are relatively harmless to humans when they fall from limited heights, but they could be harmful when they fall from greater heights.

C13.5.9.1 General. Equation 13.5-1 is derived from *Earthquake Safety Design of Windows*, published in November 1982 by the Sheet Glass Association of Japan and is similar to an equation in Bouwkamp and Meehan (1960) that permits calculation of the story drift required to cause glass-to-frame contact in a given rectangular window frame. Both calculations are based on the principle that a rectangular window frame (specifically, one that is anchored mechanically to adjacent stories of a structure) becomes a parallelogram as a result of story drift, and that glass-to-frame contact occurs when the length of the shorter diagonal of the parallelogram is equal to the diagonal of the glass panel itself. The value $\Delta_{fallout}$ represents the displacement capacity of the system and D_p represents the displacement demand.

The 1.25 factor in the requirements described above reflect uncertainties associated with calculated inelastic seismic displacements of building structures. Wright (1989) states that "post-elastic deformations, calculated using the structural analysis process, may well underestimate the actual building deformation by up to 30 percent. It would therefore be reasonable to require the curtain wall glazing system to withstand 1.25 times the computed maximum interstory displacement to verify adequate performance."

The reason for Exception 2 to Equation 13.5-1 is that the tempered glass, if shattered, would not produce an overhead falling hazard to adjacent pedestrians, although some pieces of glass may fall out of the frame.

C13.5.9.2 Seismic Drift Limits for Glass Components. As an alternative to the prescriptive approach of Section 13.5.9.1, the deformation capacity of glazed curtain wall systems may be established by test.

C13.6 MECHANIAL AND ELECTRICAL COMPONENTS

These requirements, focused on design of supports and attachments, are intended to reduce the hazard to life posed by loss of component structural stability or integrity. The requirements increase the reliability of component operation but do not address functionality directly. For critical components where operability is vital, Section 13.2.2 provides methods for seismically qualifying the component.

Traditionally, mechanical equipment without rotating or reciprocating components (such as tanks and heat exchangers) is anchored directly to the structure. Mechanical and electrical equipment with rotating or reciprocating components often is isolated from the structure by vibration isolators (such as rubber-in-shear, springs, or air cushions). Heavy mechanical equipment (such as large boilers) may not be restrained at all, and electrical equipment other than generators, which are normally isolated to dampen vibrations, usually is rigidly anchored (for example, switchgear and motor control centers).

Two distinct levels of earthquake safety are considered in the design of mechanical and electrical components. At the usual safety level, failure of the mechanical or electrical component itself due to seismic effects poses no significant hazard. In this case, design of the supports and attachments to the structure is required to avoid a life-safety hazard. At the higher safety level, the component must continue to function acceptably following the design earthquake. Such components are defined as designated seismic systems in Section 11.2 and may be required to meet the special certification requirements of Section 13.2.2.

Not all equipment or parts of equipment need to be designed for seismic forces. Where I_p is specified to be 1.0, damage to, or even failure of, a piece or part of a component does not violate these requirements as long as a life-safety hazard is not created. The restraint or containment of a falling, breaking, or toppling component (or its parts) by means of bumpers, braces, guys, wedges, shims, tethers, or gapped restraints to satisfy these requirements often is acceptable, although the component itself may suffer damage.

Judgment is required to fulfill the intent of these requirements; the key consideration is the threat to life safety. For example, a nonessential air handler package unit that is less than 4 feet (1.2 meters) tall bolted to a mechanical room floor is not a threat to life as long as it is prevented from significant displacement by having adequate anchorage. In this case, seismic design of the air handler itself is unnecessary. On the other hand, a 10-foot (3.0 meters) tall tank on 6-foot (1.8 meters) long angles used as legs, mounted on a roof near a building exit does pose a hazard. The intent of these requirements is that the supports and attachments (tank legs, connections between the roof and the legs, and connections between the legs and the

tank), and possibly even the tank itself be designed to resist seismic forces. Alternatively, restraint of the tank by guys or bracing could be acceptable.

It is not the intent of the standard to require the seismic design of shafts, buckets, cranks, pistons, plungers, impellers, rotors, stators, bearings, switches, gears, nonpressure retaining casings and castings, or similar items. Where the potential for a hazard to life exists, it is expected that design effort will focus on equipment supports including base plates, anchorages, support lugs, legs, feet, saddles, skirts, hangers, braces, or ties.

Many mechanical and electrical components consist of complex assemblies of parts that are manufactured in an industrial process that produces similar or identical items. Such equipment may include manufacturer's catalog items and often are designed by empirical (trial-and-error) means for functional and transportation loadings. A characteristic of such equipment is that it may be inherently rugged. The term "rugged" refers to an ampleness of construction that provides such equipment with the ability to survive strong motions without significant loss of function. By examining such equipment, an experienced design professional usually should be able to confirm such ruggedness. The results of an assessment of equipment ruggedness may be used in determining an appropriate method and extent of seismic design or qualification effort.

C13.6.1 General. The exception allowing unbraced suspended components has been clarified, addressing concerns about the type of nonstructural components allowed by these exceptions as well as the acceptable consequences of interaction between components. In previous editions of the standard, certain nonstructural components that could represent a fire hazard following an earthquake were exempt from lateral bracing requirements. In the revised exception, reference to Section 13.2.3 addresses such concerns while distinguishing between credible seismic interactions and incidental interactions.

The seismic demand requirements are based on component structural attributes of flexibility (or rigidity) and ruggedness. Table 13.6-1 provides seismic coefficients based on judgments of the component flexibility, expressed in the a_p term, and ruggedness expressed in the R_p term. It may also be necessary to consider the flexibility and ductility of the attachment system that provides seismic restraint.

Entries for components and systems in Table 13.6-1 are grouped and described to improve clarity of application. Components are divided into three broad groups, within which they are further classified depending on the type of construction or expected seismic behavior. For example, mechanical components include "air-side" components (such as fans and air handlers) that experience dynamic amplification but are light and deformable; "wet-side" components that generally contain liquids (such as boilers and chillers) that are more rigid and somewhat ductile; and very rugged components (such as engines, turbines, and pumps) that are of massive construction due to demanding operating loads, and generally perform well in earthquakes, if adequately anchored.

A distinction is made between components isolated using neoprene and those that are spring isolated. Spring isolated are assigned a lower R_p value since they tend to have less effective damping. Internally isolated components are classified explicitly to avoid confusion.

C13.6.2 Component Period. Component period is used to clarify components as rigid ($T \leq 0.06$s) or flexible ($T > 0.06$s). Determination of the fundamental period of a mechanical or electrical component using analytical or test methods can become very involved. If not properly performed, the fundamental period may be underestimated, producing unconservative results. The flexibility of the component's supports and attachments typically dominates response and thus fundamental component period. Therefore, analytical determinations of component period must consider those sources of flexibility. Where determined by testing, the dominant mode of vibration of concern for seismic evaluation must be excited and captured by the test setup. This dominant mode of vibration cannot be discovered through in-situ tests that measure only ambient vibrations. To excite the mode of vibration with the highest fundamental period by in-situ tests, relatively significant input levels of motion are required (that is, the flexibility of the base and attachment must be exercised). A resonant frequency search procedure, such as that given in ICC-ES AC156, may be used to identify the dominant modes of vibration of a component.

Many types of mechanical components have fundamental periods below 0.06 seconds and may be considered to be rigid. Examples include horizontal pumps, engine generators, motor generators, air compressors, and motor driven centrifugal blowers. Other types of mechanical equipment are very stiff, but may have fundamental periods up to about 0.125 seconds. Examples include vertical immersion and deep well pumps, belt driven and vane axial fans, heaters, air handlers, chillers, boilers, heat exchangers, filters, and evaporators. These fundamental period estimates do not apply where the equipment is mounted on vibration isolators.

Electrical equipment cabinets can have fundamental periods of about 0.06 to 0.3 seconds, depending upon the supported weight and its distribution, the stiffness of the enclosure assembly, the flexibility of the enclosure base, and the load path through to the attachment points. Tall, narrow motor control centers and switchboards lie at the upper end of this period range. Low- and medium-voltage switchgear, transformers, battery chargers, inverters, instrumentation cabinets, and

instrumentation racks usually have fundamental periods ranging from 0.1 to 0.2 seconds. Braced battery racks, stiffened vertical control panels, benchboards, electrical cabinets with top bracing, and wall-mounted panelboards have fundamental periods ranging from 0.06 to 0.1 seconds.

C13.6.3 Mechanical Components and C13.6.4 Electrical Components. Most mechanical and electrical equipment is inherently rugged and, where properly attached to the structure, has performed well in past earthquakes. Since the operational and transportation loads for which the equipment is designed typically are larger than those due to earthquakes, these requirements focus primarily on equipment anchorage and attachments. However, Designated Seismic Systems, which are required to function following an earthquake or which must maintain containment of flammable or hazardous materials, must themselves be designed for seismic forces or be qualified for seismic loading in accordance with Section 13.2.2.

The likelihood of post-earthquake operability can be increased where the following measures are taken:

1. Internal assemblies, subassemblies, and electrical contacts are attached sufficiently to prevent their being subjected to differential movement or impact with other internal assemblies or the equipment enclosure.
2. Operators, motors, generators, and other such components that are functionally attached to mechanical equipment by means of an operating shaft or mechanism are structurally connected or commonly supported with sufficient rigidity such that binding of the operating shaft will be avoided.
3. Any ceramic or other nonductile components in the seismic load path are specifically evaluated.
4. Adjacent electrical cabinets are bolted together and cabinet lineups are prevented from impacting adjacent structural members.

Components that could be damaged, or could damage other components, and are fastened to multiple locations of a structure must be designed to accommodate seismic relative displacements. Such components include bus ducts, cable trays, conduit, elevator guide rails, and piping systems. As discussed in Section C13.3.2.1, special design consideration is required where full story drift demands are concentrated in a fraction of the story height.

C13.6.5 Component Supports. The intent of this section is to require seismic design of all mechanical and electrical component supports to prevent sliding, falling, toppling, or other movement that could imperil life. Component supports are differentiated here from component attachments to emphasize that the supports themselves, as enumerated in the text, require seismic design even if fabricated by the mechanical or electrical component manufacturer. This is regardless of whether the mechanical or electrical component itself is designed for seismic loads.

C13.6.5.1 Design Basis. Standard supports are those developed in accordance with a reference document (Section 13.1.6). Where standard supports are not used, the seismic design forces and displacement demands of Chapter 13 are used with applicable material-specific design procedures of Chapter 14.

C13.6.5.2 Design for Relative Displacement. For some items, such as piping, seismic relative displacements between support points are of more significance than inertial forces. Components made of high deformability materials such as steel or copper can accommodate relative displacements inelastically, provided the connections also provide high deformability. Threaded and soldered connections exhibit poor ductility under inelastic displacements, even for ductile materials. Components made of less ductile materials can accommodate relative displacement effects only if appropriate flexibility or flexible connections are provided.

Detailing distribution systems that connect separate structures with bends and elbows makes them less prone to damage and less likely to fracture and fall, provided the supports can accommodate the imposed loads.

C13.6.5.3 Support Attachment to Component. As used in this Section, “integral” relates to the manufacturing process, not the location of installation. For example, both the legs of a cooling tower and the attachment of the legs to the body of the cooling tower must be designed, even if the legs are provided by the manufacturer and installed at the plant. Also, if the cooling tower has an I_p=1.5, the design must address not only the attachments (welds, bolts, etc.) of the legs to the component but also local stresses imposed on the body of the cooling tower by the support attachments.

C13.6.5.5 Additional Requirements. As reflected in this Section of the standard and in the footnote to Table 13.6-1, vibration isolated equipment with snubbers is subject to amplified loads as a result of dynamic impact.

Use of expansion anchors for non-vibration isolated mechanical equipment rated over 10 hp is prohibited based on experience with older anchor types. The ASCE/SEI 7 Seismic Subcommittee developing the 2010 edition of the standard is considering a proposal that would allow anchors qualified by simulated seismic testing and long-term vibration testing to also be exempt.

C13.6.6 Utility and Service Lines. For essential facilities (Occupancy Category IV), auxiliary on-site mechanical and electrical utility sources are recommended.

Where utility lines pass through the interface of adjacent, independent structures, they must be detailed to accommodate differential displacement computed in accordance with Section 13.3.2 and including the C_d factor of Section 12.2.1.

As specified in Section 13.1.3, nonessential piping whose failure could damage essential utilities in the event of pipe rupture are deemed Designated Seismic Systems.

C13.6.7 HVAC Ductwork. Experience in past earthquakes has shown that HVAC duct systems are rugged and perform well in strong ground shaking. Bracing in accordance with the Sheet Metal and Air Conditioning Contractors National Association ANSI/SMACNA 001 has been effective in limiting damage to duct systems. Typical failures have affected only system function, and major damage or collapse has been uncommon. Therefore, industry standard practices should prove adequate for most installations. Expected earthquake damage is limited to opening of duct joints and tears in ducts. Connection details that are prone to brittle failures, especially hanger rods subject to large amplitude cycles of bending stress, should be avoided.

The amplification factor for ductwork has been increased from 1.0 to 2.5, because even braced duct systems are relatively flexible. The R_p values also have been increased so that the resulting seismic design forces are consistent with those determined previously.

Ductwork systems that carry hazardous materials or must remain operational during and after an earthquake, are assigned a value of I_p =1.5, and require a detailed engineering analysis addressing leak-tightness.

C13.6.8 Piping Systems. In earthquakes, piping systems rarely collapse but often cause nonstructural damage due to leaking. Industry standards and guidelines address a wide variety of piping systems and materials. Construction in accordance with referenced national standards is effective in limiting damage to and avoiding loss of fluid containment in piping systems under earthquake conditions.

ASHRAE's *A Practical Guide to Seismic Restraint,* while not an ANSI standard, is in common use and may be an appropriate reference document for use in the seismic design of piping systems.

The prescriptive conditions provided in the standard under which seismic bracing for piping may be omitted are based on observed performance in past earthquakes.

C13.6.8.1 ASME Pressure Piping Systems. The R_p values tabulated for ASME B31 compliant piping systems reflect the stringent design and quality control requirements as well as the intensified stresses used in ASME design procedures.

C13.6.8.4 Other Piping Systems

Piping not designed in accordance with ASME B31 typically is assigned lower R_p values. Piping component testing suggests that the ductility capacity of carbon steel threaded and grooved joint piping component joints ranges between 1.4 and 3.0. Therefore, these types of connections have been classified as having limited deformability. Grooved couplings and other articulating type of connections may demonstrate free rotational capacity that increases the overall rotational design capacity of the connection. When considered in design, this increase should not exceed 50 percent of the total demonstrated design capacity. The free rotational capacity is the maximum articulating angle where the connection behaves essentially as a pinned joint. The remaining rotational capacity of the connection is where it behaves as a conventional joint whose design force demands are determined by traditional means.

C13.6.9 Boilers and Pressure Vessels

Experience in past earthquakes has shown that boilers and pressure vessels are rugged and perform well in strong ground motion. Construction in accordance with current requirements of the ASME *Boiler and Pressure Vessel Code* (ASME BPVC) has been shown to be effective in limiting damage to and avoiding loss of fluid containment in boilers and pressure vessels under earthquake conditions. It is, therefore, the intent of the standard that nationally recognized codes be used to design boilers and pressure vessels provided that the seismic force and displacement demands are equal to or exceed those outlined in Section 13.3. Where nationally recognized codes do not yet incorporate force and displacement requirements comparable to the requirements of Section 13.3, it is nonetheless the intent to use the design acceptance criteria and construction practices of those codes.

C13.6.10 Elevator and Escalator Design Requirements

The ASME *Safety Code for Elevators and Escalators* (ASME A17.1) has adopted many requirements to improve the seismic response of elevators; however, they do not apply to some regions covered by this chapter. These changes are to extend force requirements for elevators to be consistent with the standard.

C13.6.10.3 Seismic Switches

The purpose of seismic switches as used here is different from that of ASME A17.1, which has incorporated several requirements to improve the seismic response of elevators (such as rope snag point guards, rope retainer guards, and guide rail brackets) and which does not apply to some buildings covered by the standard. Building motions that are expected in areas not covered by the seismic provisions of ASME 17.1 are sufficiently large to impair the operation of elevators. The seismic switch is positioned high in the structure where structural response will be the most severe. The seismic switch trigger level is set to shut down the elevator where structural motions are expected to impair elevator operations.

Elevators in which the seismic switch and counterweight derail device have triggered should not be put back into service without a complete inspection. However, in the case where the loss of use of the elevator creates a life-safety hazard, an attempt to put the elevator back into service may be attempted. Operating the elevator prior to inspection may cause severe damage to the elevator or its components.

The building owner should have detailed written procedures in place defining for the elevator operator/maintenance personnel which elevators in the facility are necessary from a post-earthquake life safety perspective. It is highly recommended that these procedures be in-place, with appropriate personnel training, prior to an event strong enough to trip the seismic switch.

C13.6.10.4 Retainer Plates

The use of retainer plates is a very low cost provision to improve the seismic response of elevators.

C13.6.11 Other Mechanical and Electrical Components. The material properties set forth in Item 2 of this Section are similar to those allowed in ASME BPVC and reflect the high factors of safety necessary for seismic, service, and environmental loads.

COMMENTARY TO CHAPTER 14, MATERIAL SPECIFIC SEISMIC DESIGN AND DETAILING REQUIREMENTS

Because seismic loading is expected to cause nonlinear behavior in structures, seismic design criteria require not only provisions to govern loading, but also provisions to define the required configurations, connections, and detailing to produce material and system behavior consistent with the design assumptions. Thus, while ASCE/SEI 7-05 is primarily a loading standard, compliance with Chapter 14, which covers material specific seismic design and detailing, is required. In general, Chapter 14 adopts material design and detailing standards developed by industry material standards organizations. These materials standards organizations maintain complete commentaries covering their standards and such material is not duplicated here.

The refinements, additions, and recommended changes to the material standards produced by the Provisions Update Committee appear in Part 1 of the 2009 *NEHRP Recommended Seismic Provisions* as exceptions to ASCE/SEI 7-05 along with associated commentary.

C14.0 SCOPE

The scoping statement in this section clarifies that foundation elements are subject to all of the structural design requirements of the standard.

C14.1 STEEL

C14.1.1 Reference Documents. This section lists a series of structural standards published by the American Institute of Steel Construction (AISC), American Iron and Steel Institute (AISI), American Society of Civil Engineers (ASCE/SEI), and Steel Joist Institute (SJI) that are to be applied in the seismic design of steel members and connections in conjunction with the requirements of ASCE/SEI 7. The AISC references are available free of charge in electronic format at www.aisc.org.

C14.1.2 Seismic Design Categories B and C. For the lower Seismic Design Categories B and C, the engineer is allowed a choice in the design of a steel lateral force resisting system. The first option is to design the structure to meet the design and detailing requirements for structures assigned to higher Seismic Design Categories, with the corresponding seismic design parameters (R, Ω_0, and C_d). The second option is to use a lower R factor of 3 (and higher resulting base shear), an Ω_0 of 3, and a C_d value of 3 but without specific seismic design and detailing requirements. The concept of this option is that design for a higher base shear force will result in essentially elastic response that will compensate for the limited ductility of the members and connections, resulting in performance similar to that of more ductile systems.

C14.1.3 Seismic Design Categories D through F. For the higher Seismic Design Categories, the Engineer is not given a choice, but must follow the seismic design provisions of either AISC or AISI using the seismic design parameters specified for the chosen structural system. It is not considered appropriate to design structures without specific design and detailing for seismic response in these high Seismic Design Categories.

C14.1.4 Cold-Formed Steel. This section adopts two standards by direct reference: AISI NAS, *North American Specification for the Design of Cold-Formed Steel Structural Members*, and ASCE/SEI 8, *Specification for the Design of Cold Formed Stainless Steel Structural Members*.

Both of the adopted reference documents have specific limits of applicability. AISI NAS (Section A1.1) applies to the design of structural members that are cold-formed to shape from carbon or low-alloy steel sheet, strip, plate, or bar not more than one-inch in thickness. ASCE/SEI 8 (Section 1.1.1) governs the design of structural members that are cold-formed to shape from annealed and cold-rolled sheet, strip, plate, or flat bar stainless steels. Both documents focus on load-carrying members in buildings; however, allowances are made for applications in nonbuilding structures, if dynamic effects are considered appropriately.

Within each document, there are requirements related to general provisions for the applicable types of steel; design of elements, members, structural assemblies, connections, and joints; and mandatory testing. In addition, AISI NAS contains a chapter on the design of cold-formed steel structural members and connections undergoing cyclic loading. Both standards contain extensive commentaries for the benefit of the user.

C14.1.4.1 Light-Framed Cold-Formed Steel Construction. This subsection of cold-formed steel relates to light-framed construction, which is defined as a method of construction where the structural assemblies are formed primarily by a system

of repetitive wood or cold-formed steel framing members or subassemblies of these members (ASCE/SEI 7-05 Section 11.2). Not only does this subsection repeat the direct adoptions of AISI NAS and ASCE/SEI 8, but it also allows the user to choose from an additional suite of standards that address different aspects of construction, including the following:

1. AISI GP, *Standard for Cold-Formed Steel Framing— General Provisions*, applies to the design, construction, and installation of structural and non-structural cold-formed steel framing members where the specified minimum base metal thickness is between 18 mils and 118 mils (Section A1).
2. AISI WSD, *Standard for Cold-Formed Steel Framing – Wall Stud Design*, applies to the design and installation of cold-formed steel studs for both structural and non-structural walls in buildings (Section A1).
3. AISI Lateral, *Standard for Cold-Formed Steel Framing – Lateral Design*, contains design requirements for shear walls, diagonal strap bracing (as part of a structural wall), and diaphragms (Section A1).

The requirements of AISI GP apply to all light-framed cold-formed steel and, consequently, the standard is adopted by direct reference in both AISI WSD and AISI Lateral. In addition, all of these documents include commentaries to aid the user in the correct application of their requirements.

C14.1.5 Prescriptive Framing. This section adopts AISI PM, *Standard for Cold-Formed Steel Framing – Prescriptive Method for One and Two Family Dwellings*, which applies to the construction of detached one-and two-family dwellings, townhouses, and other attached single-family dwellings not more than two stories in height using repetitive in-line framing practices (Section A1). This document adopts AISI GP by direct reference and includes a commentary to aid the user in the correct application of its requirements.

C14.1.6 Steel Deck Diaphragms. Design of steel deck diaphragms is to be based upon recognized national standards or a specific testing program directed by a person experienced in testing procedures and steel deck. All fastener design values (welds, screws, power actuated fasteners, button punches) for attaching steel deck sheet to steel deck sheet or for attaching the steel deck to the building framing members must be per recognized national design standards or specific steel deck testing programs. All steel deck diaphragm and fastener design properties must be approved for use by the authorities in whose jurisdiction the construction project occurs. Steel deck diaphragm in-plane design forces (seismic, wind, or gravity) must be determined per ASCE/SEI 7-05 Section 12.10.1. Steel deck manufacturer test reports prepared in accordance with this provision can be used where adopted and approved by the authority having jurisdiction for the building project. The diaphragm design manual produced by the Steel Deck Institute (2004) is also a potential reference for design values.

Steel deck is assumed to have a corrugated profile consisting of alternating up and down flutes that are manufactured in various widths and heights. Use of flat sheet metal as the overall floor or roof diaphragm is permissible where designed by engineering principles, but is beyond the scope of this section. Flat or bent sheet metal may be used as closure pieces for small gaps or penetrations or for shear transfer over short distances in the steel deck diaphragm where diaphragm design forces are considered.

Steel deck diaphragm analysis must include design of chord members at the perimeter of the diaphragm and around interior openings in the diaphragm. Chord members may be steel beams attached to the underside of the steel deck designed for a combination of axial loads and bending moments due to acting gravity and lateral loads.

Where diaphragm design loads exceed the bare steel deck diaphragm design capacity, then either horizontal steel trusses or a structurally designed concrete topping slab placed over the steel deck must be provided to distribute lateral forces. Where horizontal steel trusses are used, the steel deck must be designed to transfer diaphragm forces to the steel trusses. Where a structural concrete topping over the steel deck is used as the diaphragm, the diaphragm chord members at the perimeter of the diaphragm and edges of interior openings must be either: (a) designed flexural reinforcing steel placed in the structural concrete topping or (b) steel beams located under the steel deck with connectors (that provide a positive connection) as required to transfer design shear forces between the concrete topping and steel beams.

C14.1.7 Steel Cables. These provisions reference ASCE/SEI 19-96, *Structural Applications of Steel Cables for Buildings*, for the determination of the design strength of steel cables. ASCE/SEI 19 uses service level load combinations with a safety factor relative to the cable design strength. The service level load combinations specified in ASCE/SEI 19 are adjusted in two ways. First, the prestress loading is multiplied by a factor of 1.1 to account for any over prestressing that may occur in the field. Second, the safety factor for load combinations including seismic effects is reduced from 2.0 to 1.5 to account for the dynamic nature of seismic loading and the ductility of the system. While T3 and T4 in ASCE/SEI 19 may be calculated using either wind or seismic loads, the modifications of this section apply only to load combinations including seismic loadings.

C14.1.8 Additional Detailing Requirements for Steel Piles in Seismic Design Categories D through F. Steel piles used in higher Seismic Design Categories are expected to yield just under the pile cap or foundation due to combined bending and

axial load. Design and detailing requirements of AISC 341 for H-piles are intended to produce stable plastic hinge formation in the piles. Since piles can be subjected to tension due to overturning moment, mechanical means to transfer such tension must be designed for the required tension force, but not less than 10 percent of the pile compression capacity.

C14.2 CONCRETE

The section adopts ACI 318-05, *Building Code Requirements for Structural Concrete* (ACI 318), by reference for structural concrete design and construction. In addition, modifications to ACI 318 are made to coordinate the provisions of that material design standard with the provisions of ASCE/SEI 7.

C14.2.2.1 ACI 318 Section 7.10. The reinforcement details for ties in compression members prescribed in ACI 318 Section 7.10.5 are appropriate for SDC A and B structures. This modification prescribes additional details for ties around anchor bolts of structures assigned to SDC C, D, E, or F.

C14.2.2.2 ACI 318 Section 10.5. This provision affects ordinary moment frames. It is intended to improve continuity, and thereby lateral force resistance and structural integrity, compared to that of frames designed to the provisions of Chapters1 through 18 of ACI 318 only. The provision does not apply to slab-column moment frames.

C14.2.2.3 ACI 318 Section 11.11. This requirement is intended to provide additional toughness to resist shear for columns of frames in SDC B. Otherwise the proportions of those columns make them more susceptible to shear failure under earthquake loading.

C14.2.2.4 Definitions. The first four definitions relate the wall types of ASCE/SEI 7-05 with detailing requirements of ACI 318 and distinguish between ordinary reinforced concrete structural walls and ordinary precast structural walls. These definitions are essential to the proper interpretation of the R and C_d factors for each wall type specified in Table 12.2-1.

A wall pier is recognized as a separate category of structural element in this document but not in ACI 318.

C14.2.2.5 Scope. ACI 318 uses the terminology of low, moderate, and high seismic risk for structures assigned to SDC A and B, SDC C, and SDC D through F, respectively. The modifications of this provision show how the ACI 318 provisions should be interpreted for consistency with the ASCE/SEI 7-05 provisions.

C14.2.2.6 Reinforcement in Members Resisting Earthquake-Induced Forces. ACI 318 does not allow the use of prestressing tendons in special and intermediate moment frames. This provision and ASCE/SEI 7-05 Sections 14.2.2.7 and 14.2.2.8 impose conditions that have been demonstrated to permit the safe use of such tendons.

These provisions are intended to apply to frames containing unbonded tendons only. The average prestress in plastic hinge regions is restricted to limit the strain in the prestressing steel under the design displacement to not greater than 1 percent. The strain in the prestressing steel at the design displacement should be calculated considering the anticipated inelastic mechanism of the structure.

C14.2.2.7 Anchorages for Unbonded Post-tensioning Tendons. Fatigue testing for 50 cycles of loading between 40 and 80 percent of the specified tensile strength of the prestressing strand has been an industry practice of long standing (ACI 423.6, *Specification for Unbonded Single-Strand Tendons*). The 80 percent limit is increased to 85 percent for seismic applications in order to correspond to a 1 percent limit, and therefore the effective start of yielding, in the prestressing steel. Testing over this range of stress conservatively simulates the effect of a severe earthquake on structures prestressed in accordance with the requirements of ASCE/SEI 7-05 Sections 14.2.2.6 and 14.2.2.8.

C14.2.2.8 Flexural Members of Special Moment Frames. The restrictions on the flexural strength provided by the tendons are based on the results of analytical and experimental studies (Ishizuka and Hawkins, 1987; Park and Thompson, 1977). Although satisfactory seismic performance can be obtained with greater amounts of prestressing steel, this restriction is needed to allow the use of the same response modification and deflection amplification factors as those specified for special moment frames without prestressing steel.

C14.2.2.9 Wall Piers and Wall Segments. Wall piers are typically segments between openings in walls that are thin in the direction normal to the face of the wall. In current practice these elements are often not regarded as columns or as part of the special structural walls. If not properly reinforced these elements are vulnerable to shear failure, and that failure prevents the wall from developing the assumed flexural hinging. ACI 318 Section 21.7.10 is written specifically to preclude such pre-emptive shear failure. The required shear strength in ACI 318 Section 21.4.5.1 is based on the probable shear strength, V_e, under the probable moment, M_{pr}. Wall segments with a horizontal length-to-thickness ratio less than 2.5 and a clear height-to-length ratio of at least 2 are required to be designed as columns in compliance with ACI 318 Section 21.4 if they are used as part of the lateral-force-resisting system even though the shortest cross-sectional dimension may be less than 12 inches in violation of Section 21.4.1.1. Such wall segments may be designed to comply with ACI 318 Section 21.11 if they are not

used as part of the lateral-force-resisting system. Wall segments with a horizontal length-to-thickness ratio larger than or equal to 2.5, which do not meet the definition of wall piers (ASCE/SEI 7-05 Section 14.2.2.4), must be designed as special structural walls or as portions of special structural walls in full compliance with ACI 318 Section 21.7.

C14.2.2.12 Members Not Designated as Part of the Lateral-Force-Resisting System. ACI 318 Section 21.4.3.2 permits lap splices only within the center half of the column. Section 21.11.2 applies where the magnitude of the moments induced in the column by the design displacement are explicitly checked. Section 21.11.3 applies where the effects of the design displacement are not explicitly checked. Section 21.11.2.2, if not modified, would permit lap splices to be placed at any location over the height of the column if the column is expected to yield. If, however, the column is not expected to yield the wording effectively requires the splice to be located near mid-height. This is not rational and the modification results in a more rational provision.

C14.2.2.13 Columns Supporting Reactions from Discontinuous Stiff Members. Discontinuous shear walls and other stiff members can impose large axial forces on supporting columns. The specified transverse reinforcement is to improve column toughness under anticipated seismic demands.

C14.2.2.14 Intermediate Precast Structural Walls. ACI 318 Section 21.13 imposes requirements on precast walls for moderate seismic risk applications. The intent is to produce ductile behavior by yielding of the steel elements or reinforcement between panels or between panels and foundations. The 2003 IBC restricted yielding to steel reinforcement because of concern that steel elements in the body of a connection could fracture due to strain demands.

Several steel element connections have been tested under simulated seismic loading and the adequacy of their load-deformation characteristics and strain capacity of yield has been demonstrated (Schultz and Magana, 1996). One such connection was used in the five-story building test that was part of the PRESSS Phase 3 research. The connection was used to provide damping and energy dissipation, and demonstrated a very large strain capacity (Nakaki et al., 2001). Since then several other steel element connections have been developed that can achieve similar results (Banks and Stanton, 2005; Nakaki et al., 2005). In view of these results it is appropriate to allow yielding in steel elements that have been shown experimentally to have adequate strain capacity to maintain at least 80 percent of their yield force of through the full design displacement of the structure. This provision requires the designer to determine the deformation in the connection corresponding to the earthquake design displacement, and then to check for experimental data that the connection type used can accommodate that deformation without significant strength degradation.

The wall pier requirements in the modified ACI 318 Section 21.13.5 are less stringent than those for wall piers for special structural walls as specified in the modified Section 21.7.10. Where intermediate precast structural walls are used in SDCs D, E and F, wall piers should satisfy the requirements of ASCE/SEI 7-05 Section 14.2.2.9 rather than 14.2.2.14.

C14.2.2.15 Detailed Plain Concrete Shear Walls. Design requirements for plain masonry walls have existed for many years, and the competing type of concrete construction is the plain concrete wall. To allow the use of such walls as the lateral-force-resisting system in SDC A and B, this provision requires such walls to contain at least the minimal reinforcement specified in ACI 318 Section 22.6.7.2.

C14.2.2.16 Plain Concrete in Structures Assigned to Seismic Design Category C, D, E, or F. Modifications are made to ACI 318 Section 22.10 that restrict markedly the use of ordinary and detailed structural plain concrete walls in SDC C, D, E, and F.

C14.2.2.17 General Requirements for Anchoring to Concrete. ACI 318 uses the terminology of regions of moderate or high seismic risk and structures assigned to intermediate or high seismic performance or design categories. In this modification, the only changes to ACI 318 in Sections D3.3.3 through D3.3.4 are the replacement of that terminology with the SDC terminology.

There are two changes to the provisions in ACI 318 Section D3.3.5. The first is the use of the SDC terminology, and the second is the addition of the last phrase of the provision referring to the minimum design strength of the anchors. The last phrase requires an anchor strength that is at least the maximum likely Ω_0 value (2.5) times the design force calculated as being transmitted to the attachment by the lateral-force-resisting system.

C14.2.2.18 Strength Requirements for Anchors. ACI 318 requires laboratory testing to establish the strength of anchor bolts greater than 2 inches in diameter or exceeding 25 inches in tensile embedment depth. This modification makes the ACI 318 equation giving the basic concrete breakout strength of a single anchor in tension in cracked concrete applicable irrespective of the anchor bolt diameter and tensile embedment depth.

Korean Power Engineering (KPE) has made tension tests on anchors with diameters up to 4.25 inches and embedment depths up to 45 inches and found that the diameter and embedment depth limits of ACI 318 Section D4.2.2 for the design procedure for anchors in tension (Section D5.2) can be eliminated. KPE has also made shear tests on anchors with diameters up to 3.0

inches and embedment depths as large as 30 inches and found no effect of the embedment depth on shear strength. However, the diameter tests showed that the basic shear breakout strength equation (ACI 318 Section D-24) needed some modification for the complete elimination of the 2 inch limit to be fully appropriate. Analytical work performed at the University of Stuttgart supports the need for some modification to the ACI 318 Equation D-24. Changes consistent with the Korean and Stuttgart findings have already been made to the FIB Design Guide for anchors and a change proposal consistent with those changes has been submitted to ACI 318 for consideration.

C14.2.3.1.2 Reinforcement for Uncased Concrete Piles (SDC C): The transverse reinforcing requirements in the potential plastic hinge zone of uncased concrete piles in Seismic Design Category C is a selective composite of two ACI 318 requirements. In the potential plastic hinge region of an intermediate moment-resisting concrete frame column, the transverse reinforcement spacing is restricted to the least of: (a) 8 times the diameter of the smallest longitudinal bar, (b) 24 times the diameter of the tie bar, (c) one-half the smallest cross-sectional dimension of the column, and (d) 12 inches. Outside of the potential plastic hinge region of a special moment-resisting frame column, the transverse reinforcement spacing is restricted to the smaller of: 6 times the diameter of the longitudinal column bars and 6 inches.

C14.2.3.1.5 Reinforcement for Precast Nonprestressed Concrete Piles (SDC C): Transverse reinforcement requirements inside and outside of the plastic hinge zone of precast nonprestressed piles are clarified. The transverse reinforcement requirement in the potential plastic hinge zone is a composite of two ACI 318 requirements (see Section C14.2.3.1.2). Outside of the potential plastic hinge region the eight longitudinal-bar-diameter spacing is doubled. The maximum 8-in. tie spacing comes from current building code provisions for precast concrete piles.

C14.2.3.1.6 Reinforcement for Precast Prestressed Piles (SDC C): The transverse and longitudinal reinforcing requirements given in ACI 318 Chapter 21 were never intended for slender precast prestressed concrete elements and will result in unbuildable piles. The requirements are based on the 1993 *Recommended Practice for Design, Manufacture and Installation of Prestressed Concrete Piling* by the PCI Committee on Prestressed Concrete Piling.

ASCE/SEI 7-05 Equation 14.2-1, originally from ACI 318, has always been intended to be a lower-bound spiral reinforcement ratio for larger diameter columns. It is independent of the member section properties and therefore can be applied to large or small diameter piles. For cast-in-place concrete piles and precast prestressed concrete piles, the resulting spiral reinforcing ratios from this formula are considered to be sufficient to provide moderate ductility capacities.

Full confinement per Equation 14.2-1 is required for the upper 20 feet of the pile length where curvatures are large. The amount is relaxed by 50 percent outside of that length in view of lower curvatures and in consideration of confinement provided by the soil.

C14.2.3.2.5 Reinforcement for Precast Concrete Piles (SDC D through F): The transverse reinforcement requirements for precast nonprestressed concrete piles are taken from current building code requirements and are intended to provide ductility in the potential plastic hinge zones.

C14.2.3.2.6 Reinforcement for Precast-Prestressed Piles (SDC D through F): The last paragraph provides minimum transverse reinforcement outside of the zone of prescribed ductile detailing.

C14.3 COMPOSITE STEEL AND CONCRETE STRUCTURES

This section provides guidance on the design of composite and hybrid steel-concrete structures. Composite structures are defined as those incorporating structural elements made of steel and concrete portions connected integrally throughout the structural element by mechanical connectors, bond, or both. Hybrid structures are defined as consisting of steel and concrete structural elements connected together at discrete points. Composite and hybrid structural systems mimic many of the existing steel (moment and braced frame) and concrete (moment frame and wall) configurations, but are given their own design coefficients and factors in Table 12.2-1. Their design is based on the same ductility and energy dissipation concepts used in conventional steel and reinforced concrete structures, but requires special attention to the interaction of the two materials as it affects the stiffness, strength, and inelastic behavior of the members, connections, and systems.

C14.3.1 Reference Documents. Seismic design for composite structures assigned to Seismic Design Category D, E, or F is governed primarily by *Part II: Composite Structural Steel and Reinforced Concrete Buildings* of ANSI/AISC 341. Part II of ANSI/AISC 341 is less prescriptive than Part I and provides flexibility for designers to utilize analytical tools and results of research in their practice. Composite structures assigned to Seismic Design Category A, B, or C may be designed according to principles outlined in ANSI/AISC 360 and ACI 318. ACI 318 and ANSI/AISC 360 provide little guidance on connection design; therefore, designers are encouraged to review ANSI/AISC 341 Part II for guidance on the design of joint areas. Differences between older AISC and ACI provisions for cross-sectional strength for composite columns have been minimized by changes in the latest ANSI/AISC 360. However, there is not uniform agreement between the provisions in

ACI 318 and ANSI/AISC 360 regarding detailing, limits on material strengths, stability, and shear design for composite columns. The composite design provisions in ANSI/AISC 360 are considered to be current.

C14.3.2 Metal-Cased Concrete Piles. Design of metal-cased concrete piles, which are analogous to circular concrete filled tubes, is governed by ASCE/SEI 7-05 Sections 14.2.3.1.3 and 14.2.3.2.4. The intent of these provisions is to require metal-cased concrete piles to have confinement and protection against long-term deterioration comparable to that for uncased concrete piles.

C14.4 MASONRY

Seismic design for masonry structures is governed primarily by two documents produced by the Masonry Standards Joint Committee (MSJC): ACI 530-05/ASCE/SEI 5-05/TMS 402-5, *Building Code Requirements for Masonry Structures* (the MSJC Code), and ACI 530.1-05/ASCE/SEI 6-05/TMS 602-05, *Specification for Masonry Structures* (the MSJC Specification).

C14.4.2 *R* Factors. Where intermediate and special reinforced masonry shear walls are designed using the allowable-stress provisions of the MSJC Code, these additional requirements are intended to produce a level of inelastic flexural deformation capacity consistent with that of intermediate and special reinforced masonry shear walls designed using the strength-design provisions of the MSJC Code. The additional requirements are discussed in ASCE/SEI 7-05 Section C14.4.6.

C14.4.3 Classification of Shear Walls. Section 1.14 of the 2005 MSJC Code can be interpreted as permitting, in SDCs A and B, masonry walls that need not be considered part of the lateral-force-resisting system and that do not need to be isolated. ASCE/SEI 7-05 Section 14.4.3 is intended to preclude that interpretation.

C14.4.5.1 Separation Joints. This section is intended to address force transfer across interfaces between masonry and other materials, but it is redundant. Article 3.2B of the MSJC Specification requires that the interface between concrete and masonry be cleaned and acceptable for laying of units. Further, Section 1.9.4.2.4 of the 2005 MSJC Code addresses the design and transfer of shear at interfaces, and Section 1.7.5.2 requires that a load path and force transfer between a foundation and the masonry above be maintained.

C14.4.5.2 Flanged Shear Walls. Section 1.9.4.2.3 of the MSJC Code contains the compression requirement (lesser of 6 times the flange thickness or the actual flange). The principal effect of the tension provision in ASCE/SEI 7-05 Section 14.4.5.2 is to establish the amount of tensile reinforcement used in calculating flexural capacity and maximum permitted reinforcement, but this provision is not well established technically. Research in masonry, and analogous design provisions for concrete (ACI 318 Section 21.7.5.2), suggest that effective flange widths in tension are more logically related to the total wall height rather than the floor-to-floor height. The 2005 MSJC Code and ASCE/SEI 7-05 are working together to resolve this issue and add appropriate requirements to TMS 402.

C14.4.6 Modifications to Chapter 2 of ACI 530/ASCE/SEI 5/TMS 402. Chapter 2 of the MSJC Code deals with allowable-stress design.

C14.4.6.1 Stress Increase. The MSJC Code permits allowable stresses to be increased by one-third for allowable-stress loading conditions that include wind or earthquake, provided that the legally adopted building code so permits. While the alternate allowable-stress loading combinations of the 2006 IBC do so permit, the allowable-stress loading combinations of ASCE/SEI 7-05 do not.

C14.4.6.2 Reinforcement Requirements and Details.

C14.4.6.2.1 Reinforcing Bar Size Limitations. The intent of this requirement is to prevent splitting of masonry due to the presence of reinforcement. A similar requirement is appears in Chapter 3 (Strength Design) of the 2005 MSJC Code. The MSJC is working to move that requirement to Chapter 1 (General Requirements) so that it would apply to all masonry construction.

C14.4.6.2.2 Splices. In general, the first portion of this section, which prohibits splices in plastic hinge zones, is intended to produce adequate inelastic deformation capacity in those regions. In general, the presence of splices in plastic hinge zones reduces inelastic deformation capacity because the area of steel is doubled at the splice, reducing the extent of yielding. However, there is some controversy concerning the technical validity and necessity for this requirement for masonry walls. Similar requirements apply to plastic hinge zones of reinforced concrete frames, they do not apply to plastic hinge zones of reinforced concrete walls. Also, this requirement does not distinguish between shear-critical and flexurally dominated shear walls. The MSJC is continuing to discuss related requirements for flexurally dominated, highly ductile shear walls.

The remaining portions of this section (requirements for splices) are intended to provide adequate capacity of welded splices and mechanical connections. The MSJC is developing similar provisions.

C14.4.6.2.3 Maximum Area of Flexural Tensile Reinforcement. The intent of this section is to produce adequate inelastic flexural deformation capacity in flexurally dominated masonry shear walls by placing an upper limit on flexural reinforcement, so that behavior is dominated by yielding of reinforcement rather than by crushing of the compression toe. Similar provisions appear in Chapter 3 (Strength Design) of the MSJC Code and are being developed for Chapter 2 (Allowable-Stress Design).

C14.4.7 Modifications to Chapter 3 of ACI 530/ASCE/SEI 5/TMS 402.

C14.4.7.2 Splices in Reinforcement. See Section C14.4.6.2.2.

C14.4.7.3 Coupling Beams. The intent of this requirement is to produce adequate inelastic flexural deformation capacity in coupling beams. The section is somewhat redundant with Section 3.1.3 of the MSJC Code, which requires capacity design of masonry elements for shear.

C14.4.7.4 Deep Flexural Members. The intent of this requirement is to require that the design of deep flexural members correctly addresses the presence of distributed flexural reinforcement in capacity design for shear, and that crack widths are adequately controlled.

C14.4.7.5 Shear Keys. The intent of this requirement is to increase resistance to sliding shear at the foundation level of flexurally dominated masonry shear walls. The original proposal was based on laboratory research (Leiva et al., 1990) involving isolated shear walls. In subsequent research (Seible et al., 1993), flanged walls without shear keys did not show sliding.

C14.4.7.6 Anchoring to Masonry. The intent of this requirement is to guard against brittle failure of masonry anchorages that are part of the seismic force-resisting system.

C14.4.7.7 Anchor Bolts. ASCE/SEI 7-05 Sections 14.4.7.7 and 14.4.7.8 augment the current anchor bolt provisions of MSJC Code Chapter 3 (Strength Design) to address pryout and to include an appropriate ϕ factor.

C14.4.8 Modifications to Chapter 6 of ACI 530/ASCE/SEI 5/TMS 402. There is an apparent difference in the treatment of corrugated sheet metal anchors in different chapters of the MSJC Code. Chapter 6 of that document, dealing with masonry veneer, permits corrugated sheet-metal anchors. Chapters 2 and 3 of that document do not permit multi-wythe, noncomposite masonry (functionally identical to veneer) to be bonded by corrugated sheet-metal anchors.

C14.4.9 Modifications to ACI 530.1/ASCE/SEI 6/TMS 602.

C14.4.9.1 Construction Procedures. This requirement was introduced originally as a result of the TCCMaR program as a way to address volume loss as a result of plastic shrinkage of grout. The original provision required the use of a particular admixture (Sika's Grout Aid®) in the grout. The MSJC Specification requires both consolidation and reconsolidation of masonry grout, which in combination with today's masonry construction materials can minimize grout shrinkage without the requirement of a proprietary grout admixture available from a single source.

C14.5 WOOD

C14.5.1 Reference Documents. Two national consensus standards are adopted for seismic design of engineered wood structures: the *National Design Specification* (NDS), and the *Special Design Provisions for Wind and Seismic* (SDPWS) Supplement to the NDS. Both of these standards, published by the American Forest and Paper Association (AF&PA), are presented in dual allowable stress design (ASD) and load and resistance factor design (LRFD) formats. Both standards reference a number of secondary standards for related items such as wood materials and fasteners. SDPWS addresses general principles and specific detailing requirements for shear wall and diaphragm design and provides tabulated nominal unit shear capacities for shear wall and diaphragm sheathing and fastening. The balance of member and connection design is to be in accordance with the NDS. A commentary to the NDS is published by AF&PA (2005b); commentary to the SDPWS is included in the SDPWS publication (AF&PA, 2005c).

C14.5.2 Framing. This section provides specific guidance on two general topics related to detailing. First, vertical loads on columns and posts must be transferred in and out by end bearing only or by connectors only; mixing the capacity of end bearing and connectors is prohibited due to a potential lack of deformation compatibility. Second, load path continuity for top plates, which often function as collectors, is addressed.

C14.5.3.1 ASCE/SEI 7-05 Modification to SDPWS Section 4.3.3.2, Summing Shear Capacities. This amendment to the SDPWS does not provide additional clarity; therefore, it is expected to be deleted ASCE/SEI 7-10.

COMMENTARY TO CHAPTER 15, SEISMIC DESIGN REQUIREMENTS FOR NONBUILDING STRUCTURES

C15.1.1 Nonbuilding Structures. Building codes traditionally have been perceived as minimum standards for the design of nonbuilding structures, and building code compliance of these structures is required by building officials in many jurisdictions. However, requirements in the industry reference documents are often at odds with building code requirements. In some cases, the industry documents need to be altered while in other cases the building codes need to be modified. Registered design professionals are not always aware of the numerous accepted documents within an industry and may not know whether the accepted documents are adequate. The intent of Chapter 15 of the standard is to bridge the gap between building codes and existing industry reference documents.

Differences between the ASCE/SEI 7-05 design approaches for buildings and industry document requirements for steel multi-legged water towers (Figure C15.1-1) are representative of this inconsistency. Historically, such towers have performed well when properly designed in accordance with American Water Works Association (AWWA) standards and industry practices. Those standards and practices differ from the ASCE/SEI 7-05 treatment of buildings in that tension-only rods are allowed, upset rods are preloaded at the time of installation, and connection forces are not amplified.

Figure C15.1-1 Steel multi-legged water tower.

Chapter 15 also provides an appropriate link so that the industry reference documents can be used with the seismic ground motions established in the standard. It should be noted that some nonbuilding structures are very similar to buildings and can be designed employing sections of the standard directly, whereas other nonbuilding structures require special analysis unique to the particular type of nonbuilding structure.

Note that building structures, vehicular bridges, electrical transmission towers, hydraulic structures (e.g., dams), buried utility lines and their appurtenances, and nuclear reactors are excluded from the scope of the nonbuilding structure requirements. The excluded structures are covered by other well established design criteria (e.g., electrical transmission towers and vehicular bridges), are not under the jurisdiction of local building officials (e.g., nuclear reactors, and dams), or require technical considerations beyond the scope of the standard (e.g., buried utility lines and their appurtenances).

C15.1.2 Design. Nonbuilding structures and building structures have much in common with respect to design intent and expected performance, but there are also important differences. Chapter 15 relies on other portions of the standard where possible and provides special notes where necessary.

There are two types of nonbuilding structures: those with structural systems similar to buildings, and those with structural systems not similar to buildings. Specific requirements for these two cases appear in Sections 15.5 and 15.6.

C15.1.3 Structural Analysis Procedure Selection. Nonbuilding structures that are similar to buildings are subject to the same analysis procedure limitations as building structures. Nonbuilding structures that are not similar to buildings are subject to those limitations and are subject to procedure limitations prescribed in applicable specific reference documents.

For many nonbuilding structures supporting flexible system components, such as pipe racks (Figure C15.1-2), the supported piping and platforms generally are not regarded as rigid enough to redistribute seismic forces to the supporting frames.

Figure C15.1-2 Steel pipe rack.

For nonbuilding structures supporting rigid system components, such as steam turbine generators (STGs) and heat recovery steam generators (HRSGs) (Figure C15.1-3), the supported equipment, ductwork, and other components (depending on how they are attached to the structure) may be rigid enough to redistribute seismic forces to the supporting frames. Torsional effects may need to be considered in such situations.

Section 12.6 presents seismic analysis procedures for building structures based on the Seismic Design Category; the fundamental period, *T*; and the presence of certain horizontal or vertical irregularities in the structural system. Where the fundamental period is greater than or equal to $3.5T_s$ (where $T_s = S_{D1}/S_{DS}$), the use of the equivalent lateral force procedure is not permitted in Seismic Design Categories D, E, and F. This requirement is based on the fact that, unlike the dominance of the first mode response in case of buildings with lower first mode period, higher vibration modes do contribute more significantly in situations when the first mode period is larger than 3.5*Ts*. For buildings that exhibit classic flexural deformation patterns (such as slender shear wall or braced frame systems), the second mode frequency is at least 3.5 times the first mode frequency, so where the fundamental period exceeds 3.5*Ts*, the higher modes will have larger contributions to the total response as they occur near the peak of the design response spectrum

It follows that dynamic analysis (modal response spectrum analysis, or response-history analysis) is required for building-like nonbuilding structures if the first mode period is larger than 3.5*Ts* and that the equivalent lateral force analysis is sufficient for nonbuilding structures that respond as single-degree-of-freedom systems such as single-pedestal elevated water tanks.

The recommendations for nonbuilding structures provided below are intended to supplement the designer's judgment and experience. The designer is given considerable latitude in selecting a suitable analysis method for nonbuilding structures.

Figure C15.1-3 Heat recovery steam generators.

Building-like Nonbuilding Structures. Table 12.6-1 is used in selecting analysis methods for building-like nonbuilding structures, but, as illustrated in the following three conditions, the relevance of key behavior must be considered carefully:

1. Irregularities: Table 12.6-1 requires dynamic analysis for Seismic Design Category D, E, and F structures having certain horizontal or vertical irregularities. Some of these building irregularities (defined in Section 12.3.2) are relevant to nonbuilding structures. The weak-and soft-story vertical irregularities (Types 1a, 1b, 5a, and 5b of Table 12.3-2) are pertinent to the behavior of building-like nonbuilding structures. Other vertical and horizontal irregularities may or may not be relevant as described below.

    a. Horizontal irregularities: Horizontal irregularities of Type 1a and 1b affect the choice of analysis method, but these irregularities apply only where diaphragms are rigid or semirigid and some building-like nonbuilding structures have either no diaphragms or flexible diaphragms.

    b. Vertical irregularities: Vertical irregularity Type 2 is relevant where the various levels actually support significant loads. Where a building-like nonbuilding structure supports significant mass at a single level, while other levels support small masses associated with stair landings, access platforms, and so forth, dynamic response will be dominated by the first mode, so the equivalent lateral force procedure may be applied. Vertical irregularity Type 3 addresses large differences in the horizontal dimension of the seismic force-resisting system in adjacent stories, since the resulting stiffness distribution can produce a fundamental mode shape unlike that assumed in the development of the equivalent lateral force procedure. Since the concern relates to stiffness distribution, it is the horizontal dimension of the seismic force-resisting system, not of the overall structure, that is important.

2. Arrangement of supported masses: Even where a nonbuilding structure has building-like appearance, it may not behave like a building, depending on how masses are attached. For example, the response of nonbuilding structures with suspended vessels and boilers cannot be determined reliably using the equivalent lateral force procedure because of the pendulum modes associated with the significant mass of the suspended components. The resulting pendulum modes, while potentially reducing story shears and base shear, may require large clearances to allow pendulum motion of the supported components and may produce excessive demands on attached piping. Dynamic analysis should be performed in such cases, with consideration for appropriate impact forces in the absence of adequate clearances.

3. Relative rigidity of beams: Even where a classic building model may seem appropriate, the equivalent lateral force procedure may underpredict the total response if the beams are flexible relative to the columns (of moment frames) or the braces (of braced frames). This is because higher modes associated with beam flexure may contribute more significantly to the total response (even if the first mode response is at a period less than 3.5*Ts*). This situation of flexible beams can be especially pronounced for nonbuilding structures since the "normal" floors common to buildings may be absent. Therefore, the dynamic analysis procedures are recommended for building-like nonbuilding structures with flexible beams.

Nonbuilding Structures Not Similar to Buildings. The (static) equivalent lateral force procedure is based on classic building dynamic behavior, which is an inappropriate characterization for many nonbuilding structures not similar to buildings. As discussed below, several issues should be considered for selecting either an appropriate method of dynamic analysis or a suitable distribution of lateral forces for static analysis.

1. Structural geometry: The dynamic response of nonbuilding structures with a fixed base and a relatively uniform distribution of mass and stiffness, such as bottom-supported vertical vessels, stacks, and chimneys, can be represented adequately by a cantilever (shear building) model. For these structures the equivalent lateral force procedure provided in the standard is suitable. This procedure treats the dynamic response as being dominated by the first mode. In such cases, it is necessary to identify the first mode shape (using, for instance, the Rayleigh-Ritz method or other classical methods from the literature) for distribution of the dynamic forces. For some structures, such as tanks with low height-to-diameter ratios storing granular solids, it is conservative to assume a uniform distribution of forces. Dynamic analysis is recommended for structures that have neither a uniform distribution of mass and stiffness nor an easily determined first mode shape.

2. Number of lateral supports: Cantilever models are obviously unsuitable for structures with multiple supports. Figure C15.1-4 shows a nonbuilding braced frame structure that provides non-uniform horizontal support to a piece of equipment. In such cases, the analysis should include coupled model effects. For such structures an application of the equivalent lateral force method could be used depending on the number and locations of the supports. For example, most beam-type configurations lend themselves to application of the equivalent lateral force method.

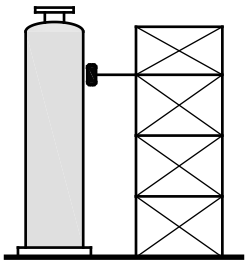

Figure C15.1-4 Multiple lateral supports.

3. Method of supporting dead weight: Certain nonbuilding structures (such as power boilers) are supported from the top. They may be idealized as pendulums with uniform mass distribution. In contrast, a suspended platform may be idealized as a classic pendulum with concentrated mass. In either case, these types of nonbuilding structures can be analyzed adequately using the equivalent lateral force method by calculating the appropriate frequency and mode shape. Figure C15.1-5 shows a nonbuilding structure containing lug supported equipment with W_P greater than $0.25(W_S + W_P)$. In such cases, the analysis should include a coupled system with the mass of the equipment and the local flexibility of the supports considered in the model. Where the support is located near the nonbuilding structure's vertical location of the center of mass, a dynamic analysis is recommended.

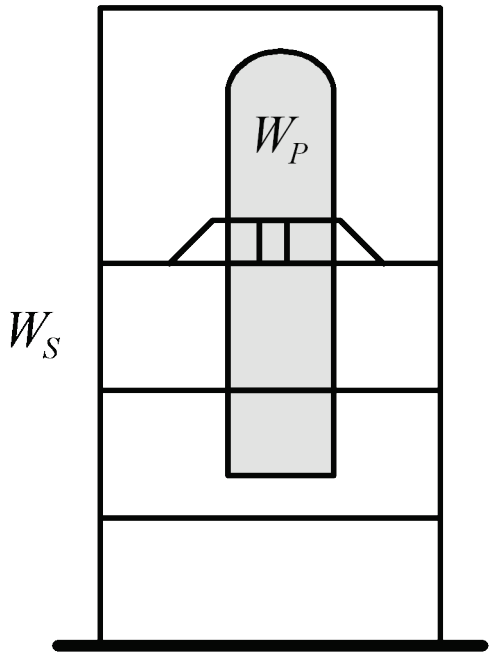

Figure C15.1-5 Unusual support of dead weight.

4. Mass irregularities: Just as in the case of building-like nonbuilding structures, the presence of significantly uneven mass distribution can render the structures unsuitable for application of the equivalent lateral force method. The dynamic analysis methods are recommended in such situations. Figure C15.1-6 illustrates two such situations. In part (a), a mass irregularity exists if W_1 is greater than $1.5W_2$ or less than $0.67W_2$. In part (b), a mass irregularity exists if W_3 is greater than either $1.5W_2$ or $1.5W_4$.

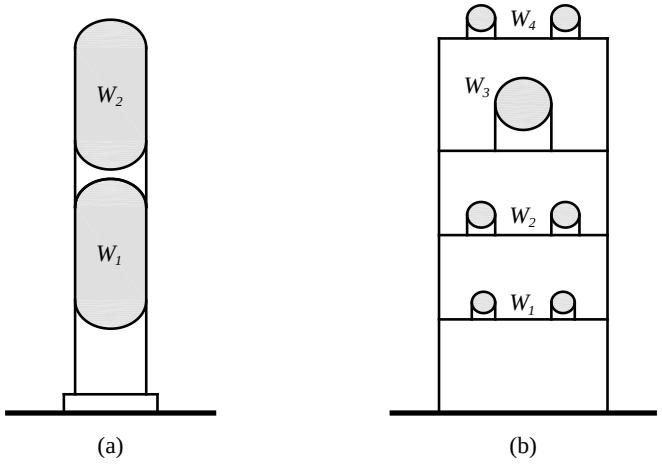

Figure C15.1-6 Mass irregularities.

5. Torsional irregularities: Structures in which the fundamental mode of response is torsional or in which modes with significant mass participation exhibit a prominent torsional component may also have inertial force distributions that are significantly different from that predicted by the equivalent lateral force method. In such cases dynamic analyses should be considered. Figure C15.1-7 illustrates one such case where a vertical vessel is attached to a secondary vessel with W_2 greater than about $0.25(W_1 + W_2)$.

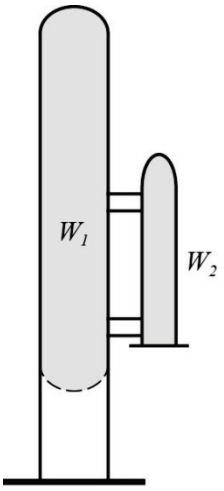

Figure C15.1-7 Torsional irregularity.

6. Stiffness/strength irregularities: Just as for building-like nonbuilding structures, abrupt changes in the distribution of stiffness or strength in a nonbuilding structure not similar to buildings can result in substantially different inertial forces that differ substantially from those indicated by the equivalent lateral force method. Figure C15.1-8 represents one such case. For structures having such configurations, consideration should be given to use of dynamic analysis procedures. Even where dynamic analysis is required, the standard does not define in any detail the degree of modeling; an adequate model may have a few dynamic degrees of freedom or tens of thousands of dynamic degrees of freedom. The important point is that the model captures the significant dynamic response features so that the resulting lateral force distribution is valid for design. The designer is responsible to determine whether dynamic analysis is warranted and, if so, the degree of detail required to address adequately the seismic performance.

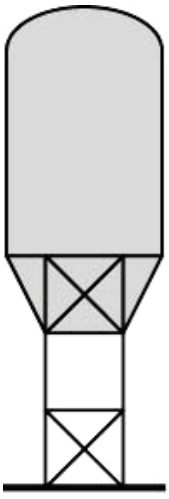

Figure C15.1-8 Soft-story irregularity.

7. Coupled Response: Where the weight of the supported structure is large compared to the weight of the supporting structure, the combined response can be affected significantly by the flexibility of the supported nonbuilding structure. In that case, dynamic analysis of the coupled system is recommended. Examples of such structures are shown in Figure C15.1-9. Part (a) shows a flexible nonbuilding structure with W_p greater than $0.25(W_s + W_p)$, supported by a relatively flexible structure; the flexibility of the supports and attachments should be considered. Part (b) shows flexible equipment connected by a large-diameter, thick-walled pipe and supported by a flexible structure; the structures should be modeled as a coupled system including the pipe.

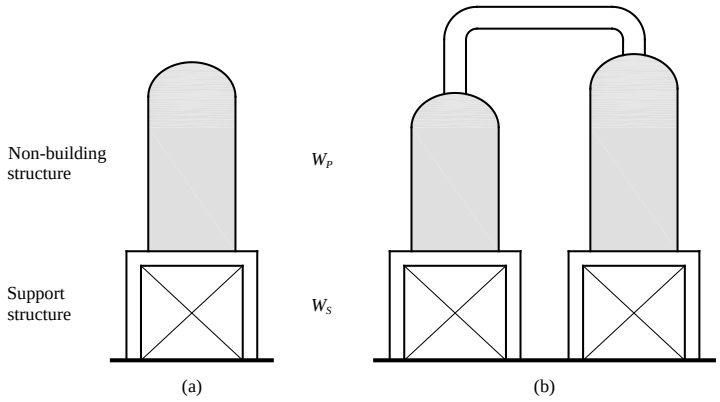

Figure C15.1-9 Coupled system.

C15.2 REFERENCE DOCUMENTS

Chapter 15 of the standard makes extensive use of reference documents in the design of nonbuilding structures for seismic forces. The documents referenced in Chapter 15 are industry documents commonly used to design specific types of nonbuilding structures. The vast majority of these reference documents contain seismic provisions that are based on the seismic ground motions of the 1997 UBC or earlier editions of the UBC. In order to use these reference documents, Chapter 15 modifies the seismic force provisions of these reference documents through the use of "bridging equations." The standard only modifies industry documents that specify seismic demand and capacity. The bridging equations are intended to be used directly with the other provisions of the specific reference documents. Unlike the other provisions of the standard, if the reference documents are written terms of allowable stress design, then the bridging equations are shown in allowable stress design format. In addition, the detailing requirements referenced in Tables 15.4-1 and Table 15.4-2 must be followed, as well as the general requirements found in Section 15.4.1. The usage of reference documents in conjunction with the requirements of Section 15.4.1 are summarized below in Table C15.2-1.

Table C15.2-1 Usage of Reference Documents in Conjunction with Section 15.4.1

Subject	Requirement
R, Ω_0, and C_d values, detailing requirements, and height limits	Use values and limits in Tables 12.2-1, 15.4-1, or 15.4-2 as appropriate. Values from the reference document are not to be used.
Minimum base shear	Use the appropriate value from Equation 15.4-1 or 15.4-2 for nonbuilding structures not similar to buildings. For structures containing liquids, gases, and granular solids supported at the base, the minimum seismic force cannot be less than that required by the reference document.
Importance factor	Use the value from Section 15.4.1.1 based on Occupancy Category. Importance factors from the reference document are not to be used unless they are greater than those provided in the standard.
Vertical distribution of lateral load	Use requirements of Section 12.8.3 or Section 12.9 or the applicable reference document.
Seismic provisions of reference documents	The seismic force provisions of reference documents may be used only if they have the same basis as Section 11.4 and the resulting values for total lateral force and total overturning moment are no less than 80 percent of the values obtained from the standard.
Load combinations	Load combinations specified in Section 2.3 (LRFD) or Section 15 (includes ASD load combinations of Section 2.4) must be used.

Currently, only two reference documents have been revised to meet the seismic requirements of the standard. AWWA D100-05 and API 650 10th Edition Addendum 4 (2005) have been adopted by reference in the standard without modification except that height limits are imposed on "elevated tanks on symmetrically braced legs (not similar to buildings)" in AWWA D100-05. Both of these reference documents apply to welded steel liquid storage tanks.

C15.3 NONBUILDING STRUCTURES SUPPORTED BY OTHER SRUCTURES

There are instances where nonbuilding structures not similar to buildings are supported by other structures or other nonbuilding structures. This section specifies how the seismic design loads for such structures are to be determined and the detailing requirements that are to be satisfied in the design.

C15.3.1 Less than 25 Percent of Combined Weight Condition. In many instances, the weight of the supported nonbuilding structure is relatively small compared to the weight of the supporting structure such that the supported nonbuilding structure will have a relatively small effect on the overall nonlinear earthquake response of the primary structure during design-level ground motions. It is permitted to treat such structures as nonstructural components and use the requirements of Chapter 13 for their design. The ratio of secondary component weight to total weight of 25 percent at which this treatment is permitted is based on judgment and was introduced into code provisions in the 1988 *Uniform Building Code* by the SEAOC Seismology Committee. Analytical studies, typically based on linear elastic primary and secondary structures, indicate that the ratio should be lower, but the SEAOC Seismology Committee judged that the 25 percent ratio is appropriate where primary and secondary structures exhibit non-linear behavior that tends to lessen the effects of resonance and interaction. In cases where a nonbuilding structures (or nonstructural component) is supported by another structure, it may be appropriate to analyze in a single model. In such cases it is intended that seismic design loads and detailing requirements be determined following the procedures of Section 15.3.2. Where there are multiple large nonbuilding structures, such as vessels supported on a primary nonbuilding structure, and the weight of an individual supported nonbuilding structure does not exceed the 25 percent limit but the combined weight of the supported nonbuilding structures does, it is recommended that the combined analysis and design approach of Section 15.3.2 be used. It is also suggested that dynamic analysis be performed in such cases, since the equivalent lateral force procedure may not capture some important response effects in some members of the supporting structure.

Where the weight of the supported nonbuilding structure does not exceed the 25 percent limit and a combined analysis is performed, the following procedure should be used to determine the F_p force of the supported nonbuilding structure based on Equation 13.3-4:

1. A modal analysis should be performed in accordance with Section 12.9. The base shear of the combined structure and nonbuilding structure should be taken as no less than 85 percent of the equivalent lateral force procedure base shear.
2. For a component supported at level *i*, the acceleration at that level should be taken as a_i, the total shear just below level *i* divided by the seismic weight at and above level *i*.
3. The elastic value of the component shear force coefficient should next be determined as the shear force from the modal analysis at the point of attachment of the component to the structure divided by the weight of the component. This value is preliminarily taken as $a_i a_p$. Since a_p cannot be taken as less than 1.0, the value of a_p is taken as $a_i a_p$ / a_i, except that the final value a_p need not be taken as greater than 2.5 and should not be taken as less than 1.0. The final value of $a_i a_p$ should be the final value of a_i determined in Step 2 multiplied by the final value of a_p determined earlier in this step.
4. The resulting value of ($a_i a_p$) should be used in Equation 13.3-4; the resulting value of F_p is subject to the maximum and minimum values of Equations 13.3-2 and 13.3-3, respectively.

C15.3.2 Greater Than or Equal to 25 Percent Combined Weight Condition. Where the weight of the supported structure is relatively large compared to the weight of the supporting structure, the overall response can be affected significantly. The standard sets forth two analysis approaches, depending on the rigidity of the nonbuilding structure. The determination of what is deemed rigid or flexible is based on the same criteria used for nonstructural components.

Where the supported nonbuilding structure is rigid, it is acceptable to treat the supporting structure as a nonbuilding structure similar to a building and to determine its design loads and detailing using the requirements of Section 15.5. The design of the rigid nonbuilding structure and its anchorage is determined using the requirements of Chapter 13 with the amplification factor, a_p, taken as 1.0. However, this is a relatively rare condition since the flexibility of any directly supporting members in the primary structure, such as floor beams, must be considered in determining the period of the component.

In the usual case, where the supported nonbuilding structure is flexible, a combined model of the supporting structure and the supported nonbuilding structure is used. The design loads and detailing are determined based on the lower *R* value of the supported nonbuilding structure or supporting structure.

Although not specifically mentioned in Section 15.3.2, another approach is permitted. A nonlinear response history analysis of the combined system can be performed in accordance with Section 16.2, and the results can be used for the design of both the supported and supporting nonbuilding structures. This option should be considered where standard static and dynamic elastic analysis approaches may be inadequate to evaluate the earthquake response (such as for suspended boilers). This option should be used with extreme caution since modeling and interpretation of results requires considerable judgment. Due to this sensitivity, Section 16.2 requires independent design review.

C15.4 STRUCTURAL DESIGN REQUIREMENTS

This section specifies the basic coefficients and minimum design forces to be used to determine seismic design loads for nonbuilding structures. It also specifies height limits and restrictions. As with building structures, it presumes that the first step in establishing the design forces is to determine the design base shear for the structure.

There are two types of nonbuilding structures: those with structural systems similar to buildings and those with structural systems not similar to buildings. Specific requirements for these two cases appear in Sections 15.5 and 15.6.

C15.4.1 Design Basis. Separate tables are provided in this section that identify the basic coefficients, associated detailing requirements, and height limits and restrictions for the two types of nonbuilding structures.

For nonbuilding structures similar to buildings, the design seismic loads are determined using the same procedures used for buildings as specified in Chapter 12 with two exceptions: fundamental periods are determined in accordance with Section 15.4.4, and Table 15.4-1 provides additional options for structural systems. Although only Section 12.8 (the equivalent lateral force procedure) is specifically mentioned in Section 15.4.1, Section 15.1.3 provides the analysis procedures that are permitted for nonbuilding structures.

In Table 15.4-1, seismic coefficients, system restrictions, and height limits are specified for a few nonbuilding structures similar to buildings. The values of R, Ω_o, and C_d, the detailing requirement references, and the structural system height limits are the same as those in Table 12.2-1 for the same systems, except for ordinary moment frames. In Chapter 12 increased height limits for ordinary moment frames structural systems apply to metal building systems, while in Chapter 15 they apply to pipe racks with end plate bolted moment connections. The seismic performance of pipe racks was judged to be similar to that of metal building structures with end plate bolted moment connections, so the height limits were made the same as those specified in previous editions.

Table 15.4-1 also provides lower R values with less restrictive height limits in Seismic Design Categories D, E, and F based on good performance in past earthquakes. For some options, no seismic detailing is required if very low values of R (and corresponding high seismic design forces) are used. The concept of extending this approach to other structural systems is the subject of future research using the methodology developed by the ATC 63 project.

For nonbuilding structures not similar to buildings, the seismic design loads are determined as in Chapter 12 with three exceptions: the fundamental periods are determined in accordance with Section 15.4.4, the minima are those specified in Section 15.4.1.2, and the seismic coefficients are those specified in Table 15.4-2.

Some entries in Table 15.4-2 may seem to be conflicting or confusing. For example, the first major entry is for elevated tanks, vessels, bins, or hoppers. A subset of this entry is for tanks on braced or unbraced legs. This subentry is intended for structures where the supporting columns are integral with the shell (such as an elevated water tank). Tension-only bracing is allowed for such a structure. Where the tank or vessel is supported by building-like frames, the frames are to be designed in accordance with all of the restrictions normally applied to building frames. The entry for tanks or vessels supported on structural towers similar to buildings assumes that the operating weight of the supported tank or vessel is less than 25 percent of the total weight; if the ratio is greater than 25 percent, the proper entry is that most closely related to the subject vessel or bin.

C15.4.1.1 Importance Factor. The importance factor for a nonbuilding structure is based on the occupancy category defined in Chapter 1 of the standard or the building code being used in conjunction with the standard. In some cases, reference standards provide a higher importance factor, in which case the higher importance factor is used.

If the importance factor is taken as 1.0 based on a Hazard and Operability (HAZOP) analysis performed in accordance with Chapter 1, the third paragraph of Section 1.5.2 requires careful consideration; worst-case scenarios (instantaneous release of a vessel or piping system) must be considered. HAZOP risk analysis consultants often do not make such assumptions, so the design professional should review the HAZOP analysis with the HAZOP consultant to confirm that such assumptions have been made in order to validate adjustment of the importance factor. Clients may not be aware that HAZOP consultants do

not normally consider the worst-case scenario of instantaneous release but tend to focus on other more hypothetical limited-release scenarios, such as those associated with a 2-inch square hole in a tank or vessel.

C15.4.2 Rigid Nonbuilding Structures. The definition of rigid (having a natural period of less than 0.06 second) was selected judgmentally. Below that period, the energy content of seismic ground motion is generally believed to be very low, and therefore the building response is not likely to be excessively amplified. Also, it is unlikely that any building will have a first mode period as low as 0.06 second, and it is even unusual for a second mode period to be that low. Thus, the likelihood of either resonant behavior or excessive amplification becomes quite small for equipment having periods below 0.06 second.

The analysis to determine the period of the nonbuilding structure should include the flexibility of the soil subgrade.

C15.4.3 Loads. As for buildings, the seismic weight must include the range of design operating weight of permanent equipment.

C15.4.4 Fundamental Period. A significant difference between building structures and nonbuilding structures is that the approximate period formulas and limits of Section 12.8.2.1 may not be used for nonbuilding structures. In lieu of calculating a specific period for a nonbuilding structure for determining seismic lateral forces, it is of course conservative to assume a period of T_s (= S_{D1}/S_{DS}) which results in the largest lateral design forces. Computing the fundamental period is not considered a significant burden, since most commonly used computer analysis programs can perform the required calculations.

C15.4.8 Site-Specific Response Spectra. Where site-specific response spectra are required, they should be developed in accordance with Chapter 21 of the standard. If determined for other recurrence intervals, Section 21.1 applies, but Sections 21.2 through 21.4 apply only to MCE determinations. Where other recurrence intervals are used, it should be demonstrated that the requirements of Chapter 15 also are satisfied.

C15.5 NONBUILDING STRUCTURES SIMILAR TO BUILDINGS

C15.5.1 General. Although certain nonbuilding structures exhibit behavior similar to that of building structures, their functions and occupancies are different. Section 15.5 of the standard addresses the differences.

C15.5.2 Pipe Racks. Free-standing pipe racks supported at or below grade with framing systems that are similar to building systems are designed in accordance with Section 12.8 or 12.9 and Section 15.4. Single-column pipe racks that resist lateral loads should be designed as inverted pendulums.

Based on good performance in past earthquakes, Table 15.4-1 sets forth the option of lower *R* values and less restrictive height limits for structural systems commonly used in pipe racks. The *R* value versus height limit trade-off recognizes that the size of some nonbuilding structures is determined by factors other than traditional loadings and results in structures that are much stronger than required for seismic loadings. Therefore, the ductility demand is generally much lower than that for a corresponding building. The intent is to obtain the same structural performance at the increased heights. This option will prove to be economical in most situations due to the relative cost of materials and construction labor. The lower *R* values and increased height limits of Table 15.4-1 apply to nonbuilding structures similar to buildings; they cannot be applied to building structures. Table C15.5-1 illustrates the *R* values and height limits for a 70-foot-high steel ordinary moment frame (OMF) pipe rack.

Table C15.5-1 *R* Value Selection Example for Steel OMF Pipe Racks

SDC	*R*	ASCE/SEI 7-05 Table	System	Seismic Detailing Requirements
C	3.5	12.2-1 or 15.4-1	Ordinary steel moment frame	AISC 341
C	3	12.2-1	Structural steel systems not specifically detailed for seismic resistance	None
D or E	2.5	15.4-1	Steel OMF with permitted height increase	AISC 341 (AISC Seismic)
D, E, or F	1	15.4-1	Steel OMF with unlimited height	None

C15.5.3 Steel Storage Racks. The two approaches to the design of steel storage racks set forth by the standard are intended to produce comparable results.

These recommendations address the concern that storage racks in warehouse-type retail stores may pose a greater seismic risk to the general public than exists in low-occupancy warehouses or more conventional retail environments. Under normal conditions, retail stores have a far higher occupant load than an ordinary warehouse of a comparable size. Failure of a

storage rack system in a retail environment is much more likely to cause personal injury than a similar failure in a storage warehouse. To provide an appropriate level of additional safety in areas open to the public, an importance factor of 1.50 is specified. Storage rack contents, while beyond the scope of the standard, may pose a potentially serious threat to life should they fall from the shelves in an earthquake. It is recommended that restraints be provided, as shown in Figure C15.5-1, to prevent the contents of rack shelving open to the general public from falling during strong ground shaking.

Figure C15.5-1 Merchandise restrained by netting.

C15.5.4 Electrical Power Generating Facilities. Electrical power plants closely resemble building structures, and their performance in seismic events has been good. For reasons of mechanical performance, lateral drift of the structure must be limited. The lateral bracing system of choice has been the concentrically braced frame. In the past, the height limits on braced frames in particular have been an encumbrance to the design of large power generating facilities. Based on acceptable past performance, Table 15.4-1 permits the use of CBRs with both lower *R* values and less restrictive height limits. This option is particularly effective for boiler buildings that generally are 300 feet or more in height. A peculiarity of large boiler buildings is the general practice of suspending the boiler from the roof structures; this results in an unusual mass distribution as discussed in Section C15.1.3.

C15.5.5 Structural Towers for Tanks and Vessels. The requirements of this section apply to structural towers that are not integral with the supported tank. Elevated water tanks designed in accordance with AWWA D100-06 are not subject to Section 15.5.5.

C15.5.6 Piers and Wharves. Current industry practice recognizes the distinct differences between the two categories of piers and wharves described in the standard. Piers and wharves with public occupancy, described in Section 15.5.6.2, are commonly treated as the "foundation" for buildings or building-like structures; design is performed using the standard, likely under the jurisdiction of the local building official. Piers and wharves without occupancy by the general public are often treated differently and are outside the scope of the standard; in many cases, these structures do not fall under the jurisdiction of building officials, and design is performed using other industry-accepted approaches.

Design decisions associated with these structures often reflect economic considerations by both owners and local, regional, or state jurisdictional entities with interest in commercial development. Where building officials have jurisdiction but lack experience analyzing pier and wharf structures, reliance on other industry-accepted design approaches is common.

Where occupancy by the general public is not a consideration, seismic design of structures at major ports and marine terminals often uses a performance-based approach, with criteria and methods that are very different from those used for buildings, as provided in the standard. Design approaches most commonly used are generally consistent with the practices and criteria described in the following documents:

1. *Seismic Design Guidelines for Port Structures*, Working Group No. 34 of the Maritime Navigation Commission (PIANC/MarCom/WG34), A. A. Balkema, Lisse, Netherlands, 2001.
2. *Seismic Criteria for California Marine Oil Terminals*, Vol. 1 and Vol. 2, Technical Report TR-2103-SHR, Naval Facilities Engineering Service Center, Ferritto, J., Dickenson, S., Priestley N., Werner, S., Taylor, C., Burke D., Seelig

W., and Kelly, S., Port Hueneme, CA, 1999.

3. *Seismic Design and Retrofit of Bridges*, Priestley, N.J.N., Siebel, F., and Calvi, G.M., New York, 1996.
4. *Seismic Guidelines for Ports*, by the Ports Committee of the Technical Council on Lifeline Earthquake Engineering, ASCE/SEI, edited by Stuart D. Werner, Monograph No. 12, published by ASCE, Reston, Virginia, March 1998.
5. *MOTEMS, 2005, "Marine Oil Terminal Engineering and Maintenance Standards"*, 2001 Title 24, Part 2, California Building Code, Chapter 31F, January 31, 2005.

These alternative approaches have been developed over a period of many years by working groups within the industry, and they reflect the historical experience and performance characteristics of these structures, which are very different from those of building structures.

The main emphasis of the performance-based design approach is to provide criteria and methods that depend on the economic importance of a facility. Adherence to the performance criteria in the documents listed above does not seek to provide uniform margins of collapse for all structures; their application is expected to provide at least as much inherent life-safety as for buildings designed using the standard. The reasons for the higher inherent level of life-safety for these structures include the following:

1. These structures have relatively infrequent occupancy, with few working personnel and very low density of personnel. Most of these structures consist primarily of open area, with no enclosed structures that can collapse onto personnel. Small control buildings on marine oil terminals or similar secondary structures are commonly designed in accordance with the local building code.
2. These pier or wharf structures typically are constructed of reinforced concrete, prestressed concrete, or steel and are highly redundant due to the large number of piles supporting a single wharf deck unit. Tests done at the University of California at San Diego for the Port of Los Angeles have shown that very high ductilities (10 or more) can be achieved in the design of these structures using practices currently employed in California ports.
3. Container cranes, loading arms, and other major structures or equipment on piers or wharves are specifically designed not to collapse in an earthquake. Typically, additional piles and structural members are incorporated into the wharf or pier specifically to support such items.
4. Experience has shown that seismic "failure" of wharf structures in zones of strong seismicity is indicated not by collapse but by economically irreparable deformations of the piles. The wharf deck generally remains level or slightly tilting, but has shifted out of position. Complete failure that could endanger life-safety due to earthquake loading has never occurred historically where the structure in the marine environment has been maintained properly.
5. The performance-based criteria of the listed documents address reparability of the structure, which is much more stringent criteria than collapse prevention and results in a greater margin for life-safety.

Lateral load design of these structures in low, or even moderate, seismic regions often is governed by other marine conditions.

C15.6 GENERAL REQUIREMENTS FOR NONBUILDING STRUCTURES NOT SIMILAR TO BUILDINGS

Nonbuilding structures not similar to buildings exhibit behavior markedly different from that of building structures. Most of these types of structures have reference documents that address their unique structural performance and behavior. The ground motion in the standard requires appropriate translation to allow use with industry standards.

C15.6.1 Earth-Retaining Structures. Section C11.8.3 presents commonly used approaches for the design of nonyielding walls and yielding walls for bending, overturning, sliding, etc., taking into account the varying soil types, importance, and site seismicity.

C15.6.2 Stacks and Chimneys. The design of stacks and chimneys to resist natural hazards generally is governed by wind design considerations. The exceptions to this general rule involve locations with high seismicity, stacks and chimneys with large elevated masses, and stacks and chimneys with unusual geometries. It is prudent to evaluate the effect of seismic loads in all but those areas with the lowest seismicity. Although not specifically required, it is recommended that the special seismic details required elsewhere in the standard be considered for application to stacks and chimneys.

Guyed steel stacks and chimneys generally are lightweight. As a result, the design loads due to natural hazards generally are governed by wind. On occasion, large flares or other elevated masses located near the top may require in-depth seismic analysis. Although it does not specifically address seismic loading, Chapter 6 of Troitsky (1982) provides a methodology appropriate for resolution of the seismic forces defined in the standard.

C15.6.4 Special Hydraulic Structures. The most common special hydraulic structures are baffle walls and weirs that are used in water treatment and waste water treatment plants. Because there are openings in the walls, during normal operations the fluid levels are equal on each side of the wall, exerting no net horizontal force. Sloshing during a seismic event can exert large forces on the wall, as illustrated in Figure C15.6-1. The walls can fail unless they are designed properly to resist the dynamic fluid forces.

C15.6.5 Secondary Containment Systems. This section reflects the judgment that designing all impoundment dikes for the MCE ground motion when full and sizing all impoundment dikes for the sloshing wave is too conservative. Designing an impoundment dike as full for the MCE assumes failure of the primary containment and occurrence of a significant aftershock. Such significant aftershocks (of the same magnitude as the MCE ground motion) are rare and do not occur in all locations. While explicit design for aftershocks is not a requirement of the standard, secondary containment must be designed full for an aftershock to protect the general public. The use of two-thirds of the MCE ground motion as the magnitude of the design aftershock is supported by Bath's Law, according to which the maximum expected aftershock magnitude may be estimated to be 1.2 scale units below the main shock magnitude.

The risk assessment and risk management plan described in Section 1.5.2 are used to determine where the secondary containment must be designed full for the MCE. The decision to design secondary containment for this more severe condition should be based on the likelihood of a significant aftershock occurring at the particular site, considering the risk posed to the general public by the release of hazardous material from the secondary containment.

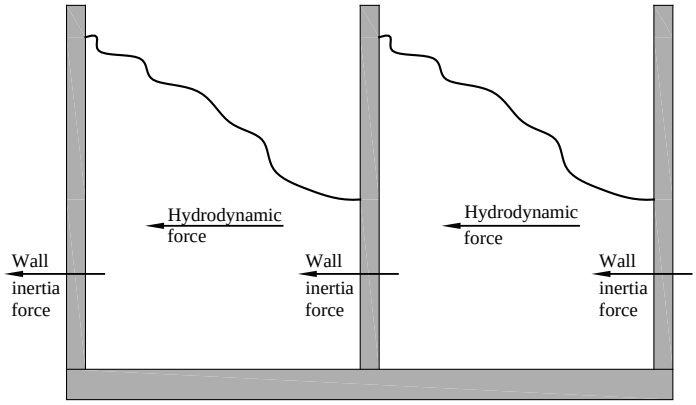

Figure C15.6-1 Wall forces.

Secondary containment systems must be designed to contain the sloshing wave where the release of liquid would place the general public at risk by exposing them to hazardous materials, by scouring of foundations of adjacent structures, or by causing other damage to adjacent structures.

C15.6.6 Telecommunication Towers. Telecommunication towers support small masses, and their design generally is governed by wind forces. Although telecommunication towers have a history of experiencing seismic events without failure or significant damage, seismic design in accordance with the standard is required.

Typically bracing elements bolt directly (without gusset plates) to the tower legs, which consist of pipes or bent plates in a triangular plan configuration.

C15.7 TANKS AND VESSELS

C15.7.1 General. Methods for seismic design of tanks, currently adopted by a number of reference documents, have evolved from earlier analytical work by Jacobsen, Housner, Veletsos, Haroun, and others. The procedures used to design flat-bottom storage tanks and liquid containers are based on the work of Housner, Wozniak, and Mitchell. The reference documents for tanks and vessels have specific requirements to safeguard against catastrophic failure of the primary structure based on observed behavior in seismic events since the 1930s. Other methods of analysis, using flexible shell models, have been proposed but at present are beyond the scope of the standard.

The industry-accepted design methods employ three basic steps:

1. Dynamic modeling of the structure and its contents. When a liquid-filled tank is subjected to ground acceleration, the lower portion of the contained liquid, identified as the impulsive component of mass, W_i, acts as if it were a solid mass

rigidly attached to the tank wall. As this mass accelerates, it exerts a horizontal force, P_i, on the wall; this force is directly proportional to the maximum acceleration of the tank base. This force is superimposed on the inertia force of the accelerating wall itself, P_s. Under the influence of the same ground acceleration, the upper portion of the contained liquid responds as if it were a solid mass flexibly attached to the tank wall. This portion, which oscillates at its own natural frequency, is identified as the convective component, W_c, and exerts a horizontal force, P_c, on the wall. The convective component oscillations are characterized by sloshing whereby the liquid surface rises above the static level on one side of the tank and drops below that level on the other side.

2. Determination of the period of vibration, T_i, of the tank structure and the impulsive component; and determination of the natural period of oscillation (sloshing), T_c, of the convective component.
3. Selection of the design response spectrum. The response spectrum may be site-specific or it may be constructed on the basis of seismic coefficients given in national codes and standards. Once the design response spectrum is constructed, the spectral accelerations corresponding to T_i and T_c are obtained and are used to calculate the dynamic forces P_i, P_s, and P_c.

Detailed guidelines for the seismic design of circular tanks, incorporating these concepts to varying degrees, have been the province of at least four industry reference documents: AWWA D100 for welded steel tanks (since 1964); API 650 for petroleum storage tanks; AWWA D110 for prestressed, wire-wrapped tanks (since 1986); and AWWA D115 for prestressed concrete tanks stressed with tendons (since 1995). In addition, API 650 and API 620 contain provisions for petroleum, petrochemical, and cryogenic storage tanks. The detail and rigor of analysis prescribed in these documents have evolved from a semi-static approach in the early editions to a more rigorous approach at present, reflecting the need to include the dynamic properties of these structures.

The requirements in Section 15.7 are intended to link the latest procedures for determining design-level seismic loads with the allowable stress design procedures based on the methods in the standard. These requirements, which in many cases identify specific substitutions to be made in the design equations of the reference documents, will assist users of the standard in making consistent interpretations.

ACI has published ACI 350.3-01, "*Seismic Design of Liquid-Containing Concrete Structures.*" This document, which addresses all types of concrete tanks (prestressed and non-prestressed, circular and rectilinear), has provisions that are consistent with the seismic criteria of the 2000 *Provisions.* The document serves as both a practical "ho-to" loading reference and a guide to supplement application of ACI 318 Chapter 21.

C15.7.2 Design Basis. In the case of the seismic design of nonbuilding structures, standardization requires adjustments to industry reference documents to minimize existing inconsistencies among them, while recognizing that structures designed and built over the years in accordance with these documents have performed well in earthquakes of varying severity. Of the inconsistencies among reference documents, the ones most important to seismic design relate to the base shear equation. The traditional base shear takes the following form:

$$V = \frac{ZIS}{R_w} CW \qquad \text{(C15.7-1)}$$

An examination of those terms as used in the different references reveals the following:

1. *ZS:* The seismic zone coefficient, *Z*, has been rather consistent among all the documents since it usually has been obtained from the seismic zone designations and maps in the model building codes. On the other hand, the soil profile coefficient, *S*, does vary from one document to another. In some documents these two terms are combined.
2. *I*: The importance factor, *I*, has varied from one document to another, but this variation is unavoidable and understandable owing to the multitude of uses and degrees of importance of tanks and vessels.
3. *C:* The coefficient *C* represents the dynamic amplification factor that defines the shape of the design response spectrum for any given ground acceleration. Since *C* is primarily a function of the frequency of vibration, inconsistencies in its derivation from one document to another stem from at least two sources: differences in the equations for the determination of the natural frequency of vibration, and differences in the equation for the coefficient itself. (For example, for the shell/impulsive liquid component of lateral force, the steel tank documents use a constant design spectral acceleration [constant *C*] that is independent of the "impulsive" period, *T*.) In addition, the value of *C* will vary depending on the damping ratio assumed for the vibrating structure (usually between 2 percent and 7 percent of critical).
4. Where a site-specific response spectrum is available, calculation of the coefficient *C* is not necessary except in the case of the convective component (coefficient C_c) which is assumed to oscillate with 0.5 percent of critical damping and whose period of oscillation is usually long (greater than 2.5 seconds). Since site-specific spectra are usually constructed for high damping values (3 percent to 7 percent of critical) and since the site-specific spectral profile may not be well-

defined in the long-period range, an equation for C_c applicable to a 0.5 percent damping ratio is necessary in order to calculate the convective component of the seismic force.

5. R_w: The response modification factor, R_w, is perhaps the most difficult to quantify, for a number of reasons. While R_w is a compound coefficient that is supposed to reflect the ductility, energy-dissipating capacity, and redundancy of the structure, it is also influenced by serviceability considerations, particularly in the case of liquid-containing structures.

In the standard the base shear equation for most structures has been reduced to $V = C_s W$, where the seismic response coefficient, C_s, replaces the product ZSC/R_w. C_s is determined from the design spectral response acceleration parameters S_{DS} and S_{D1} (at short periods and at a period of 1, respectively) which, in turn, are obtained from the mapped MCE spectral accelerations S_s and S_1. As in the case of the prevailing industry reference documents, where a site-specific response spectrum is available, C_s is replaced by the actual values of that spectrum.

The standard contains several bridging equations, each designed to allow proper application of the design criteria of a particular reference document in the context of the standard. These bridging equations associated with particular types of liquid-containing structures and the corresponding reference documents are discussed below. Calculation of the periods of vibration of the impulsive and convective components is in accordance with the reference documents, and the detailed resistance and allowable stresses for structural elements of each industry structure are unchanged, except where new information has led to additional requirements.

It is expected that the bridging equations of Sections 15.7.7.3 and 15.7.10.7 will be eliminated as the relevant reference documents are updated to conform to the standard. The bridging equations previously provided for AWWA D100 and API 650 already have been eliminated as a result of updates of these documents.

C15.7.3 Strength and Ductility. As is the case for building structures, ductility and redundancy in the lateral support systems for tanks and vessels are desirable and necessary for good seismic performance. Tanks and vessels are not highly redundant structural systems, and therefore ductile materials and well-designed connection details are needed to increase the capacity of the vessel to absorb more energy without failure. The critical performance of many tanks and vessels is governed by shell stability requirements rather than by yielding of the structural elements. For example, contrary to building structures, ductile stretching of anchor bolts is a desirable energy absorption component where tanks and vessels are anchored. The performance of cross-braced towers is highly dependent on the ability of the horizontal compression struts and connection details to develop fully the tension yielding in the rods. In such cases, it is also important to preclude both premature failure in the threaded portion of the connection and failure of the connection of the rod to the column prior to yielding of the rod.

C15.7.4 Flexibility of Piping Attachments. Poor performance of piping connections (tank leakage and damage) due to seismic deformations is a primary weakness observed in recent seismic events. While commonly used piping connections can impart mechanical loads to the tank shell, proper design in seismic areas results in only negligible mechanical loads on tank connections subject to the displacements shown in Table 15.7-1. API 650 treats the values shown in Table 15.7-1 as allowable stress based values and therefore requires that these values be multiplied by 1.4 where strength-based capacity values are required for design.

In addition, interconnected equipment, walkways, and bridging between multiple tanks must be designed to resist the loads and accommodate the displacements imposed by seismic forces. Unless connected tanks and vessels are founded on a common rigid foundation, the calculated differential movements must be assumed to be out of phase.

C15.7.5 Anchorage. Many steel tanks can be designed without anchors by using annular plate detailing in accordance with reference documents. Where tanks must be anchored due to overturning potential, proper anchorage design will provide both a shell attachment and an embedment detail that will yield the bolt without tearing the shell or pulling the bolt out of the foundation. Properly designed anchored tanks have greater reserve strength to resist seismic overload than do unanchored tanks.

Where anchor bolts and attachments are misaligned such that the anchor nut or washer does not bear evenly on the attachment, additional bending stresses in threaded areas may cause premature failure before anchor yielding.

C15.7.6 Ground-Supported Storage Tanks for Liquids

C15.7.6.1 General. The response of ground storage tanks to earthquakes is well documented by Housner, Mitchell and Wozniak, Veletsos, and others. Unlike building structures, the structural response of these tanks is influenced strongly by the fluid-structure interaction. Fluid-structure interaction forces are categorized as sloshing (convective) and rigid (impulsive) forces. The proportion of these forces depends on the geometry (height-to-diameter ratio) of the tank. API 650, API 620, AWWA D100, AWWA D110, AWWA D115, and ACI 350.3 provide the data necessary to determine the relative masses and moments for each of these contributions.

The standard requires that these structures be designed in accordance with the prevailing reference documents, except that the height of the sloshing wave, δ_s, must be calculated using Equations 15.7-13. Note that API 650 and AWWA D100 include this requirement in their latest editions.

Equations 15.7-10 and 15.7-11 provide the spectral acceleration of the sloshing liquid for the constant-velocity and constant-displacement regions of the response spectrum, respectively. The 1.5 factor in these equations is an adjustment for 0.5 percent damping.

Small-diameter tanks and vessels are more susceptible to overturning and vertical buckling. As a general rule, a greater ratio of *H*/*D* produces lower resistance to vertical buckling. Where *H*/*D* is greater than 2, overturning approaches "rigid mass" behavior (the sloshing mass is small). Large-diameter tanks may be governed by additional hydrodynamic hoop stresses in the middle regions of the shell.

The impulsive period (the natural period of the tank components and the impulsive component of the liquid) is typically in the 0.25 to 0.6 second range. Many methods are available for calculating the impulsive period. The Veletsos flexible-shell method is commonly used by many tank designers. For example, see Velestos (1974) and Malhotra, Wenk, and Wieland (2000).

C15.7.6.1.1 Distribution of Hydrodynamic and Inertia Forces. Most of the reference documents for tanks define reaction loads at the base of shell-foundation interface, without indicating the distribution of loads on the shell as a function of height. ACI 350.3 specifies the vertical and horizontal distribution of such loads.

The overturning moment at the base of the shell in the industry reference documents is only the portion of the moment that is transferred to the shell. The total overturning moment also includes the variation in bottom pressure, which is an important consideration for design of pile caps, slabs, or other support elements that must resist the total overturning moment. Wozniak and Mitchell (1978) and TID 7024 (1963) provide additional information.

C15.7.6.1.2 Sloshing. In past earthquakes, sloshing contents in ground storage tanks has caused both leakage and non-catastrophic damage to the roof and internal components. Even this limited damage, and the associated costs and inconvenience, can be significantly mitigated where the following items are considered:

1. Effective masses and hydrodynamic forces in the container.
2. Impulsive and pressure loads at
    a. The sloshing zone (that is, the upper shell and edge of the roof system),
    b. The internal supports (such as roof support columns and tray-supports), and
    c. The internal equipment (such as distribution rings, access tubes, pump wells, and risers).
3. Freeboard (which depends on the sloshing wave height).

A minimum freeboard of $0.7\delta_s$ is recommended for economic considerations but is not required.

Tanks and vessels storing biologically or environmentally benign materials typically do not require freeboard to protect the public health and safety. However, providing freeboard in areas of frequent seismic occurrence for vessels normally operated at or near top capacity may lessen damage (and the cost of subsequent repairs) to the roof and upper container.

The sloshing wave height specified in Section 15.7.6.1.2 is based on the design earthquake defined in the standard. For economic reasons, freeboard for tanks assigned to Occupancy Category I, II, or III may be calculated using a fixed value of T_L equal to 4 seconds (as indicated in Section 15.7.6.1, Note d) but using the appropriate importance factor taken from Table 11.5-1. Due to life-safety concerns, freeboard for tanks assigned to Occupancy Category IV must be based on the mapped value of T_L. Because use of the mapped value of T_L results in the theoretical maximum value of freeboard, the calculation of freeboard in the case of Occupancy Category IV tanks is based on an importance factor equal to 1.0 (as indicated in Section 15.7.6.1, Note c).

If the freeboard provided is less than the computed sloshing height, δ_s, the sloshing liquid will impinge on the roof in the vicinity of the roof-to-wall joint, subjecting it to a hydrodynamic force. This force may be approximated by considering the sloshing wave as a hypothetical static liquid column having a height, δ_s. The pressure exerted at any point along the roof at a distance y_s above the at-rest surface of the stored liquid may be assumed equal to the hydrostatic pressure exerted by the hypothetical liquid column at a distance $\delta_s - y_s$ from the top of that column. A better approximation of the pressure exerted on the roof is found in Malhotra (2005 and 2006).

Another effect of a less-than-full freeboard is that the restricted convective (sloshing) mass "converts" into an impulsive mass thus increasing the impulsive forces. This effect should be taken into account in the tank design. A method for converting the

restricted convective mass into an impulsive mass is found in Malhotra (2005 and 2006). It is recommended that sufficient freeboard to accommodate the full sloshing height be provided wherever possible.

C15.7.6.1.4 Internal Components. Wozniak and Mitchell (1978) provides a recognized analysis method for determining the lateral loads on internal components due to sloshing liquid.

C15.7.6.1.5 Sliding Resistance. Historically, steel ground-supported tanks full of product have not slid off foundations. A few unanchored, empty tanks or bulk storage tanks without steel bottoms have moved laterally during earthquake ground shaking. In most cases, these tanks may be returned to their proper locations. Resistance to sliding is obtained from the frictional resistance between the steel bottom and the sand cushion on which bottoms are placed. Because tank bottoms usually are crowned upward toward the tank center and are constructed of overlapping, fillet-welded, individual steel plates (resulting in a rough bottom), it is reasonably conservative to take the ultimate coefficient of friction as 0.70 (AISC, 1986), and therefore a value of tan 30^o (= 0.577) is used in design. The value of 30^o represents the internal angle of friction of sand. The vertical weight of the tank and contents, as reduced by the component of vertical acceleration, provides the net vertical load. An orthogonal combination of vertical and horizontal seismic forces, following the procedure in Section 12.5.3, may be used.

C15.7.6.1.6 Local Shear Transfer. The transfer of seismic shear from the roof to the shell and from the shell to the base is accomplished by a combination of membrane shear and radial shear in the wall of the tank. For steel tanks, the radial (out-of-plane) seismic shear is very small and usually is neglected; thus, the shear is assumed to be resisted totally by membrane (in-plane) shear. For concrete walls and shells, which have a greater radial shear stiffness, the shear transfer may be shared. The ACI 350.3 commentary provides further discussion.

C15.7.6.1.7 Pressure Stability. Internal pressure may increase the critical buckling capacity of a shell. Provision to include pressure stability in determining the buckling resistance of the shell for overturning loads is included in AWWA D100. Recent testing on conical and cylindrical shells with internal pressure yielded a design methodology for resisting permanent loads in addition to temporary wind and seismic loads. See Miller, Meier, and Czaska (1997).

C15.7.6.1.8 Shell Support. Anchored steel tanks should be shimmed and grouted to provide proper support for the shell and to reduce impact on the anchor bolts under reversible loads. The high bearing pressures on the toe of the tank shell may cause inelastic deformations in compressible material (such as fiberboard), creating a gap between the anchor and the attachment. As the load reverses, the bolt is no longer snug and an impact of the attachment on the anchor can occur. Grout is a structural element and should be installed and inspected as an important part of the vertical- and lateral-force-resisting system.

C15.7.6.1.9 Repair, Alteration, or Reconstruction. During their service life, storage tanks are frequently repaired, modified, or relocated. Repairs often are related to corrosion, improper operation, or overload from wind or seismic events. Modifications are made for changes in service, updates to safety equipment for changing regulations, or installation of additional process piping connections. It is imperative these repairs and modifications be designed and implemented properly to maintain the structural integrity of the tank or vessel for seismic loads as well as the design operating loads.

The petroleum steel tank industry has developed specific guidelines in API 653 that are statutory requirements in some states. It is recommended that the provisions of API 653 also be applied to other liquid storage tanks (water, wastewater, chemical, etc.) as it relates to repairs, modifications, or relocation that affects the pressure boundary or lateral force-resisting system of the tank or vessel.

C15.7.7 Water Storage and Water Treatment Tanks and Vessels. The AWWA design requirements for ground-supported steel water storage structures use allowable stress design procedures that conform to the requirements of the standard.

C15.7.8 Petrochemical and Industrial Tanks and Vessels Storing Liquids

C15.7.8.1 Welded Steel. The American Petroleum Institute (API) uses an allowable stress design procedure that conforms to the requirements of the standard.

The most common damage to tanks observed during past earthquakes includes the following:

1. Buckling of the tank shell near the base due to excessive axial membrane forces. This buckling damage is usually evident as “elephant foot” buckles a short distance above the base or as diamond-shaped buckles in the lower ring. Buckling of the upper ring also has been observed.
2. Damage to the roof due to impingement on the underside of the roof of sloshing liquid with insufficient freeboard.
3. Failure of piping or other attachments that are overly restrained.
4. Foundation failures.

Other than the above damage, the seismic performance of floating roofs during earthquakes has generally been good, with damage usually confined to the rim seals, gage poles, and ladders. However, floating roofs have sunk in some earthquakes due to lack of adequate freeboard or the proper buoyancy and strength required by API 650. Similarly the performance of open tops with top wind girder stiffeners designed per API 650 has been generally good.

C15.7.8.2 Bolted Steel. Bolted steel tanks are often used for temporary functions. Where use is temporary, it may be acceptable to the jurisdictional authority to design bolted steel tanks for no seismic loads or for reduced seismic loads based on a reduced return period. For such reduced loads based on reduced exposure time, the owner should include a signed removal contract with the fixed removal date as part of the submittal to the authority having jurisdiction.

C15.7.9 Ground-Supported Storage Tanks for Granular Materials

C15.7.9.1 General. The response of a ground-supported storage tank storing granular materials to a seismic event is highly dependent on its height-to-diameter (*H*/*D*) ratio and the characteristics of the stored product. The effects of intergranular friction are described in more detail in C15.7.9.3.1 (increased lateral pressure), C15.7.9.3.2 (effective mass), and C15.7.9.3.3 (effective density).

Long-term increases in shell hoop tension due to temperature changes after the product has been compacted also must be included in the analysis of the shell; Anderson (1966) provides a suitable method.

C15.7.9.2 Lateral Force Determination. Seismic forces acting on ground-supported liquid storage tanks are divided between impulsive and convective (sloshing) components. However, in a ground-supported storage tank for granular materials, all seismic forces are of the impulsive type and relate to the period of the storage tank itself. Due to the relatively short period of a tank shell, the response is normally in the constant acceleration region of the response spectrum, which relates to S_{DS}. Therefore, the seismic base shear is calculated as follows:

$$V = \frac{S_{DS}}{\left(\frac{R}{I}\right)} W_{Effective} \qquad \text{(C15.7-2)}$$

where V, S_{DS}, I, and R have been previously defined, and $W_{Effective}$ is the gross weight of the stored product multiplied by an effective mass factor and an effective density factor, as described in Sections C15.7.9.3.2 and C15.7.9.3.3, plus the dead weight of the tank. Unless substantiated by testing, it is recommended that the product of the effective mass factor and the effective density factor be taken as no less than 0.5 due to the limited test data and the highly variable properties of the stored product.

C15.7.9.3 Force Distribution to Shell and Foundation

C15.7.9.3.1 Increased Lateral Pressure. In a ground-supported tank storing granular materials, increased lateral pressures develop as a result of rigid body forces that are proportional to ground acceleration. Information concerning design for such pressure is scarce. Trahair et al. (1983) describes both a very simple, conservative method and a very difficult, analytical method using failure wedges based on the Mononobe-Okabe modifications of the classical Coulomb method.

C15.7.9.3.2 Effective Mass. For ground-supported tanks storing granular materials, much of the lateral seismic load can be transferred directly into the foundation, via intergranular shear, before it can reach the tank shell. The effective mass that loads the tank shell is highly dependent on the *H*/*D* ratio of the tank and the characteristics of the stored product. Quantitative information concerning this effect is scarce, but Trahair et al. (1983) describes a very simple, conservative method to determine the effective mass. That method presents reductions in effective mass, which may be significant, for *H*/*D* ratios less than 2. This effect is absent for elevated tanks.

C15.7.9.3.3 Effective Density. Granular material stored in tanks (both ground-supported and elevated) does not behave as a solid mass. Energy loss through intergranular movement and grain-to-grain friction in the stored material effectively reduces the mass subject to horizontal acceleration. This effect may be quantified by an effective density factor less than 1.0.

Based on Chandrasekaran and Jain (1968) and on shake-table tests reported in Chandrasekaran et al. (1968), ACI 313 recommends an effective density factor of not less than 0.8 for most granular materials. According to Chandrasekaran and Jain (1968), an effective density factor of 0.9 is more appropriate for materials with high moduli of elasticity, such as aggregates and metal ores.

C15.7.9.3.4 Lateral Sliding. Most ground-supported steel storage tanks for granular materials rest on a base ring and do not have a steel bottom. To resist seismic base shear, a partial bottom or annular plate is used in combination with anchor bolts or a curb angle. An annular plate can be used alone to resist the seismic base shear through friction between the plate and the foundation, in which case the friction limits of Section 15.7.6.1.5 apply. The curb angle detail serves to keep the base of the

shell round while allowing it to move and flex under seismic load. Various base details are shown in Figure 13 of Kaups and Lieb (1985).

C15.7.9.3.5 Combined Anchorage Systems. This section is intended to apply to combined anchorage systems that share loads based on their relative stiffnesses, and not to systems where sliding is resisted completely by one system (such as a steel annular plate) and overturning is resisted completely by another system (such as anchor bolts).

C15.7.10 Elevated Tanks and Vessels for Liquids and Granular Materials

C15.7.10.1 General. The three basic lateral load-resisting systems for elevated water tanks are defined by their support structure:

1. Multi-leg braced steel tanks (trussed towers, as shown in Figure C15.7-1),
2. Small-diameter single-pedestal steel tanks (cantilever columns, as shown in Figure C15.7-2), and
3. Large-diameter single-pedestal tanks of steel or concrete construction (load-bearing shear walls, as shown in Figure C15.7-3).

Unbraced multi-leg tanks are uncommon. These types of tanks differ in their behavior, redundancy, and resistance to overload. Multi-leg and small-diameter pedestal tanks have longer fundamental periods (typically greater than 2 seconds) than the shear wall type tanks (typically less than 2 seconds). The lateral load failure mechanisms usually are brace failure for multi-leg tanks, compression buckling for small-diameter steel tanks, compression or shear buckling for large-diameter steel tanks, and shear failure for large-diameter concrete tanks. Connection, welding, and reinforcement details require careful attention in order to mobilize the full strength of these structures. To provide a greater margin of safety, *R* factors used with elevated tanks typically are less than those for other comparable lateral load-resisting systems.

C15.7.10.4 Transfer of Lateral Forces into Support Tower. The vertical loads and shears transferred at the base of a tank or vessel supported by grillage or beams typically vary around the base due to the relative stiffness of the supports, settlements, and variations in construction. Such variations must be considered in the design for vertical and horizontal loads.

C15.7.10.5 Evaluation of Structures Sensitive to Buckling Failure. Nonbuilding structures with little structural redundancy for lateral loads may exhibit total failure when loaded only slightly beyond the design loads. Tanks and vessels supported on shell skirts or pedestals that are governed by buckling require evaluation for this critical condition.

The design spectral response acceleration, S_a, used in this evaluation includes site factors. The I/R coefficient is taken as 1.0 for this critical check. The structural capacity of the shell is taken as the critical buckling strength (that is, the factor of safety is 1.0). Vertical and orthogonal combinations need not be considered for this evaluation, since the probability of peak values occurring simultaneously is very low.

While the standard requires this evaluation only for structures assigned to Occupancy Category IV, it may be applied to any buckling-sensitive structure. Where such optional evaluations are performed, an *R* value of 2 or 3 can be used. In most cases, the design of the structure will be governed by this additional evaluation.

C15.7.10.7 Concrete Pedestal (Composite) Tanks. A composite elevated water-storage tank is comprised of a welded steel tank for watertight containment, a single pedestal concrete support structure, a foundation, and accessories. The lateral load-resisting system is a load-bearing concrete shear wall. Since the seismic provisions in ACI 371R-98 are based on an older edition of ASCE/SEI 7, appropriate bridging equations are provided in Section 15.7.10.7.

C15.7.11 Boilers and Pressure Vessels. The support system for boilers and pressure vessels must be designed for the seismic forces and displacements presented in the standard. Such design must include consideration of the support, the attachment of the support to the vessel (even if "integral"), and the body of the vessel itself, which is subject to local stresses imposed by the support connection.

C15.7.12 Liquid and Gas Spheres. The commentary in Section C15.7.11 also applies to liquid and gas spheres.

C15.7.13 Refrigerated Gas Liquid Storage Tanks and Vessels. Some refrigerated storage tanks and vessels, such as those storing LNG, are required to be designed for ground motions and performance goals in excess of those found in the standard, so such structures are outside the scope of the standard. All other welded steel refrigerated storage tanks and vessels must be designed in accordance with the requirements of the standard, the requirements of API 620, and the seismic requirements of API 650. Note that the seismic requirements of API 620 (10^{th} Edition, Addendum 1) are note used as they are inconsistent with the requirements of the standard.

C15.7.14 Horizontal, Saddle Supported Vessels for Liquid or Vapor Storage. Past practice has been to assume that a horizontal, saddle supported vessel (including its contents) behaves as a rigid structure (with natural period, *T*, less than 0.06 seconds). For this situation, seismic forces would be determined using the requirements of Section 15.4.2. For large horizontal, saddle-supported vessels (length-to-diameter ratio of 6 or more), this assumption can be unconservative, so Section 15.7.14.3 requires that the natural period be determined assuming the vessel to be a simply supported beam.

COMMENTARY TO CHAPTER 16, SEISMIC RESPONSE HISTORY PROCEDURES

C16.1 LINEAR RESPONSE HISTORY PROCEDURE

The standard does not require the use of linear response history analysis. However, the use of such analysis may be useful in validation of the results of the analysis methods presented in Chapter 12, or as a step in a series of analyses that culminate in a nonlinear response history analysis. While not commonly used in the past to design typical structures, this technique is seeing increased use in the design of some structures including structures that are neither damped nor base isolated.

The purpose of the linear response history procedure is to determine design forces for structural components and to compute displacements and story drifts, which must be within the limits specified by Table 12.12-1. In this sense, the linear response history procedure shares the force-based philosophy of the Equivalent Lateral Force (ELF) procedure and the Modal Response Spectrum (MRS) analysis procedure (both of which are specified in Chapter 12). Response history analysis offers several advantages over modal response spectrum analysis: it is more accurate mathematically, signs of response quantities (such as tension or compression in a brace) are not lost as a result of the combination of modal responses, and story drifts are computed more accurately. The principal disadvantages of response history analysis are the need to select and scale an appropriate suite of ground motions, and the necessity to perform analysis for several (usually seven) such motions. See Section C16.1.3 for discussion of ground motion selection and scaling techniques.

C16.1.1 Analysis Requirements. In response history analysis, the seismic hazard is characterized by a number of ground acceleration records. Using these records and a detailed mathematical model of the structure, nodal displacements and component forces are computed, step-by-step, by integration of the equations of motion. Two basic approaches for solving the equations may be used. In the first approach, called direct analysis, all the equilibrium equations for the entire system are solved simultaneously in each step. The number of equations solved equals the number of degrees of freedom in the structure.

In the second approach, called modal analysis, the equilibrium equations are transformed, by change of coordinates, into a number of single-degree-of-freedom (SDOF) systems. The maximum number of SDOF systems that can be formed is equal to the number of mass degrees of freedom in the structure. The SDOF equations are solved individually in time, and then the computed displacement histories are transformed back to the original coordinates and superimposed to obtain the system response history. The transformation of coordinates in the modal analysis approach is usually based on the undamped natural mode shapes of the structure. Other bases, such as a set of orthogonal load-dependent Ritz vectors, may be preferable in certain cases (Wilson et al., 1982).

Where modal analysis uses the full set of mode shapes and the damping ratios in each mode are identical to those obtained from the equations of motion used in the direct analysis, the two approaches produce identical results. A distinct advantage of the modal analysis approach is that a limited number of modes may be used to produce reasonably accurate results. While some accuracy is sacrificed where fewer modes are used, the computer resources required to perform the analysis are significantly less than those required for direct analysis. The number of modes required for a “reasonably” accurate analysis is discussed in Section C12.9.1.

C16.1.2 Modeling. The mathematical model used for linear response history analysis is usually identical to that used for modal response spectrum analysis, and it often reflects a preliminary design developed using the ELF procedure. The main modeling difference between response history analysis and modal response spectrum analysis is that the inherent damping (taken as 5 percent of critical) is included in the design response spectrum for response spectrum analysis, while it must be assigned explicitly for response history analysis.

In the modal analysis approach to response history analysis, damping is simply assigned to each mode that is included in the response (Wilson and Penzien, 1970). Although not specified in the standard, the damping used for each mode should be 5 percent of critical for consistency with the design response spectrum.

Direct response history analysis requires an explicit damping matrix. However, such a matrix cannot be formed from first principles; it is common to use a damping matrix that is proportional to the mass, the stiffness, or a linear combination of the two:

$$C = \alpha M + \beta K \qquad \text{(C16.1-1)}$$

where C is the damping matrix, M is the mass matrix, K is the stiffness matrix, and α and β are scalar constants of proportionality. Such damping is often referred to as Rayleigh damping.

The proportionality constants are determined as follows:

$$\begin{Bmatrix} \alpha \\ \beta \end{Bmatrix} = 2 \begin{bmatrix} 1/\omega_a & \omega_a \\ 1/\omega_b & \omega_b \end{bmatrix}^{-1} \begin{Bmatrix} \xi_a \\ \xi_b \end{Bmatrix} \qquad \text{(C16.1-2)}$$

where ξ_a and ξ_b are the desired damping ratios at any two system circular frequencies, ω_a and ω_b, where $\omega_b > \omega_a$. It is common, but not necessary, for the two specified frequencies to correspond to two of the system's lower natural frequencies (such as the first and third mode frequencies).

If both damping values are the same ($\xi = \xi_a = \xi_b$), which is usually the case, the mass and stiffness proportionality constants may be determined as follows:

$$\alpha = \xi \frac{2\omega_a \omega_b}{\omega_a + \omega_b}$$
$$\beta = \xi \frac{2}{\omega_a + \omega_b} \qquad \text{(C16.1-3)}$$

The advantage of Rayleigh damping is that it is simple to implement because all the analyst has to do is to specify the two proportionality constants α and β, and these can be established using Equation C16.1-2 given the two desired damping ratios and corresponding frequencies. The disadvantage is that the damping ratios increase with frequency and may cause the higher mode contributions to response to be over-damped. This effect is shown in Figure C16.1-1, where the damping ratios ξ have been set at 0.05 at frequencies of 4.2 and 12.5 radians per second. The damping at all other frequencies is given by the curve marked "Total". For frequencies above approximately 32 radians per second, the damping is greater than 10 percent of critical and may be excessive.

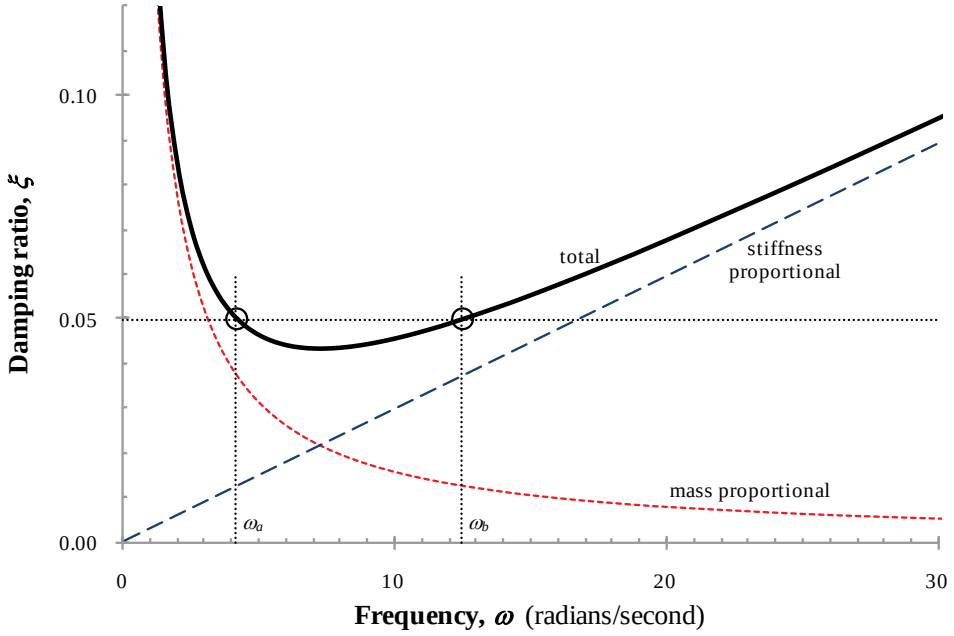

Figure C16.1-1 Example of Rayleigh damping.

C16.1.3 Ground Motion. One of the most demanding aspects of response history analysis is the selection and scaling of an appropriate suite of ground motions (Anderson and Bertero, 1987). It is considered appropriate to select records that have magnitudes, fault distances, source mechanisms, and soil conditions that are characteristic of the site. This poses quite a challenge even for sites in the western United States, where numerous records from large-magnitude earthquakes are available; it is virtually impossible in the central and eastern United States, where there are no recorded ground motions from large-magnitude events. (The web site for the Pacific Earthquake Engineering Research Center (PEER) provides a large number of ground motion acceleration records that may be used in response history analysis. In addition to the ground

motions, the PEER site provides detailed background information on the source characteristics of the ground motions and on the instrument and site characteristics of the particular station that recorded the acceleration record.)

Because of the scarcity of available recorded motions, use of simulated ground motions is permitted. To this end, available records may be modified for site distance and soil conditions. Such modification is considered part of the ground motion selection.

The standard requires that at least three ground motions (or ground motion pairs, in the case of three-dimensional analysis) be used, and it provides an incentive for using at least seven motions (as discussed in Section C16.1.4).

The scaling technique specified in Sections 16.1.3.1 and 16.1.3.2 is one of several that have been proposed. See Shome and Cornell (1998), Shome et al. (1998), Somerville et al. (1998), Mehrain and Naiem (2003), and Iervolino and Cornell (2005) for background on ground motion selection and scaling. (Applied Technology Council (ATC) Projects 58 and 63 are also investigating scaling techniques.)

C16.1.3.1 Two-Dimensional Analysis. This scaling method begins with ground motions that have been selected (and modified as necessary) to have magnitude, distance, and site conditions compatible with the maximum considered earthquake. The 5 percent damped pseudo-acceleration response spectra for these records are scaled for consistency with the design ground motion spectrum shown in Figure 11.4-1. For two-dimensional analysis, the ground motion spectra must be scaled such that the average of the spectra is not less than the design spectrum in the period range from $0.2T$ to $1.5T$, where T is the fundamental period of vibration of the structure being designed. The short period of the range ($0.2T$) is set to capture higher mode response, and the long period of the range ($1.5T$) is set to allow for period lengthening that would be associated with inelastic response.

C16.1.3.2 Three-Dimensional Analysis. Approaches to scaling ground motions for three-dimensional analysis are similar to those for two-dimensional analysis. The two orthogonal components within each pair must have the same scale factor, but the individual pairs may have different scale factors. Within 10 kilometers of a fault, ground motion components often are selected to represent fault-normal and fault-parallel directions, but this is not required. For certain structures, the response under both horizontal and vertical ground motions should be considered. It is noted, however, that vertical ground motion spectra are not readily available, so the scaling of the vertical components of ground motion would be problematic.

The 1.3 factor in the comparison of the average of the SRSS spectra to the design spectrum is intended to compensate for the increase associated with taking the SRSS of the two components of each ground motion pair. If the two components are perfectly correlated (identical response spectra in both directions), the SRSS would be larger than the average by the square root of 2. Because real ground motions are not perfectly correlated, a smaller factor is acceptable. The judgment of the writers (after two cycles of revision) is to allow a factor of 1.3 and to allow the results to be low by as much as 10 percent (producing an effective factor of 1.18).

Given a set of appropriate ground motions, there are an infinite number of scaling factors that may be applied to the individual motions to meet the requirements of Sections 16.1.3.1 and 16.1.3.2. Thus, two analysts, working with the same set of ground motions, are likely to produce a different set of scale factors. While this difference in scaling would have little impact in linear analysis, it may lead to vastly different results in nonlinear analysis. For this reason, the process of selection and scaling of ground motions should be included in the design review (Section 16.2.5 of the standard) that is required wherever nonlinear response history analysis is used.

Both amplitude scaling and spectral matching procedures can be used to satisfy the scaling technique specified in Sections 16.1.3.1 and16.1.3.2. Both procedures provide reasonable estimates of mean response for the individual response parameters. Spectral matching can provide mean estimates with a smaller suite of motions, although seven suites are still required as outlined in Section 16.1.4. Neither scaling approach, however, is adequate to give an accurate estimate of the variability, although amplitude scaling gives a better understanding of the potential variability than spectral matching.

C16.1.4 Response Parameters. The responses derived from the response history analysis are multiplied by I to provide enhanced strength and stiffness for more important facilities, and are divided by R to account for inelastic behavior. For consistency with the ELF procedure and the MRS analysis procedure, the displacements computed from the response histories that have been further modified by I/R should be multiplied by C_d to obtain the displacement histories to use for computing the story drift histories. (The requirement to multiply displacements by C_d was incorrectly omitted in the standard.)

If for any ground motion the peak base shear is less than that computed from Equation 12.8-5 or 12.8-6, the entire response history must be scaled up such that the peak base shear is not less than that computed from Equation 12.8-5 or 12.8-6, as applicable. The base shear typically is computed from component elastic forces. A slightly different shear would be computed from the total inertial forces, with the difference being due to damping. Note that while the results of MRS

analysis must be scaled up such that the corresponding base shear is not less than 85 percent of the base shear that would be computed from an ELF analysis (see Section C12.9.4), the scaling for linear response history analysis considers only the applicable minimum base shear coefficient.

If seven or more ground motions are used, the design values may be taken as the average of the scaled values from the response history analysis. This provides some difficulty for components for which the capacity depends on multiple values. For a column, for example, both the axial force and the concurrent bending moment are needed to compare demand and capacity. In that instance, if seven or more ground motions are used, the column is deemed suitable if the average of the seven peak demand-to-capacity ratios for the column is less than 1.0. Where fewer than seven ground motions are used, the column is deemed suitable if the maximum demand-to-capacity ratio is less than 1.0.

The direction of loading requirements of Section 12.5 and the modeling requirements of Section 12.7 apply to response history analysis, but Chapter 16 of the standard does not address additional requirements such as accidental torsion, amplification of accidental torsion, or detailed consideration of P-delta effects. These effects should be included in a manner consistent with the requirements of Section 12.9.

C16.2 NONLINEAR RESPONSE HISTORY PROCEDURE

Nonlinear response history analysis is not used as part of the normal design process for typical structures. In some cases, however, nonlinear analysis is recommended, and in certain cases required, to obtain a more realistic assessment of structural response and verify the results of simpler methods of analysis. Such is the case for systems with friction-based passive energy dissipation devices, nonlinear viscous dampers, seismically isolated systems, self-centering systems, or systems that have components with highly irregular force-deformation relationships.

The principal aim of nonlinear response history analysis is to determine if the computed deformations of the structure are within appropriate limits. Strength requirements for the designated lateral load-resisting elements do not apply because element strengths are established prior to the analysis. These initial strengths typically are determined from a preliminary design using linear analysis.

The nonlinear response history analysis may also provide useful information on the strength requirements for nonstructural components, which are often assumed to remain elastic in the analysis.

Where displacements computed from the nonlinear response history analysis are excessive, a typical remedy is to increase the stiffness of the structure, which is likely to affect the computed strength.

Nonlinear response history analysis offers several advantages over linear response history analysis, including the ability to model a wide variety of nonlinear material behaviors, geometric nonlinearities (including large displacement effects), gap opening and contact behavior, and nonclassical damping, and to identify the likely spatial and temporal distributions of inelasticity. Nonlinear response history analysis has several disadvantages, including increased effort to develop the analytical model, increased time to perform the analysis (which is often complicated by difficulties in obtaining converged solutions), sensitivity of computed response to system parameters, and the inapplicability of superposition to combine live, dead, and seismic load effects.

C16.2.1 Analysis Requirements. Nonlinear response history analysis of structures with widely distributed inelastic behavior is usually carried out using the direct analysis approach (described in Section C16.1.1), wherein all equations are solved simultaneously at each time step. In some cases, it is possible to use a highly efficient nonlinear modal analysis approach called Fast Nonlinear Analysis, or FNA (Wilson, 2004). The class of nonlinear structures that may be analyzed by the FNA approach consists of structures with a very limited number of discrete sources of well-defined nonlinear behavior. Such structures include seismically isolated structures and structures with damping systems. Because of the limited applicability of FNA, this commentary discusses only the direct analysis approach.

The sensitivity of nonlinear response history analysis may be evidenced by results that appear to be chaotic or even counter-intuitive, although they may be correct. For example, it is possible for the analysis to predict that a structure collapses when subjected to a given ground motion, while surviving at higher intensity of the same motion. Similarly, the results from analyses of the same structure for several ground motions with similar spectral shapes and amplitudes often differ substantially. A systematic approach to assess the sensitivity of structures to different ground motions and structural system parameters, using Incremental Dynamic Analysis (IDA), is reported by Vamvatsikos (2002). The IDA method has become an important tool in earthquake engineering research.

C16.2.2 Modeling. Nonlinear response history analysis requires a mathematical description of the hysteretic behavior of those portions of the structure that are expected to exhibit inelastic behavior during an earthquake. Such models must reflect the expected properties, accounting for the following effects as appropriate:

1. Material overstrength and strain hardening
2. Cyclic degradation of stiffness and strength
3. In-cycle degradation of stiffness and strength (Applied Technology Council, 2009)
4. Pinching
5. Buckling
6. Axial-flexural-shear interaction

Most of the available mathematical models are phenomenological and represent yielding portions as distinct elements (such as plastic hinges). More exact analysis may be performed by subdividing yielding portions into a number of slices or fibers. This more exact approach is preferable but is more computationally demanding.

An inelastic three-dimensional analysis is particularly useful for buildings that are prone to torsional response in plan, even where the main seismic force-resisting systems resist loads predominantly in their own plane. If only two-dimensional software is available, a "pseudo" three-dimensional analysis may be performed (Mehrain and Naeim, 2003).

In moment resisting steel frames, the elastic and inelastic behavior of beam-column joint regions should be modeled explicitly. P-delta effects should be considered explicitly in the analysis. Nonstructural components also should be included in the model if it is expected that their stiffness and strength have a significant effect on the response.

Nonlinear response history analysis requires that inherent damping be set for the structure. As for linear response history analysis, nonlinear response history analysis typically is performed assuming inherent damping of 5 percent of critical. Some analysts and designers advocate the use of lower levels of inherent damping (perhaps 2 percent of critical), especially for steel frames, but there is no widespread agreement on this point.

The mechanism used to include inherent damping in the analytical model is critically important to the accuracy of the computed response. Most nonlinear analysis programs use a form of Rayleigh damping, wherein the damping matrix (used for direct integration of the equations of motion) is represented as a linear combination of the mass and stiffness matrices. (See Section C16.1.2.) If the damping matrix is based on the initial stiffness of the system, artificial damping may be generated by system yielding. In some cases, the artificial damping can completely skew the computed response (Chrisp, 1980; Carr, 2004; Charney, 2006; Hall, 2006). One method to counter this occurrence is to base the damping matrix on the mass and the instantaneous tangent stiffness. (Where basing the damping on tangent stiffness, care must be taken so that the damping is not negative when the tangent stiffness is negative.) Other approaches have been suggested, such as capped Rayleigh damping (Hall, 2006) and hysteretic damping (Charney, 2006). Several commercial programs, including SAP2000, Perform 2D, and Ruaomoko, provide for tangent stiffness-based damping.

Three-dimensional analysis must be used where certain plan irregularities are present. For structures composed of two-dimensional seismic force-resisting elements connected by floor and roof diaphragms, the diaphragms should be modeled as flexible in-plane, particularly where the vertical elements of the seismic force-resisting system are of different types (such as moment frames and walls). Where structures are modeled in three dimensions, axial force-biaxial bending interaction should be considered for corner columns, nonrectangular walls, and other similar elements.

As mentioned above, P-delta effects should be included where significant. The significance of P-delta effects on the overall response may be assessed by performing analyses with and without P-delta effects, and comparing story drift response histories. Destabilizing effects of gravity loads are often manifested by accumulated residual deformations, and these deformations, if not controlled, can lead to dynamic instability of the structure.

C16.2.3 Ground Motion and Other Loading. Since linear superposition cannot be used with nonlinear analysis, each response history analysis must begin with an initial gravity load, consisting of the expected dead load and live load. The live load may be as little as 25 percent of the unfactored design live load because multiple transient loads are unlikely to attain their maxima simultaneously.

C16.2.4 Response Parameters. As discussed above, the principal aim of nonlinear response history analysis is to determine deformation demands in structural and nonstructural components for comparison with accepted limits. Where at least seven ground motions are used, the member and connection deformations may be taken as the average of the values computed from the analyses. If fewer than seven motions are used, the maximum values among all analyses must be used. It is very important to note, however, that assessment of deformations in this manner should not be done without careful inspection of the story displacement histories of each analysis. It is possible that the maximum displacement or drift may be completely dominated by the response from one ground motion, and such dominance, when due to ratcheting (increasing deformations in one direction resulting in a high residual deformation), may be a sign of imminent dynamic instability. Where these kinds of dynamic instabilities are present, the analyst should attempt to determine the system characteristics that produce such effects. The ground motion that produces dynamic instability should not be replaced with one that does not.

C16.2.4.1 Member Strength. The strength design load combinations of Section 12.4 need not be assessed because linear combinations of load are not applicable in nonlinear analysis. Overstrength effects are evaluated directly since hysteretic force-deformation relationships are modeled explicitly and the material properties so used include overstrength and strain hardening (as required by Section 16.2.2).

C16.2.4.2 Member Deformation. This section requires that member and connection deformations be assessed on the basis of tests performed for similar configurations.

C16.2.4.3 Story Drift. The 25 percent increase in allowable story drift is provided because the nonlinear analysis is generally more accurate than linear analysis and because member deformations are assessed explicitly.

C16.2.5 Design Review. As discussed above, nonlinear response history analysis is quite complex, and the results may be strongly influenced by subtle changes in ground motion or system properties. Hence, such analysis must only be conducted by experienced professionals with training in engineering seismology, earthquake engineering, structural dynamics, stability, nonlinear analysis, and inelastic behavior of structures. Regardless of the level of expertise of the individual or individuals who perform the analysis and design, a design (peer) review of the structural system and the nonlinear analysis is required wherever the design is based on the nonlinear response history procedure.

COMMENTARY TO CHAPTER 17, SEISMIC DESIGN REQUIREMENTS FOR SEISMICALLY ISOLATED STRUCTURES

C17.1 GENERAL

Seismic isolation, commonly referred to as base isolation, is a method used to decouple substantially the response of a structure from potentially damaging earthquake motions. This decoupling can result in response that is reduced significantly from that of a conventional, fixed-base building.

The potential advantages of seismic isolation and the recent advancements in isolation-system technology have led to the design and construction of a large number of seismically isolated buildings and bridges in the United States.

Design requirements for seismically isolated structures were first codified in the United States as an appendix to the 1991 *Uniform Building Code*, based on "General Requirements for the Design and Construction of Seismic-Isolated Structures" developed by the Structural Engineers Association of California State Seismology Committee. In the intervening years, those provisions have developed along two parallel tracks into the design requirements in Chapter 17 of the standard and the rehabilitation requirements in Section 9.2 of ASCE/SEI 41, *Seismic Rehabilitation of Existing Buildings*. The design and analysis methods of both standards are quite similar, but ASCE/SEI 41 permits more liberal design for the superstructure of rehabilitated buildings. The AASHTO *Guide Specification for Seismic Isolation Design* provides a systematic approach to determining bounding values of mechanical properties of isolators for analysis and design. Rather than addressing a specific method of seismic isolation, the standard provides general design requirements applicable to a wide range of possible seismic isolation systems. Because the design requirements are general, testing of isolation-system hardware is required to confirm the engineering parameters used in the design and to verify the overall adequacy of the isolation system. Use of isolation systems whose adequacy is not proved by testing is prohibited. In general, acceptable systems: (a) remain stable when subjected to design displacements, (b) provide increasing resistance with increasing displacement, (c) do not degrade under repeated cyclic load, and (d) have quantifiable engineering parameters (such as force-deflection characteristics and damping).

The force-deflection behavior of isolation systems falls into four categories, as shown in Figure C17.1-1, where each idealized curve has the same design displacement, D_D. A linear isolation system (Curve A) has an effective period independent of displacement, and the force generated in the superstructure is directly proportional to the displacement of the isolation system.

with increasing displacement, the procedures of the standard cannot be applied, and use of the system is prohibited.

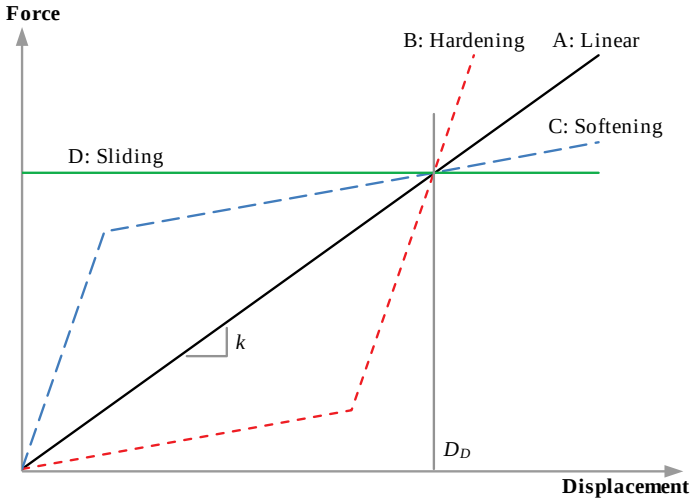

Figure C17.1-1 Idealized force-deflection relationships for isolation systems (stiffness effects of sacrificial wind-restraint systems not shown for clarity).

A hardening isolation system (Curve B) is soft initially (long effective period) and then stiffens (effective period shortens) as displacement increases. Where displacements exceed the design displacement, the superstructure is subjected to larger forces and the isolation system to smaller displacements than for a comparable linear system.

A softening isolation system (Curve C) is stiff initially (short effective period) and then softens (effective period lengthens) as displacement increases. Where displacements exceed the design displacement, the superstructure is subjected to smaller forces and the isolation system to larger displacements than for a comparable linear system.

The response of a purely sliding isolation system (Curve D) is governed by the friction force at the sliding interface. For increasing displacement, the effective period lengthens, and loads on the superstructure remain constant. For isolation systems governed solely by friction forces, the total displacement due to repeated earthquake cycles is highly dependent on the characteristics of the ground motion and may exceed the design displacement, D_D. Since such systems do not have increasing resistance

Chapter 17 provides isolator design displacements, shear forces for structural design, and other specific requirements for seismically isolated structures. All other design requirements, including loads (other than seismic), load combinations, allowable forces and stresses, and horizontal shear distribution, are the same as those for conventional, fixed-base structures.

C17.1.1 Variations in Material Properties. For analysis, the mechanical properties of seismic isolators generally are based on values provided by isolator manufacturers. Values of the mechanical properties should be in the range that accounts for natural variability and uncertainty, and variability of properties among isolater of different manufacturers. Examples may be found in Constantinou et al. (2007b). Prototype testing is used to confirm the values assumed for design. Unlike conventional materials whose properties do not vary substantially with time, the materials used in seismic isolators have properties that generally will vary with time. Because mechanical properties can vary over the life of a structure and the testing protocol of Section 17.8 cannot account for the effects of aging, contamination, scragging (temporary degradation of mechanical properties with repeated cycling), temperature, velocity effects, and wear, the designer must account for these effects by explicit analysis. One approach to accommodate these effects, introduced in Constantinou et al. (1999), is to use property modification factors. Information on variations in material properties of seismic isolators and dampers is reported in Constantinou et al. (2007).

C17.2 GENERAL DESIGN REQUIREMENTS

Ideally, most of the lateral displacement of an isolated structure will be accommodated by deformation of the isolation system rather than distortion of the structure above. Accordingly, the seismic-force-resisting system of the structure above the isolation system is designed to have sufficient stiffness and strength to avoid large, inelastic displacements. Therefore, the standard contains criteria that limit the inelastic response of the structure above the isolation system. Although damage control is not an explicit objective of the standard, design to limit inelastic response of the structural system also will reduce the level of damage that would otherwise occur during an earthquake. In general, isolated structures designed in accordance with the standard are expected:

1. To resist minor and moderate levels of earthquake ground motion without damage to structural elements, nonstructural components, or building contents and
2. To resist major levels of earthquake ground motion without failure of the isolation system, significant damage to structural elements, extensive damage to nonstructural components, or major disruption to facility function.

Isolated structures are expected to perform much better than fixed-base structures during moderate and major earthquakes. Table C17.2-1 compares the performance expected for isolated and fixed-base structures designed in accordance with the standard.

Table C17.2-1 Performance Expected for Minor, Moderate, and Major Earthquakes[a]

Performance Measure	Earthquake Ground Motion Level		
	Minor	Moderate	Major
Life safety: loss of life or serious injury is not expected	F, I	F, I	F, I
Structural damage: significant structural damage is not expected	F, I	F, I	I
Nonstructural damage: significant nonstructural or contents damage is not expected	F, I	I	I

[a] F indicates fixed base; I indicates isolated.

Loss of function is not included in Table C17.2-1. For certain fixed-base facilities, loss of function would not be expected unless there is significant structural damage causing closure or restricted access to the building. In other cases, a facility with only limited or no structural damage would not be functional as a result of damage to vital nonstructural components or contents. Isolation would be expected to mitigate structural and nonstructural damage and to protect the facility against loss of function.

C17.2.4 Isolation System

C17.2.4.1 Environmental Conditions. Environmental conditions that may adversely affect isolation system performance must be investigated thoroughly. Related research has been conducted since the 1970s in Europe, Japan, New Zealand, and the United States.

C17.2.4.2 Wind Forces. Lateral displacement over the depth of the isolator zone resulting from wind loads must be limited to a value similar to that required for other story heights.

C17.2.4.3 Fire Resistance. While fire may adversely affect the lateral performance of the isolation system, its gravity-load resistance must be maintained as required for other elements of the structure.

C17.2.4.4 Lateral Restoring Force. The restoring-force requirement is intended to limit residual displacement as a result of an earthquake, so that the isolated structure will survive aftershocks and future earthquakes.

C17.2.4.5 Displacement Restraint. The use of a displacement restraint is discouraged. Where a displacement restraint system is used, explicit analysis of the isolated structure for maximum considered earthquake response is required to account for the effects of engaging the displacement restraint.

C17.2.4.6 Vertical-load Stability. The vertical loads to be used in checking the stability of any given isolator should be calculated using bounding values of dead load and live load and the peak earthquake demand of the maximum considered earthquake. Since earthquake loads are reversible in nature, peak earthquake load should be combined with bounding values of dead and live load in a manner which produces both the maximum downward force and the maximum upward force on any isolator. Stability of each isolator should be verified for these two extreme values of vertical load at peak maximum considered earthquake displacement of the isolation system.

C17.2.4.7 Overturning. The intent of this requirement is to prevent both global structural overturning and overstress of elements due to local uplift. Isolator uplift is acceptable so long as the isolation system does not disengage from its horizontal-resisting connection detail. The connection details used in some isolation systems are such that tension is not permitted on the system. Where the tension capacity of an isolator is used to resist uplift forces, design and testing in accordance with Sections 17.2.4.6 and 17.8.2.5 must be performed to demonstrate the adequacy of the system to resist tension forces at the total maximum displacement.

C17.2.4.8 Inspection and Replacement. Although most isolation systems will not need to be replaced after an earthquake, access for inspection and replacement must be provided, and periodic inspection is required. After an earthquake, the isolation system should be inspected and any damaged elements replaced or repaired.

C17.2.4.9 Quality Control. A testing and inspection program is necessary for both fabrication and installation of the isolator units. Because seismic isolation is a rapidly evolving technology, it may be difficult to reference standards for testing and inspection. Reference can be made to standards for some materials, such as elastomeric bearings (ASTM D 4014). Similar standards are yet to be developed for other isolation systems. Special inspection procedures and load testing to verify manufacturing quality must be developed for each project. The requirements will vary depending on the type of isolation system used.

C17.2.5 Structural System

C17.2.5.2 Building Separations. A minimum separation between the isolated structure and rigid obstructions is required to allow free movement of the superstructure in all lateral directions during an earthquake.

C17.2.6 Elements of Structures and Nonstructural Components. To accommodate the differential movement between the isolated building and the ground, flexible utility connections are required. In addition, stiff elements crossing the isolation interface (such as stairs, elevator shafts, and walls) must be detailed to accommodate the total maximum displacement without compromising life safety.

C17.3 GROUND MOTION FOR ISOLATED STRUCTURES

C17.3.1 Design Spectra. Seismically isolated structures located on Site Class F sites and on sites with $S_1 \geq 0.6$ must be analyzed using response history analysis. For those cases, the response spectra must be site-specific in order to account, in

the analysis, for near-fault effects and for soft soil conditions, both of which are known to be important in the assessment of displacement demands in seismically isolated structures.

C17.3.2 Ground Motion Histories. The selection and scaling of ground motions for response history analysis requires fitting to the response spectra in the period range of $0.5T_D$ to $1.25T_M$, a range that is different from that for conventional structures $0.2T$ to $1.5T$. The following sections provide background on the two period ranges:

1. Period Range – Isolated Structures. The effective (fundamental) period of an isolated structure is based on amplitude-dependent, nonlinear (pushover) stiffness properties of the isolation system. The effective periods, T_D and T_M, correspond to design earthquake displacement and maximum considered earthquake displacement, respectively, in the direction under consideration. Values of effective (fundamental) periods, T_D and T_M, are typically in the range of 2 to 4 seconds, and the value of the effective period, T_D, typically is 15 to 25 percent less than the corresponding value of effective period, T_M.

   The response of an isolated structure is dominated by the fundamental mode in the direction of interest. The specified period range, $0.5T_D$ to $1.25T_M$, conservatively bounds amplitude-dependent values of the effective (fundamental) period of the isolated structure in the direction of interest, considering that individual earthquake records can affect response at effective periods somewhat longer than T_M, or significantly shorter than T_D.

2. Period Range – Conventional, Fixed-Base Structures. The fundamental period, T, of a conventional, fixed-base structure is based on amplitude-independent, linear-elastic stiffness properties of the structure. In general, response of conventional, fixed-base structures is influenced by both the fundamental mode and higher modes in the direction under consideration. The period range, $0.2T$ to $1.5T$, is intended to bound the fundamental period, considering some period lengthening due to nonlinear response of the structure (that is, inelastic periods up to $1.5T$) and periods corresponding to the more significant higher modes (that is, second and possibly third modes in the direction of interest).

C17.4 ANALYSIS PROCEDURE SELECTION

Three different analysis procedures are available for determining design-level seismic loads: the equivalent lateral force procedure, the response spectrum procedure, and the response history procedure. For the first procedure simple, lateral-force formulas (similar to those for conventional, fixed-base structures) are used to determine peak lateral displacement and design forces as a function of spectral acceleration and isolated-structure period and damping. For the second and third procedures, which are required for geometrically complex or especially flexible buildings, dynamic analysis (either the response spectrum procedure or the response history procedure) is used to determine peak response of the isolated structure.

The three procedures are based on the same level of seismic input and require a similar level of performance from the building. Where more complex analysis procedures are used, slightly lower design forces and displacements are permitted. The design requirements for the structural system are based on the design earthquake, taken as two-thirds of the maximum considered earthquake. The isolation system—including all connections, supporting structural elements, and the "gap"—is required to be designed (and tested) for 100 percent of maximum considered earthquake demand. Structural elements above the isolation system are not required to be designed for the full effects of the design earthquake but may be designed for slightly reduced loads (that is, loads reduced by a factor of up to 2) if the structural system is able to respond inelastically without sustaining significant damage. A similar fixed-base structure would be designed for loads reduced by a factor of 8 rather than 2.

This section delineates the requirements for the use of the equivalent lateral force procedure and dynamic methods of analysis. The limitations on the simplified lateral-force design procedure are quite restrictive. Limitations relate to the site location with respect to major, active faults; soil conditions of the site; the height, regularity, and stiffness characteristics of the building; and selected characteristics of the isolation system. Response-history analysis is required to determine the design displacement of the isolation system (and the structure above) for the following isolated structures:

1. Isolated structures with a "nonlinear" isolation system including, but not limited to, isolation systems with effective damping values greater than 30 percent of critical, isolation systems incapable of producing a significant restoring force, and isolation systems that restrain or limit extreme earthquake displacement; and
2. Isolated structures located on a Class E or Class F site (that is, a soft soil site that amplifies long-period ground motions).

Lower-bound limits on isolation system design displacements and structural-design forces are specified by the standard in Section 17.6 as a percentage of the values prescribed by the equivalent lateral force procedure, even where dynamic analysis is used as the basis for design. These lower-bound limits on key design parameters provide consistency in the design of

isolated structures and serve as a "safety net" against gross underdesign. Table C17.4-1 provides a summary of the lower-bound limits on dynamic analysis specified by the standard.

C17.5 EQUIVALENT LATERAL FORCE PROCEDURE

C17.5.3 Minimum Lateral Displacements. The lateral displacement given by Equation 17.5-1 approximates peak design earthquake displacement of a single-degree-of-freedom, linear-elastic system of period, T_D, and equivalent viscous damping, β_D. Similarly, the lateral displacement given by Equation 17.5-3 approximates peak maximum considered earthquake displacement of a single-degree-of-freedom, linear-elastic system of period, T_M, and equivalent viscous damping, β_M.

Table C17.4-1 Lower-Bound Limits on Dynamic Procedures Specified in Relation to ELF Procedure Requirements

Design Parameter	ELF Procedure	Dynamic Procedure	
		Response Spectrum	Response History
Design displacement – D_D	$D_D = (g/4\pi^2)(S_{D1}T_D/B_D)$	—	—
Total design displacement - D_{TD}	$D_{TD} \geq 1.1D_D$	$\geq 0.9D_{TD}$	$\geq 0.9D_{TD}$
Maximum displacement – D_M	$D_M = (g/4\pi^2)(S_{M1}T_M/B_M)$	—	—
Total maximum displacement - D_{TM}	$D_{TM} \geq 1.1D_M$	$\geq 0.8D_{TM}$	$\geq 0.8D_{TM}$
Design shear – V_b (at or below the isolation system)	$V_b = k_{Dmax}D_D$	$\geq 0.9V_b$	$\geq 0.9V_b$
Design shear – V_s ("regular" superstructure)	$V_s = k_{Dmax}D_D/R_I$	$\geq 0.8V_s$	$\geq 0.6V_s$
Design shear – V_s ("irregular" superstructure)	$V_s = k_{Dmax}D_D/R_I$	$\geq 1.0V_s$	$\geq 0.8V_s$
Drift (calculated using R_I for C_d)	$0.015h_{sx}$	$0.015h_{sx}$	$0.020h_{sx}$

Equation 17.5-1 is an estimate of peak displacement in the isolation system for the design earthquake. In this equation, the spectral acceleration term, S_{D1}, is the same as that required for design of a conventional, fixed-base structure of period, T_D. A damping term, B_D, is used to decrease (or increase) the computed displacement where the equivalent damping coefficient of the isolation system is greater (or smaller) than 5 percent of critical damping. Values of coefficient B_D (or B_M for the maximum considered earthquake) are given in Table 17.5-1 for different values of isolation system damping, β_D (or β_M).

A comparison of values obtained from Equation 17.5-1 and those obtained from nonlinear time-history analyses are given in Kircher et al. (1988) and Constantinou et al. (1993).

Consideration should be given to possible differences in the properties used for design of the isolation system and those of the isolation system as installed in the structure. Similarly, consideration should be given to possible changes in isolation system properties due to different design conditions or load combinations. If the true deformational characteristics of the isolation system are not stable or if they vary with the nature of the load (being rate-, amplitude-, or time-dependent), the design displacements should be based on deformational characteristics of the isolation system that give the largest possible deflection (k_{Dmin}), the design forces should be based on deformational characteristics of the isolation system that give the largest possible force (k_{Dmax}), and the damping level used to determine design displacements and forces should be based on deformational characteristics of the isolation system that represent the minimum amount of energy dissipated during cyclic response at the design level.

The isolation system for a seismically isolated structure should be configured to minimize eccentricity between the center of mass of the superstructure and the center of rigidity of the isolation system. In this way, the effect of torsion on the displacement of isolation elements will be reduced. As for conventional structures, allowance must be made for accidental eccentricity in both horizontal directions. Figure C17.5-1 illustrates the terminology used in the standard. Equation 17.5-5 (or Equation 17.5-6 for the maximum considered earthquake) provides a simplified formula for estimating the response due to torsion in lieu of a more refined analysis. The additional component of displacement due to torsion increases the design displacement at the corner of a structure by about 15 percent (for one perfectly square in plan) to about 30 percent (for one very long and rectangular in plan) if the eccentricity is 5 percent of the maximum plan dimension. These calculated torsional

displacements are for structures with an isolation system whose stiffness is uniformly distributed in plan. Isolation systems that have stiffness concentrated toward the perimeter of the structure, or certain sliding systems that minimize the effects of mass eccentricity, will have smaller torsional displacements. The standard permits values of D_{TD} as small as $1.1D_D$, with proper justification.

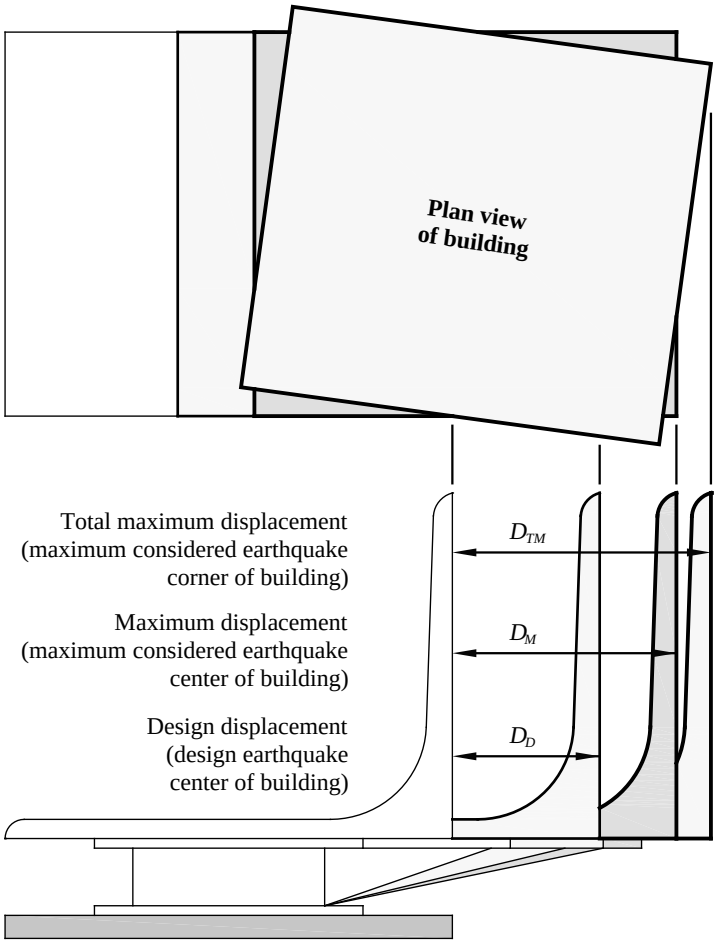

Figure C17.5-1 Displacement terminology.

C17.5.4 Minimum Lateral Forces. Figure C17.5-2 illustrates the terminology for elements at, below, and above the isolation system. Equation 17.5-7 specifies the peak seismic shear for design of all structural elements at or below the isolation system (without reduction for ductile response). Equation 17.5-8 specifies the peak seismic shear for design of structural elements above the isolation system. For structures that have appreciable inelastic-deformation capability, this equation includes an effective reduction factor of up to 2 for response beyond the strength-design level.

The reduction factor is based on use of strength-design procedures. A factor of at least 2 is assumed to exist between the design-force level and the true-yield level of the structural system. An investigation of 10 specific buildings indicated that this factor varied between 2 and 5 (ATC, 1982). Thus, a reduction factor of 2 is appropriate to produce a structural system that remains essentially elastic for the design earthquake.

In Section 17.5.4.3, the limits given on V_S provide at least a factor of 1.5 between the nominal yield level of the superstructure and (a) the yield level of the isolation system, (b) the ultimate capacity of a sacrificial wind-restraint system that is intended to fail and release the superstructure during significant lateral load, or (c) the break-away friction level of a sliding system.

These limits are needed so that the superstructure will not yield prematurely before the isolation system has been activated and significantly displaced.

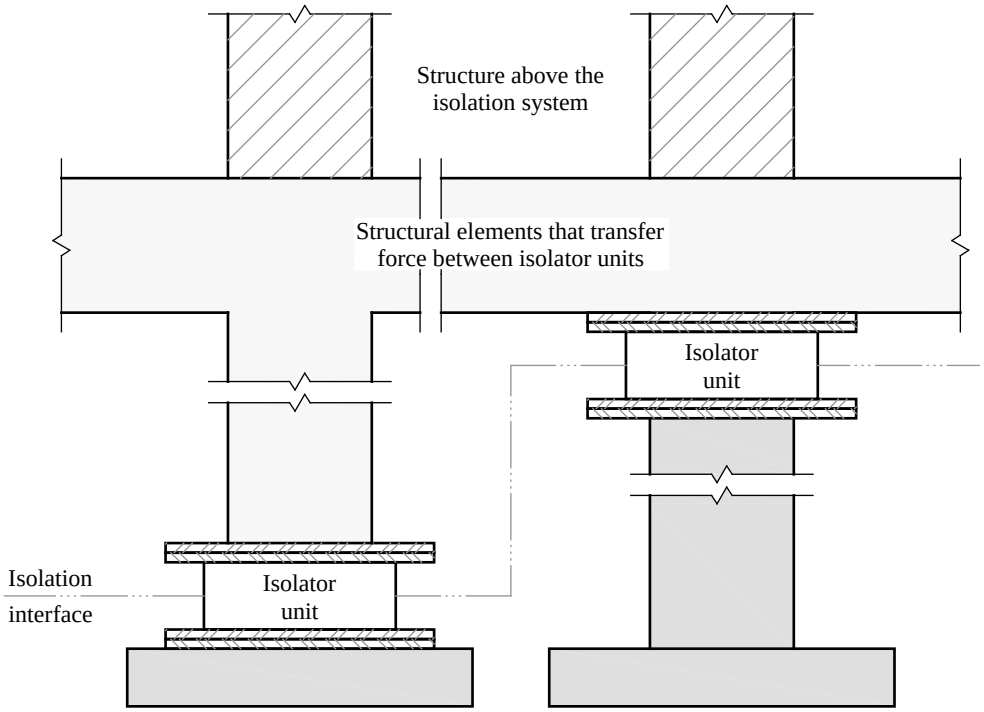

Figure C17.5-2 Isolation system terminology.

The design shear force, V_S, specified in this section results in an isolated structural system being subjected to significantly lower inelastic demands than a conventionally designed structural system. Further reduction in V_S, such that the inelastic demand on a seismically isolated structure would be the same as the inelastic demand on a conventionally designed structure, was not considered during development of these requirements but may be considered in the future.

Using a smaller value of R_I in Equation 17.5-8 will reduce or eliminate inelastic response of the superstructure for the design-basis event, thus further improving the structural performance.

C17.5.5 Vertical Distribution of Forces. Equation 17.5-9 produces a vertical distribution of lateral forces consistent with a triangular profile of seismic acceleration over the height of the structure above the isolation interface. Kircher et al. (1988) and Constantinou et al. (1993) show that Equation 17.5-9 provides a conservative estimate of the distributions obtained from more detailed, nonlinear analysis studies for the type of structures for which use of Equation 17.5-9 is allowed.

C17.5.6 Drift Limits. The maximum story drift permitted for design of isolated structures is constant for all Occupancy Categories, as shown in Table C17.5-1. For comparison, the drift limits prescribed by the standard for fixed-base structures also are summarized in that table.

Table C17.5-1 Comparison of Drift Limits for Fixed-Base and Isolated Structures

Structure	Occupancy Category	Fixed-Base	Isolated
Buildings (other than masonry) four stories or less in height with component drift design	I or II	$0.025h_{sx}/(C_d/R)$	$0.015h_{sx}$
	III	$0.020h_{sx}/(C_d/R)$	$0.015h_{sx}$
	IV	$0.015h_{sx}/(C_d/R)$	$0.015h_{sx}$
Other (non-masonry) buildings	I or II	$0.020h_{sx}/(C_d/R)$	$0.015h_{sx}$
	III	$0.015h_{sx}/(C_d/R)$	$0.015h_{sx}$
	IV	$0.010h_{sx}/(C_d/R)$	$0.015h_{sx}$

Drift limits in Table C17.5-1 are divided by C_d/R for fixed-base structures since displacements calculated for lateral loads reduced by R are multiplied by C_d before checking drift. The C_d term is used throughout the standard for fixed-base structures to approximate the ratio of actual earthquake response to response calculated for "reduced" forces. Generally, C_d

is 1/2 to 4/5 the value of R. For isolated structures, the R_I factor is used both to reduce lateral loads and to increase displacements (calculated for reduced lateral loads) before checking drift. Equivalency would be obtained if the drift limits for both fixed-base and isolated structures were based on their respective R factors. It may be noted that the drift limits for isolated structures generally are more conservative than those for conventional, fixed-base structures, even where fixed-base structures are assigned to Occupancy Category IV.

C17.6 DYNAMIC ANALYSIS PROCEDURES

This section specifies the requirements and limits for dynamic procedures. The design displacement and force limits on response spectrum and response history procedures are shown in Table C17.4-1.

A more detailed or refined study can be performed in accordance with the analysis procedures described in this section. The intent of this section is to provide procedures that are compatible with the minimum requirements of Section 17.5. Reasons for performing a more refined study include:

1. The importance of the building.
2. The need to analyze possible structure/isolation-system interaction where the fixed-base period of the building is greater than one-third of the isolated period.
3. The need to explicitly model the deformational characteristics of the lateral-force-resisting system where the structure above the isolation system is irregular.
4. The desirability of using site-specific ground-motion data, especially for very soft or liquefiable soils (Site Class F) or for structures located where S_1 is greater than 0.60.
5. The desirability of explicitly modeling the deformational characteristics of the isolation system. This is especially important for systems that have damping characteristics that are amplitude-dependent, rather than velocity-dependent, since it is difficult to determine an appropriate value of equivalent viscous damping for these systems.

Section C17.4 discusses other conditions that require use of the response history procedure. As shown in Table C17.4-1, the drift limit for isolated structures is relaxed where story drifts are computed using nonlinear response history analysis.

Where response history analysis is used as the basis for design, the design displacement of the isolation system and design forces in elements of the structure above are computed from not fewer than three separate analyses, each using a different ground motion selected and scaled in accordance with Section 17.3.2. Where the configuration of the isolation system or of the superstructure is not symmetric, additional analyses are required to satisfy the requirement of Section 17.6.3.4 to consider the most disadvantageous location of eccentric mass. As appropriate, near-field phenomena may also be incorporated. As in the nuclear industry, where at least seven ground motions are used for nonlinear response history analysis, it is considered appropriate to base design of seismically isolated structures on the average value of the response parameters of interest.

C17.7 DESIGN REVIEW

Review of the design and analysis of the isolation system and design review of the isolator testing program is mandated by the standard for two key reasons:

1. The consequences of isolator failure could be catastrophic.
2. Isolator design and fabrication technology is evolving rapidly and may be based on technologies unfamiliar to many design professionals.

The standard requires review to be performed by a team of registered design professionals that are independent of the design team and other project contractors. The review team should include individuals with special expertise in one or more aspects of the design, analysis, and implementation of seismic isolation systems.

The review team should be formed prior to the development of design criteria (including site-specific ground shaking criteria) and isolation system design options. Further, the review team should have full access to all pertinent information and the cooperation of the design team and regulatory agencies involved with the project.

C17.8 TESTING

The design displacements and forces determined using the standard assume that the deformational characteristics of the isolation system have been defined previously by comprehensive testing. If comprehensive test data are not available for a system, major design alterations in the structure may be necessary after the tests are complete. This would result from

variations in the isolation-system properties assumed for design and those obtained by test. Therefore, it is advisable that prototype systems be tested during the early phases of design, if sufficient test data are not available on an isolation system.

Typical force-deflection (or hysteresis) loops are shown in Figure C17.8-1; also illustrated are the values defined in Section 17.8.5.1.

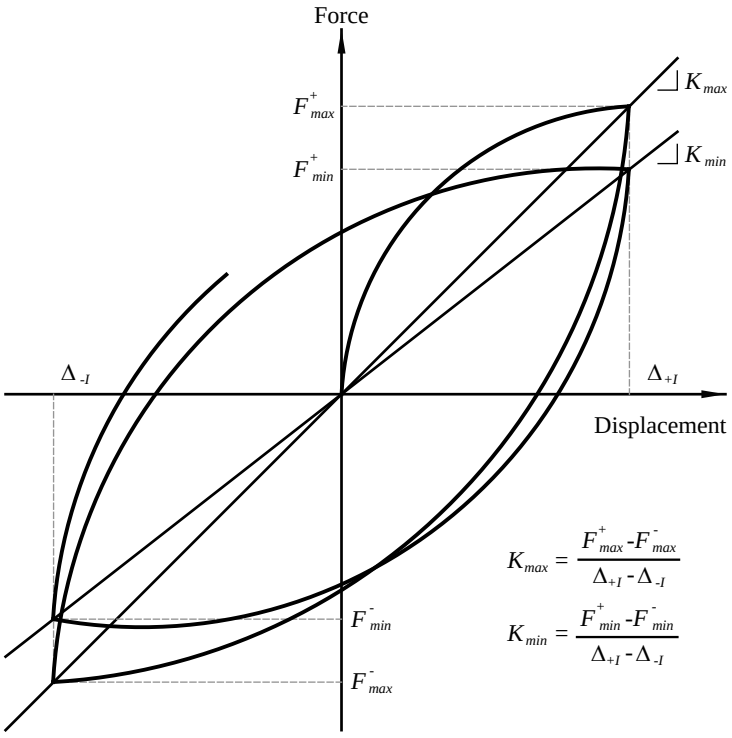

Figure C17.8-1 The effect of stiffness on an isolation bearing.

The required sequence of tests will verify experimentally the following:

1. The assumed stiffness and capacity of the wind-restraining mechanism;
2. The variation of the isolator's deformational characteristics with amplitude (and with vertical load, if it is a vertical load-carrying member);
3. The variation of the isolator's deformational characteristics for a realistic number of cycles of loading at the design displacement; and
4. The ability of the system to carry its maximum and minimum vertical loads at the maximum displacement.

Force-deflection tests are not required if similarly sized components have been tested previously using the specified sequence of tests.

The variations in the vertical loads required for tests of isolators which carry vertical, as well as lateral, load are necessary to determine possible variations in the system properties with variations in overturning force.

C17.8.5 Design Properties of the Isolation System

C17.8.5.1 Maximum and Minimum Effective Stiffness. The effective stiffness is determined from the hysteresis loops as shown in Figure C17.8-1. Stiffness may vary considerably as the test amplitude increases but should be reasonably stable (within 15 percent) for more than three cycles at a given amplitude.

The intent of these requirements is that the deformational properties used in design result in the maximum design forces and displacements. For determining design displacement, this means using the smallest damping and effective stiffness values. For determining design forces, this means using the smallest damping value and the largest stiffness value.

C17.8.5.2 Effective Damping. The determination of equivalent viscous damping is reasonably reliable for systems whose damping characteristics are velocity dependent. For systems that have amplitude-dependent energy-dissipating mechanisms,

significant problems arise in determining an equivalent viscous-damping value. Since it is difficult to relate velocity- and amplitude-dependent phenomena, it is recommended that where the equivalent-viscous damping assumed for the design of amplitude-dependent energy-dissipating mechanisms (such as pure-sliding systems) is greater than 30 percent, the design-basis force and displacement be determined using the response history procedure, as discussed in Section C17.4.

COMMENTARY TO CHAPTER 18, SEISMIC DESIGN REQUIREMENTS FOR STRUCTURES WITH DAMPING SYSTEMS

C18.1 GENERAL

The requirements of this chapter apply to all types of damping systems including both displacement-dependent damping devices of hysteretic or friction systems and velocity-dependent damping devices of viscous or visco-elastic systems (Soong and Dargush, 1997; Constantinou et al., 1998; Hanson and Soong, 2001). Compliance with these requirements is intended to produce performance comparable to that for a structure with a conventional seismic-force-resisting system, but the same methods can be used to achieve higher performance.

The damping system (DS) is defined separately from the seismic-force-resisting system (SFRS), although the two systems may have common elements. As illustrated in Figure C18.1-1, the damping system may be external or internal to the structure and may have no shared elements, some shared elements, or all elements in common with the seismic-force-resisting system. Elements common to the damping system and the seismic-force-resisting system must be designed for a combination of the two loads of the two systems. When the DS and SFRS have no common elements, the damper forces must be collected and transferred to members of the SFRS.

C18.2 GENERAL DESIGN REQUIREMENTS

C18.2.2 System Requirements. Structures with a damping system must have a seismic-force-resisting system that provides a complete load path. The seismic-force-resisting system must comply with all of the height, Seismic Design Category, and redundancy limitations and with the detailing requirements specified in this standard for the specific seismic-force-resisting system. The seismic-force-resisting system without the damping system (as if damping devices were disconnected) must be designed to have not less than 75 percent of the strength required for undamped structures having that type of seismic-force-resisting system (and not less than 100 percent if the structure is horizontally or vertically irregular). The damping systems, however, may be used to meet the drift limits (whether the structure is regular or irregular). Having the SFRS designed for a minimum of 75 percent of the strength required for undamped structures provides safety in the event of damping system malfunction and produces a composite system with sufficient stiffness and strength to have controlled lateral displacement response.

The damping system must be designed for the actual (unreduced) earthquake forces (such as, peak force occurring in damping devices) and deflections. For certain elements of the damping system (such as the connections or the members into which the damping devices frame), other than damping devices, limited yielding is permitted provided such behavior does not affect damping system function or exceed the amount permitted for elements of conventional structures by the standard.

C18.2.4 Procedure Selection. Linear static and response spectrum analysis methods can be used for design of structures with damping systems that meet certain configuration and other limiting criteria (for example, at least two damping devices at each story configured to resist torsion). In such cases, additional nonlinear response history analysis shall be used to confirm peak responses when the structure is located at a site with S_1 greater than or equal to 0.6. The analysis methods damperd structures are based on nonlinear static "pushover" characterization of the structure and calculation of peak response using effective (secant) stiffness and effective damping properties of the first (pushover) mode in the direction of interest. These are the concepts used in Chapter 17 to characterize the force-deflection properties of isolation systems, modified to incorporate explicitly the effects of ductility demand (post-yield response) and higher-mode response of structures with dampers. Like conventional structures, dampered structures generally yield during strong ground shaking, and their performance can be influenced strongly by response of higher modes.

The response spectrum and equivalent lateral force procedures presented in the standard have several simplifications and limits, as outlined below:

1. A multi-degree-of-freedom (MDOF) structure with a damping system can be transformed into equivalent single-degree-of-freedom (SDOF) systems using modal decomposition procedures. This assumes that the collapse mechanism for the structure is a single-degree-of-freedom mechanism so that the drift distribution over height can be estimated reasonably using either the first mode shape or another profile, such as an inverted triangle. Such procedures do not strictly apply to either yielding buildings or buildings that are non-proportionally damped.
2. The response of an inelastic single-degree-of-freedom system can be estimated using equivalent linear properties and a 5-percent-damped response spectrum. Spectra for damping greater than 5 percent can be established using damping

coefficients, and velocity-dependent forces can be established either by using the pseudo-velocity and modal information or by applying correction factors to the pseudo-velocity.

3. The nonlinear response of the structure can be represented by a bilinear hysteretic relationship with zero post-elastic stiffness (elasto-plastic behavior).
4. The yield strength of the structure can be estimated either by performing simple plastic analysis or by using the specified minimum seismic base shear and values of R, Ω_0, and C_d.
5. Higher modes need to be considered in the equivalent lateral force procedure in order to capture their effects on velocity-dependent forces. This is reflected in the residual mode procedure.

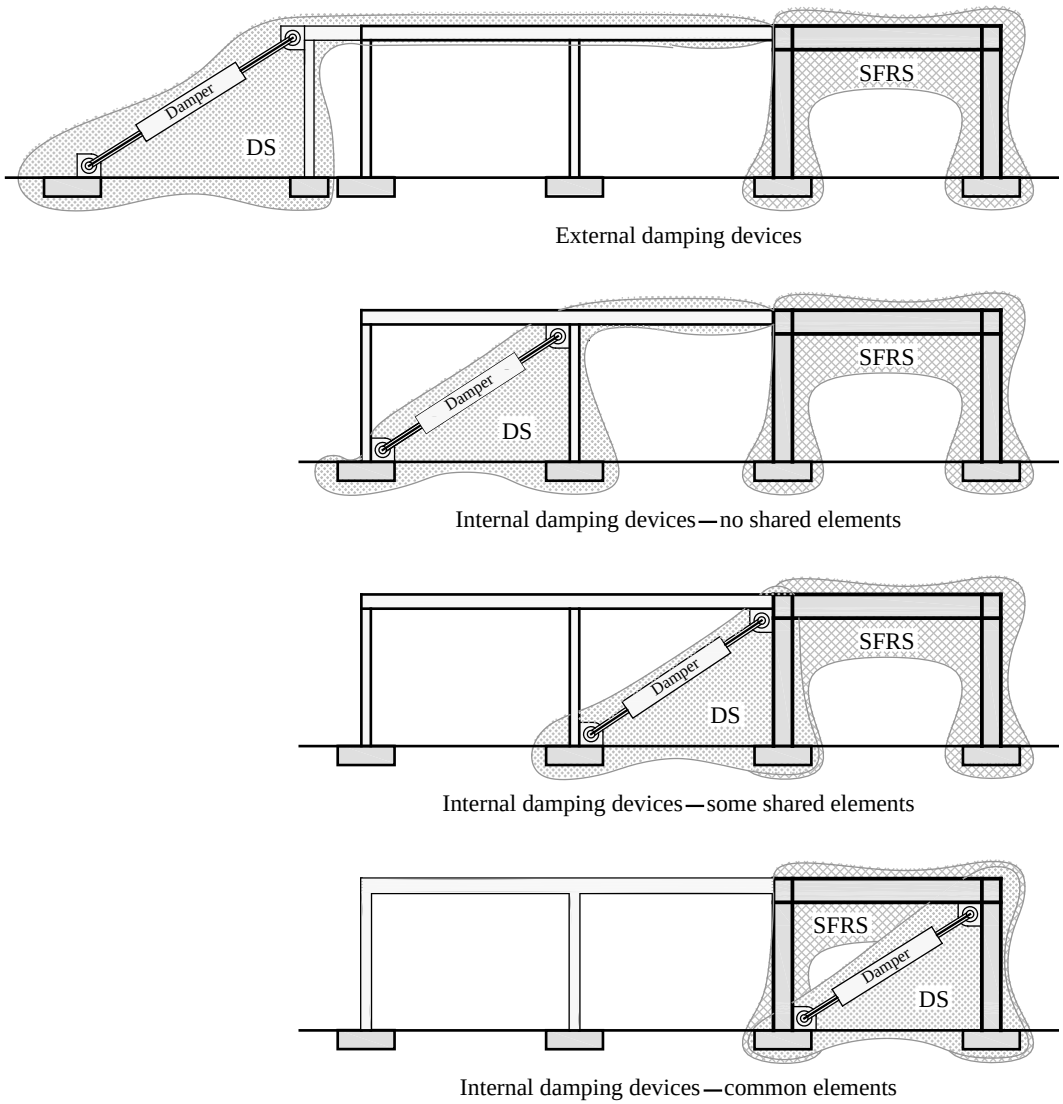

Figure C18.1-1 Damping system (DS) and seismic-force-resisting system (SFRS) configurations.

FEMA 440 (Applied Technology Council, 2005) presents a review of simplified procedures for the analysis of yielding structures. The combined effects of the simplifications mentioned above are reported by Ramirez et al. (2001) and Pavlou and Constantinou (2004) based on studies of 3-story and 6-story buildings with damping systems designed by the procedures of the standard. The response spectrum and equivalent lateral force procedures of the standard are found to provide conservative predictions of drift and predictions of damper forces and member actions that are of acceptable accuracy when compared to results of nonlinear dynamic response history analysis. When designed in accordance with the standard, structures with damping systems are expected to have structural performance at least as good as that of structures without damping systems. Pavlou and Constantinou (2006) report that structures with damping systems designed in accordance with

the standard provide the benefit of reduced secondary system response, although this benefit is restricted to systems with added viscous damping.

C18.3 NONLINEAR PROCEDURES

For designs in which the seismic-force-resisting-system is essentially elastic (assuming an overstrength of 50 percent), the only nonlinear characteristics that must be modeled in the analysis are those of the damping devices. For designs in which the seismic-force-resisting system will yield, the post-yield behavior of the structural elements must be modeled explicitly.

C18.4 RESPONSE SPECTRUM PROCEDURES and C18.5 EQUIVALENT LATERAL FORCE PROCEDURE

Effective Damping

In the standard the reduced response of a structure with a damping system is characterized by the damping coefficient, B, based on the effective damping, β, of the mode of interest. This is the same approach as that used for isolated structures. Like isolation, effective damping of the fundamental-mode of a damped structure is based on the nonlinear force-deflection properties of the structure. For use with linear analysis methods, nonlinear properties of the structure are inferred from the overstrength factor, Ω_0, and other terms.

Figure C18.4-1 illustrates reduction in design earthquake response of the fundamental mode due to increased effective damping (represented by coefficient, B_{1D}). The capacity curve is a plot of the nonlinear behavior of the fundamental mode in spectral acceleration-displacement coordinates. The reduction due to damping is applied at the effective period of the fundamental mode of vibration (based on the secant stiffness).

In general, effective damping is a combination of three components:

1. Inherent Damping (β_I)—Inherent damping of the structure at or just below yield, excluding added viscous damping (typically assumed to be 5 percent of critical for structural systems without dampers).
2. Hysteretic Damping (β_H)—Post-yield hysteretic damping of the seismic-force-resisting system and elements of the damping system at the amplitude of interest (taken as 0 percent of critical at or below yield).
3. Added Viscous Damping (β_V)—Viscous component of the damping system (taken as 0 percent for hysteretic or friction-based damping systems).

Both hysteretic damping and added viscous damping are amplitude-dependent, and the relative contributions to total effective damping change with the amount of post-yield response of the structure. For example, adding dampers to a structure decreases post-yield displacement of the structure and, hence, decreases the amount of hysteretic damping provided by the seismic-force-resisting system. If the displacements are reduced to the point of yield, the hysteretic component of effective damping is zero, and the effective damping is equal to inherent damping plus added viscous damping. If there is no damping system (as in a conventional structure), effective damping simply equals inherent damping (typically assumed to be 5 percent of critical for most conventional structures).

Linear Analysis Methods

The section specifies design earthquake displacements, velocities, and forces in terms of design earthquake spectral acceleration and modal properties. For equivalent lateral force (ELF) analysis, response is defined by two modes: the fundamental mode and the residual mode. The residual mode is a new concept used to approximate the combined effects of higher modes. While typically of secondary importance to story drift, higher modes can be a significant contributor to story velocity and, hence, are important for design of velocity-dependent damping devices. For response spectrum analysis, higher modes are explicitly evaluated.

For both the ELF and the response spectrum analysis procedures, response in the fundamental mode in the direction of interest is based on assumed nonlinear (pushover) properties of the structure. Nonlinear (pushover) properties, expressed in terms of base shear and roof displacement, are related to building capacity, expressed in terms of spectral coordinates, using mass participation and other fundamental-mode factors shown in Figure C18.4-2. The conversion concepts and factors shown in Figure C18.4-2 are the same as those defined in Chapter 9 of *Seismic Rehabilitation of Existing Buildings* (ASCE/SEI 41), which addresses seismic rehabilitation of a structure with damping devices.

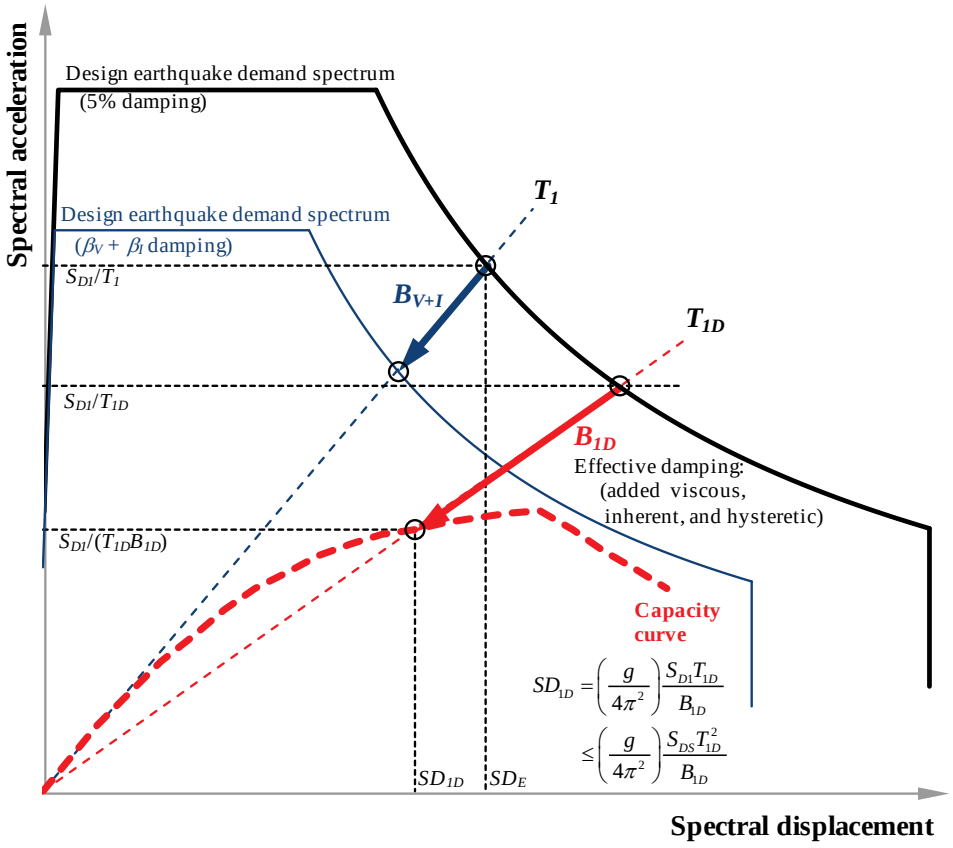

Figure C18.4-1 Effective damping reduction of design demand.

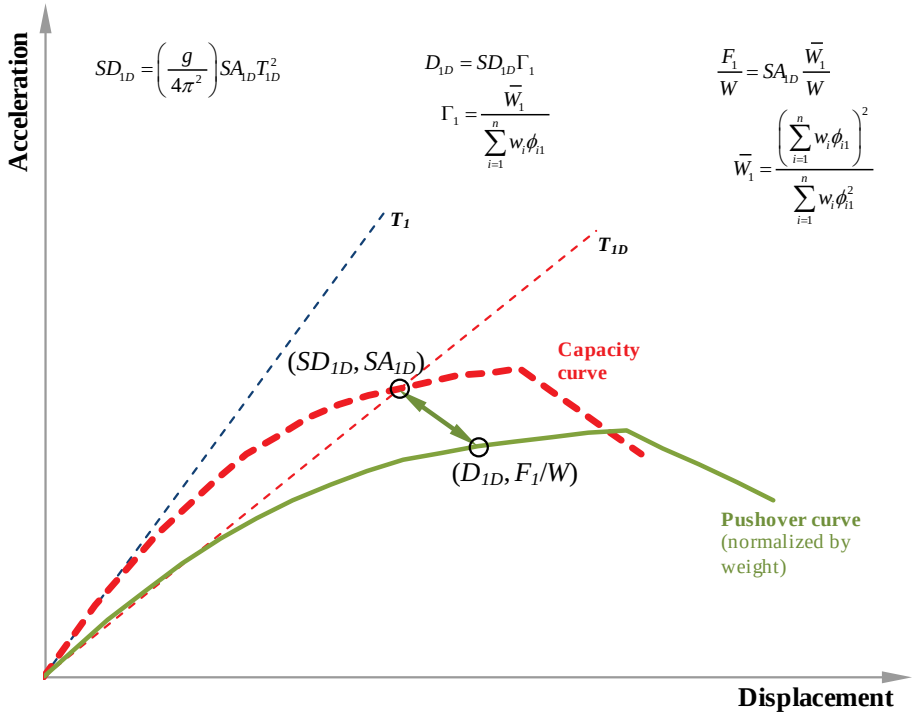

Figure C18.4-2 Pushover and capacity curves.

Where using linear analysis methods, the shape of the fundamental-mode pushover curve is not known, so an idealized elasto-plastic shape is assumed, as shown in Figure C18.4-3. The idealized pushover curve is intended to share a common point with the actual pushover curve at the design earthquake displacement, D_{1D}. The idealized curve permits definition of the global ductility demand due to the design earthquake, μ_D, as the ratio of design displacement, D_{1D}, to yield displacement, D_Y. This ductility factor is used to calculate various design factors; it must not exceed the ductility capacity of the seismic-force-resisting system, μ_{max}, which is calculated using factors for conventional structural response. Design examples using linear analysis methods have been developed and found to compare well with the results of nonlinear time history analysis (Ramirez et al., 2001).

Elements of the damping system are designed for fundamental-mode design earthquake forces corresponding to a base shear value of V_Y (except that damping devices are designed and prototypes tested for maximum considered earthquake response). Elements of the seismic-force-resisting system are designed for reduced fundamental-mode base shear, V_1, where force reduction is based on system overstrength (represented by Ω_0), multiplied by C_d/R for elastic analysis (where actual pushover strength is not known). Reduction using the ratio C_d/R is necessary because the standard provides values of C_d that are less than those for R. Where the two parameters have equal value and the structure is 5 percent damped under elastic conditions, no adjustment is necessary. Because the analysis methodology is based on calculating the actual story drifts and damping device displacements (rather than the displacements calculated for elastic conditions at the reduced base shear and then multiplied by C_d), an adjustment is needed. Since actual story drifts are calculated, the allowable story drift limits of Table 12.12-1 are multiplied by R/C_d before use.

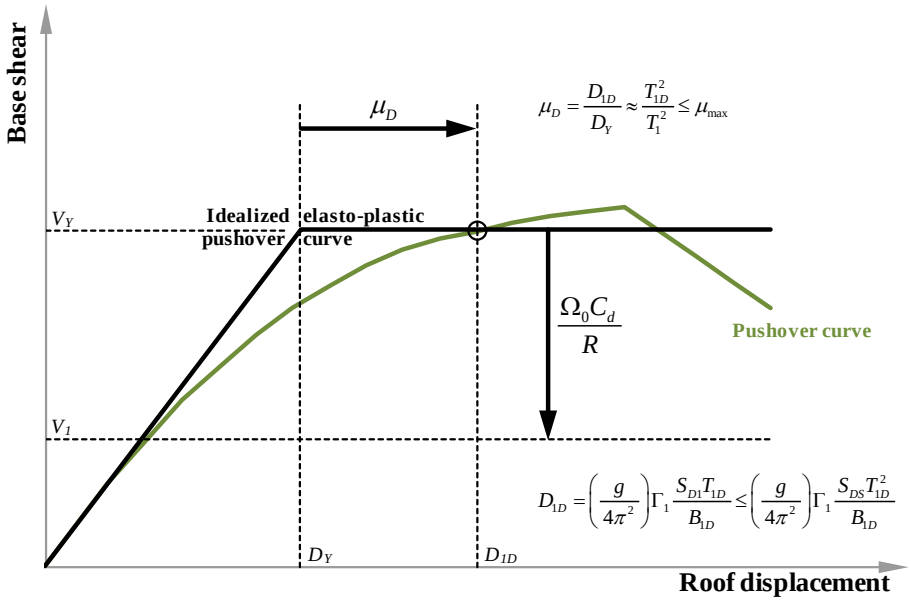

Figure C18.4-3 Idealized elasto-plastic pushover curve used for linear analysis.

C18.6 DAMPED RESPONSE MODIFICATION

C18.6.1 Damping Coefficient

Values of the damping coefficient, B, in Table 18.6-1 for design of damped structures are the same as those in Table 17.5-1 for isolated structures at damping levels up to 20 percent, but extend to higher damping levels based on results presented in Ramirez et al. (2001). Table C18.6-1 compares values of the damping coefficient as found in the standard and various resource documents and codes. FEMA 440 and the draft of Eurocode 8 present equations for the damping coefficient, B, whereas the other documents present values of B in tabular format.

The equation in FEMA 440 is

$$B = \frac{4}{5.6 - \ln(100\beta)}$$

The equation in Eurocode 8 is

$$B = \sqrt{\frac{0.05 + \beta}{0.10}}$$

Table C18.6-1 Values of Damping Coefficient, *B*

Effective Damping, β (%)	Table 17.5-1, 1999 AASHTO, 2001 CBC (seismically isolated structures)	Table 18.6-1 (structures with damping systems)	FEMA 440	EUROCODE 8
2	0.8	0.8	0.8	0.8
5	1.0	1.0	1.0	1.0
10	1.2	1.2	1.2	1.2
20	1.5	1.5	1.5	1.6
30	1.7	1.8	1.8	1.9
40	1.9	2.1	2.1	2.1
50	2.0	2.4	2.4	2.3

C18.6.2 Effective Damping. The effective damping is calculated assuming the structural system exhibits perfectly bi-linear hysteretic behavior characterized by the effective ductility demand, μ, as described in Ramirez et al. (2001). Effective damping is adjusted using the hysteresis loop adjustment factor, q_H, which is the actual area of the hysteresis loop divided by the area of the assumed perfectly bi-linear hysteretic loop. In general, values of this factor are less than unity. In Ramirez et al. (2001) expressions for this factor (which they call Quality Factor) are too complex to serve as a simple rule. Equation 18.6-5 provides a simple estimate of this factor. The equation predicts correctly the trend in the constant acceleration domain of the response spectrum, and it is believed to be conservative for flexible structures.

C18.7 SEISMIC LOAD CONDITIONS AND ACCEPTANCE CRITERIA

C18.7.2.5 Seismic Load Conditions and Combination of Modal Responses. Seismic design forces in elements of the damping system are calculated at three distinct stages: maximum displacement, maximum velocity, and maximum acceleration. All three stages need to be checked for structures with velocity-dependent damping systems. For displacement-dependent damping systems, the first and third stages are identical, whereas the second stage is inconsequential.

Force coefficients C_{mFD} and C_{mFV} are used to combine the effects of forces calculated at the stages of maximum displacement and maximum velocity to obtain the forces at maximum acceleration. The coefficients are presented in tabular form based on analytic expressions presented in Ramirez et al. (2001) and account for nonlinear viscous behavior and inelastic structural system behavior.

COMMENTARY FOR CHAPTER 19, SOIL STRUCTURE INTERACTION FOR SEISMIC DESIGN

C19.1 GENERAL

The response of a structure to earthquake shaking is affected by interactions between three linked systems: the structure, the foundation, and the geologic media underlying and surrounding the foundation. A seismic Soil-Structure Interaction (SSI) analysis evaluates the collective response of these systems to a specified free-field ground motion. The term "free-field" refers to motions not affected by structural vibrations and represents the condition for which the design spectrum is derived using the procedures given in Chapter 11.

SSI effects are absent for the theoretical condition of rigid foundation and soil conditions. Accordingly, SSI effects reflect the differences between the actual response of the structure and the response for the theoretical, rigid base condition. Visualized within this context, three SSI effects can significantly affect the response of building structures:

1. Foundation stiffness and damping. Inertia developed in a vibrating structure gives rise to base shear, moment, and torsional excitation, and these loads in turn cause displacements and rotations of the foundation relative to the free field. These relative displacements and rotations are only possible because of compliance in the soil-foundation system, which can significantly contribute to the overall structural flexibility in some cases. Moreover, the relative foundation-free field motions give rise to energy dissipation via radiation damping (i.e., damping associated with wave propagation into the ground away from the foundation, which acts as the wave source) and hysteretic soil damping, and this energy dissipation can significantly affect the overall damping of the soil-foundation-structure system. Since these effects are rooted in the structural inertia, they are referred to as inertial interaction effects.
2. Variations between free-field and foundation-level ground motions. The differences between foundation and free-field motions result from two processes. The first is known as kinematic interaction and results from the presence of stiff foundation elements on or in soil, which cause foundation motions to deviate from free-field motion as a result of base slab averaging, wave scattering, and embedment effects. Procedures for modifying design spectra to account for these effects are given in FEMA 440 and ASCE/SEI 41. The second process is related to the structure and foundation inertia and consists of the relative foundation-free field displacements and rotations described above.
3. Foundation deformations. Flexural, axial, and shear deformations of foundation elements occur as a result of loads applied by the superstructure and the supporting soil medium. Such deformations represent the seismic demand for which foundation components should be designed. These deformations can also significantly affect the overall system behavior, especially with respect to damping.

Chapter 19 treats only the inertial interaction effects (the first item above). Inertial interaction in buildings tends to be important for stiff structural systems (such as shear walls and braced frames), particularly where the foundation soil is relatively soft (i.e., Site Classes C to E). Kinematic interaction effects are neglected in these provisions. Foundation design is covered in Section 12.13.

The procedures in Chapter 19 are used to modify the fixed-base properties (period and damping) of a structural system. If fixed-base properties are obtained from an analytical model of the structure, the fixed-base properties correspond to a condition without soil springs. If soil springs are included in the analytical model of the structure, then the procedures given in Chapter 19 should not be used to modify the building period. The damping procedures in Chapter 19 could still be used in this case if the foundation springs are linear (thus introducing no damping) and there are no dashpots in parallel with the springs. In the remainder of this commentary, it is assumed that the structural period and damping ratio that are being modified for SSI effects correspond to a fixed-base condition.

In design procedures that utilize response spectra to establish design values of base shear (i.e., force-based methods such as those given in Chapter 12), the effects of inertial SSI on the seismic response of buildings is represented as a function of the ratio of flexible- to fixed-base first-mode natural period, $\tilde{T}_1/T_1$, and system damping, β_0, attributable to foundation-soil interaction. The flexible-base first-mode damping ratio, $\tilde{\beta}$, is calculated using Equation 19-9. Figure C19-1 illustrates two possible effects of inertial SSI on the peak base shear, which is commonly computed from spectral acceleration at the first-mode. The spectral acceleration for a flexible-based structure ($\tilde{S}_a = \tilde{C}_s/g$) is obtained by entering the spectrum drawn for effective damping ratio, $\tilde{\beta}$, at the corresponding elongated period, $\tilde{T}$. For buildings with periods greater than about 0.5 s, using $\tilde{S}_a$ in lieu of S_a (=C_s/g) typically reduces base shear demand, whereas in very stiff structures SSI can increase the base

shear. Most equivalent lateral force methods feature a flat spectral shape at low periods that, when coupled with the requirement that $\tilde{\beta} > \beta$, results in modeling of inertial SSI that can only decrease the base shear demand.

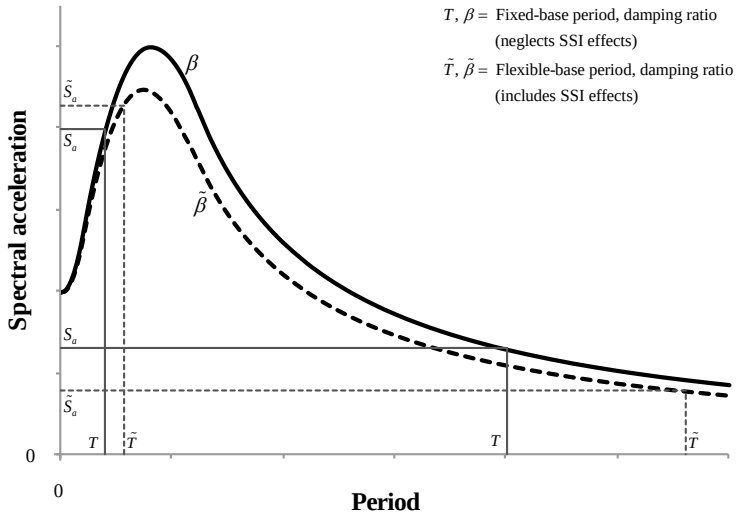

Figure C19-1 Schematic showing effects of period lengthening and foundation damping on design spectral accelerations.

The method given in Chapter 19 for evaluating inertial SSI effects is optional and has rarely been used in practice. There are several reasons for this. First, because the guidelines were written such that base shear demand can only decrease through consideration of SSI, SSI effects are ignored in order to be conservative. Second, many design engineers who have attempted to apply the method on projects have done so for major, high-rise buildings for which they felt evaluating SSI effects could provide cost savings. Unfortunately, inertial interaction effects are negligible for these tall, flexible structures, and hence the design engineers realized no benefit for their efforts and thereafter discontinued use of the procedures. The use of the procedures actually yield the most benefit for short-period ($T < 1$ sec), stiff structures with stiff, interconnected foundation systems (i.e., mats or interconnected footings) founded on soil.

C19.2 EQUIVALENT LATERAL FORCE PROCEDURE

This procedure considers the response of the structure in its fundamental mode of vibration and accounts for the contributions of the higher modes to story shears implicitly through the choice of the effective weight of the structure and the vertical distribution of the lateral forces. The effects of soil-structure interaction are accounted for on the assumption that they influence only the contribution of the fundamental mode of vibration.

C19.2.1 Base Shear. Base shear is reduced for the effects of SSI as indicated in Equation 19.2-1 and 19.2-2. As indicated in Equation 19.2-2, the change in base shear is related to the change in seismic coefficient (or spectral acceleration, as shown in Figure C19-1). The term $(0.05/\tilde{\beta})^{0.4}$ in Equation 19.2-2 represents the reduction in spectral ordinate associated with a change of damping from the fixed base value of $\beta = 0.05$ to the flexible base value of $\tilde{\beta}$.

C19.2.1.1 Effective Building Period. The fixed base period, T, is lengthened to the flexible-base period, $\tilde{T}$, using Equation 19.2-3, which was derived by Veletsos and Meek (1974). Terms K_y and K_θ represent the translational and rocking stiffnesses of the foundation, respectively. The standard does not provide guidance on the evaluation of these stiffness terms. Equations for K_y and K_θ are given by Gazetas (1991), and a number of practical considerations associated with the analysis of these terms are reviewed in FEMA 440 (2005). For convenience, simplified guidelines are presented below for these stiffness terms for use with the standard.

For building foundation systems having lateral continuity, such as mats or footings interconnected with grade beams, stiffnesses K_y and K_θ can often be approximated as:

$$K_y = \frac{8}{2-\nu} G r_a \qquad \text{(C19-2)}$$

$$K_\theta = \frac{8}{3(1-\nu)} G r_m^3 \alpha_\theta \qquad \text{(C19-3)}$$

where: r_a = an equivalent foundation radius that matches the area of the foundation, A_0 (i.e., $r_a = \sqrt{(A_0/\pi)}$); r_m = an equivalent foundation radius that matches the moment of inertia of the foundation in the direction of shaking (i.e., $r_m = \sqrt[4]{4I_0/\pi}$); G = the strain-dependent shear modulus, as defined in the standard; ν = the soil Poisson's ratio (generally taken as 0.3 for sands and 0.45 for clays); and α_θ = a dimensionless coefficient that depends on the period of excitation, the dimensions of the foundation, and the properties of the supporting medium (Luco, 1974; Veletsos and Verbic, 1973; Veletsos and Wei, 1971). A similar coefficient exists for translation (α_y), but can be taken as 1.0 without introducing significant error, and hence is not shown in Equation C19-2.

As noted in the standard, shear modulus G is evaluated from small-strain shear wave velocity as $G = (G/G_o)G_o = (G/G_o)\gamma v_{s0}^2/g$ (all terms defined in the standard). Shear wave velocity, v_{s0}, should be evaluated as the average small-strain shear wave velocity within the effective depth of influence below the foundation. The effective depth should be taken as $0.75r_a$ for horizontal vibrations of the foundation and $0.75r_m$ for rocking vibrations (Stewart et al., 2003). Methods for measuring v_{s0} (preferred) or estimating it from other soil properties are summarized elsewhere (e.g., Kramer, 1996).

The dynamic modifier for rocking, α_θ, can significantly affect the computed response of some building structures. In the absence of more detailed analyses, for ordinary building structures with an embedment ratio $d/r_m < 0.5$ (where d = depth of embedment, measured from ground surface to base of foundation), the factor α_θ can be estimated as follows (Stewart et al., 2003):

$r_m/(v_{s0}T)$	α_θ
< 0.05	1.0
0.15	0.85
0.35	0.7
0.5	0.6

Foundation embedment has the effect of increasing the stiffnesses K_y and K_θ. For embedded foundations for which there is positive contact between the side walls and the surrounding soil, K_y and K_θ may be determined from the following approximate formulas (Kausel, 1974):

$$K_y = \frac{8Gr_a}{2-\nu}\left[1+\left(\frac{2}{3}\right)\left(\frac{d}{r_a}\right)\right] \qquad \text{(C19-4)}$$

$$K_\theta = \frac{8Gr_m^3}{3(1-\nu)}\left[1+2\left(\frac{d}{r_m}\right)\right] \qquad \text{(C19-5)}$$

Experimental studies and field performance data (Stokoe and Erden, 1975; Stewart et al., 1999) indicate that the effects of foundation embedment are sensitive to the condition of the backfill and that judgment must be exercised in using Equations C19-4 and C19-5. For example, if contact is lost between the soil and basement walls, stiffnesses K_y and K_θ should be determined from the formulas for surface-supported foundations. More generally, the quantity d above should be interpreted as the effective depth of foundation embedment for the conditions that would prevail during the design earthquake ground motion.

The formulas for K_y and K_θ presented above can be applied to most soil profiles in which soil shear wave velocity, v_{s0}, changes with depth. However, if the soil profile consists of a surface stratum of soil underlain by a much stiffer deposit with a shear wave velocity more than twice that of the surface layer, K_y and K_θ may be determined from the following two generalized formulas in which G is the shear modulus of the surface soil and D_s is the total depth of the stratum:

$$K_y = \frac{8Gr_a}{2-\nu}\left[1+\left(\frac{2}{3}\right)\left(\frac{d}{r_a}\right)\right]\left[1+\left(\frac{1}{2}\right)\left(\frac{r_a}{D_s}\right)\right]\left[1+\left(\frac{5}{4}\right)\left(\frac{d}{D_s}\right)\right] \qquad \text{(C19-6)}$$

$$K_\theta = \frac{8Gr_m^3}{3(1-\nu)}\left[1+2\left(\frac{d}{r_m}\right)\right]\left[1+\left(\frac{1}{6}\right)\left(\frac{r_m}{D_s}\right)\right]\left[1+0.7\left(\frac{d}{D_s}\right)\right] \qquad \text{(C19-7)}$$

The above formulas are based on analyses of a stratum supported on a rigid base (Elsabee et al., 1977; Kausel and Roesset, 1975) and apply for $r/D_s < 0.5$ and $d/r < 1$ (r taken as either r_a or r_m). The applicability of those rigid base solutions to practical situations (non-rigid geologic media) was evaluated by Stewart et al. (2003), resulting in the recommendations provided above.

For buildings supported on footing foundations, the above formulas can generally be used with r_a and r_m calculated using the full building footprint dimensions, provided that the footings are interconnected with grade beams. An exception can occur for buildings with both shear walls and frames, for which the rotation of the foundation beneath the wall may be independent of that for the foundation beneath the column (this is referred to as weak rotational coupling). In such cases, r_m is often best calculated using the dimensions of the wall footing. Very stiff foundations, which provide strong rotational coupling, are best described using an r_m value that reflects the full foundation dimension. Regardless of the degree of rotational coupling, r_a should be calculated using the full foundation dimension if foundation elements are interconnected or continuous. Further discussion can be found in FEMA (2005). The use of discrete (non-interconnected) spread footing foundations in seismic regions is not recommended.

For buildings supported on pile foundations, lateral stiffness, K_y, can be taken as the sum of the lateral head stiffnesses of the supporting piles. These stiffness values are generally calculated using a beam on Winkler foundation model, which is discussed in detail elsewhere (e.g., Salgado, 2006). Rotational stiffness, K_θ, can be calculated from the vertical stiffness of the individual piles, k_{zi}, as follows:

$$K_\theta \approx \sum_i k_{zi} y_i^2 \qquad \text{(C19-8)}$$

where y_i = horizontal distance from the foundation centroidal axis to pile i measured in the direction of shaking. The approximation in Equation C19-8 assumes an infinitely rigid pile cap and neglects the rotational stiffness of individual piles, which is typically a small contribution. Quantity k_{zi} can be calculated for an individual pile using well-established methods, such as discrete element modeling with t-z curves (e.g., Salgado, 2006).

The alternate approach in the standard, represented by Equation 19.2-5, was derived using Poisson's ratio $\nu = 0.4$, and is generally sufficient for non-embedded foundations that are laterally continuous across the building footprint and for which there is no "rigid" layer at depth in the profile (which would require the use of Equations C19-6 and C19-7 to calculate foundation stiffness). The value of relative weight parameter, α (defined in the standard), can be taken as approximately 0.15 for typical buildings.

C19.2.1.2 Effective Damping. Bielak (1975, 1976) and Veletsos and Nair (1975) expressed the flexible-base first-mode damping ratio, $\tilde{\beta}$, as indicated in Equation 19.2-9. This equation is based on analyses of the harmonic response of single-degree-of-freedom oscillators supported on a visco-elastic medium with hysteretic damping. Foundation damping factor β_0 incorporates the effects of energy dissipation into the soil due to radiation damping and hysteretic damping in the soil.

Figure 19.2-1 shows β_0 as a function of period lengthening ratio and was derived from the analytical solution presented in Veletesos and Nair (1975) for the condition of zero foundation embedment. Additional damping can be realized for embedded foundations, and the use of damping values from Figure 19.2-1 is conservative for such conditions. More exact solutions can be obtained using procedures given in FEMA (2005).

Equation 19.2-9, in combination with the information presented in Figure 19.2-1, may lead to damping factors for the soil-foundation-structure system, $\tilde{\beta}$, that are smaller than the fixed base structural damping, β (assumed to be 0.05). However, it is recommended that $\tilde{\beta}$ never be taken as less than 0.05 for design applications. The use of values of $\tilde{\beta} > \beta$ is well-justified from field case-history data (Stewart et al., 1999, 2003).

The presence of a stiff layer at depth in the soil profile can impede radiation damping, rendering the values in Figure 19.2-1 too high. If a site consists of a relatively uniform layer of depth, D_s, overlying a very stiff layer with a shear wave velocity more than twice that of the surface layer, damping values should be reduced as indicated by Equation 19.2-12.

C19.2.2 Vertical Distribution of Seismic Forces. The vertical distributions of the equivalent lateral forces for flexibly and rigidly supported structures are similar, and it is recommended that the same distribution be used in both cases, changing only the magnitude of the forces to correspond to the appropriate base shear. A greater degree of refinement in this step would be inconsistent with the approximations embodied in the requirements for rigidly supported structures.

With the vertical distribution of the lateral forces established, the overturning moments and the torsional effects about a vertical axis are computed as for rigidly supported structures. The above procedure is applicable to planar structures and, with some extension, to three-dimensional structures.

C19.2.3 Other Effects. In addition to its effect on base shear, inertial SSI also can increase the horizontal displacements of the structure relative to its base (because of rocking). This can increase the required spacing between structures and secondary design forces associated with *P*-delta effects. Such effects can be significant for stiff structural systems (e.g., walls and braced frames).

C19.3 MODAL ANALYSIS PROCEDURE

The procedure outlined above in Section C19.2 is applicable to a modal analysis by adjusting the modal period and damping ratio of the fundamental mode only. Higher modes are relatively unaffected by SSI (e.g., Bielak, 1976; Chopra and Gutierrez, 1974; Veletsos, 1977). Hence, the contributions of higher modes are computed as if the structure were fixed at the base, and the maximum value of a response quantity is determined as for fixed-base structures but with the adjusted first-mode responses.

COMMENTARY FOR CHAPTER 20, SITE CLASSIFICATION PROCEDURE FOR SEISMIC DESIGN

C20.1 SITE CLASSIFICATION

Site classification procedures are given in Chapter 20 for the purpose of classifying the site and determining site coefficients and site-adjusted maximum considered earthquake ground motions in accordance with Section 11.4.3. Site classification procedures are also used to define the site conditions for which site-specific site response analyses are required to obtain site ground motions in accordance with Section 11.4.7 and Chapter 21.

C20.3 SITE CLASS DEFINITIONS

C20.3.1 Site Class F. Site conditions for which the site coefficients F_a and F_v in Tables 11.4-1 and 11.4-2 may not be applicable and for which site-response analyses are required by Section 11.4.7. For short-period structures it is permissible to determine values of F_a and F_v assuming that liquefaction does not occur, because ground motion data obtained in liquefied soil areas during earthquakes indicate that short-period ground motions generally are attenuated due to liquefaction whereas long-period ground motions may be amplified. This exception does not affect the requirements in Section 11.8 to assess liquefaction potential as a geologic hazard and to develop hazard mitigation measures as required.

C20.3.2 through C20.3.5. These sections and Table 20.3-1 provide definitions for Site Classes A through E. Except for the additional definitions for Site Class E in Section 20.3.2, the site classes are defined fundamentally in terms of the average small-strain shear wave velocity in the top 100 feet (30 meters) of the soil or rock profile. If shear wave velocities are available for the site, they should be used to classify the site. However, recognizing that in many cases shear wave velocities are not available for the site, alternative definitions of the site classes also are included. These definitions are based on geotechnical parameters: standard penetration resistance for cohesionless soils and rock, and standard penetration resistance and undrained shear strength for cohesive soils. The alternative definitions are intended to be conservative since the correlation between site coefficients and these geotechnical parameters is more uncertain than the correlation with shear wave velocity. That is, values of F_a and F_v will tend to be smaller if the site class is based on shear wave velocity rather than on the geotechnical parameters. Also, the site class definitions should not be interpreted as implying any specific numerical correlation between shear-wave velocity and standard penetration resistance or undrained shear strength.

Although the site class definitions in Sections 20.3.2 through 20.3.5 are straightforward, there are aspects of these assessments that may require additional judgment and interpretation. Highly variable subsurface conditions beneath a building footprint could result in overly conservative or unconservative site classification. Isolated soft soil layers within an otherwise firm soil site may not affect the overall site response if the predominant soil conditions do not include such strata. Conversely, site response studies have shown that continuous, thin, soft clay strata may affect the site amplification.

The site class should reflect the soil conditions that will affect the ground motion input to the structure or a significant portion of the structure. For structures receiving substantial ground motion input from shallow soils (for example, structures with shallow spread footings, with laterally flexible piles, or with basements where substantial ground motion input to the structure may come through the side walls), it is reasonable to classify the site on the basis of the top 100 feet (30 meters) of soils below the ground surface. Conversely, for structures with basements supported on firm soils or rock below soft soils, it may be reasonable to classify the site on the basis of the soils or rock below the mat, if it can be justified that the soft soils contribute very little to the response of the structure.

Buildings on sites with sloping bedrock or having highly variable soil deposits across the building area require careful study since the input motion may vary across the building (for example, if a portion of the building is on rock and the rest is over weak soils). Site-specific studies including two- or three-dimensional modeling may be used in such cases to evaluate the subsurface conditions and site and superstructure response. Other conditions that may warrant site-specific evaluation include the presence of low shear wave velocity soils below a depth of 100 feet (30 meters), location of the site in a sedimentary basin, or subsurface or topographic conditions with strong two- and three-dimensional site-response effects. Individuals with appropriate expertise in seismic ground motions should participate in evaluations of the need for and nature of such site-specific studies.

C20.4 DEFINITION OF SITE CLASS PARAMETERS

Section 20.4 provides formulas for defining Site Classes in accordance with definitions in Section 20.3 and Table 20.3-1. Equation 20.4-1 is for determining the effective average small-strain shear-wave velocity, $\overline{v}_s$, to a depth of 100 feet (30

meters) at a site. This equation defines $\overline{v}_s$ as 100 feet (30 meters) divided by the sum of the times for a shear wave to travel through each layer within the upper 100 feet (30 meters), where travel time for each layer is calculated as the layer thickness divided by the small-strain shear wave velocity for the layer. It is important that this method of averaging be used as it may result in a significantly lower effective average shear wave velocity than the velocity that would be obtained by directly averaging the velocities of the individual layers.

For example, consider a soil profile having four 25-foot-thick layers with shear wave velocities of 500, 1,000, 1,500, and 2,000 ft/s. The arithmetic average of the shear wave velocities is 1250 ft/s (corresponding to Site Class C), but Equation 20.4-1 produces a value of 960 ft/s (corresponding to Site Class D). The Equation 20.4-1 value is appropriate as the four layers are being represented by one layer with the same wave passage time.

Equation 20.4-2 is for classifying the site using the average standard penetration resistance blow count, $\overline{N}$, for cohesionless soils, cohesive soils, and rock in the upper 100 feet (30 meters). A method of averaging analogous to the method of Equation 20.4-1 for shear wave velocity is used. The maximum value of N that may be used for any depth of measurement in soil or rock is 100 blows/foot. For the common situation where rock is encountered, the standard penetration resistance, N, for rock layers is taken as 100.

Equations 20.4-3 and 20.4-4 are for classifying the site using the standard penetration resistance of cohesionless soil layers, N_{ch}, and the undrained shear strength of cohesive soil layers, s_u, within the top 100 feet (30 meters). These equations are provided as an alternative to using Equation 20.4-2 for which N-values in all geologic materials in the top 100 feet (30 meters) are used. Where using Equations 20.4-3 and 20.4-4, only the respective thicknesses of cohesionless soils and cohesive soils within the top 100 feet (30 meters) are used.

COMMENTARY FOR CHAPTER 21, SITE-SPECIFIC GROUND MOTION PROCEDURES FOR SEISMIC DESIGN

GENERAL

Site-specific procedures for computing earthquake ground motions include dynamic site response analyses and probabilistic and deterministic seismic hazard analyses (PSHA and DSHA), which may include dynamic site response analysis as part of the calculation. Use of site-specific procedures may be required in lieu of the general procedure in Sections 11.4.1 through 11.4.6; Section C11.4.7 explains the conditions under which the use of these procedures is required. Such studies must be comprehensive and incorporate current scientific interpretations. Because there is typically more than one scientifically credible alternative for models and parameter values used to characterize seismic sources and ground motions, it is important to formally incorporate these uncertainties in a site-specific analysis. For example, uncertainties may exist in seismic source location, extent and geometry; maximum earthquake magnitude; earthquake recurrence rate; ground-motion attenuation; local site conditions, including soil layering and dynamic soil properties; and possible two- or three-dimensional wave-propagation effects. The use of peer review for a site-specific ground-motion analysis is encouraged.

Site-specific ground-motion analysis can consist of one of the following approaches: (a) PSHA and possibly DSHA if the site is near an active fault, (b) PSHA/DSHA followed by dynamic site-response analysis, and (c) dynamic site response analysis only. The first approach is used to compute ground motions for bedrock or stiff soil conditions (not softer than Site Class D). In this approach, if the site consists of stiff soil overlying bedrock, for example, the analyst has the option of either (a) computing the bedrock motion from the PSHA/DSHA and then using the site-coefficient (F_a and F_v) tables in Section 11.4.3 to adjust for the stiff soil overburden or (b) computing the response spectrum at the ground surface directly from the PSHA/DSHA. The latter requires the use of attenuation equations for computing stiff soil-site response spectra (instead of bedrock response spectra).

The second approach is used where softer soils overlie the bedrock or stiff soils. The third approach assumes that a site-specific PSHA/DSHA is not necessary, but that a dynamic site response analysis should or must be performed. This analysis requires the definition of an outcrop ground motion, which can be based on the 5 percent damped response spectrum computed from the PSHA/DSHA or obtained from the general procedure in Section 11.4. A representative set of acceleration time histories are selected and scaled to be compatible with this outcrop spectrum. Dynamic site response analyses using these acceleration histories as input are used to compute motions at the ground surface. The response spectra of these surface motions are used to define a maximum considered earthquake (MCE) ground motion response spectrum.

The approaches described above have advantages and disadvantages. In many cases, user preference governs the selection, but geotechnical conditions at the site may dictate the use of one approach over the other. On the one hand, if bedrock is at a depth much greater than the extent of the site geotechnical investigations, the direct approach of computing the ground-surface motion in the PSHA/DSHA may be more reasonable. On the other hand, if bedrock is shallow and a large impedance contrast exists between it and the overlying soil (i.e., density times shear-wave velocity of bedrock is much greater than that of the soil), the two-step approach might be more appropriate.

Use of peak ground acceleration as the anchor for a generalized site-dependent response spectrum is discouraged because sufficiently robust ground-motion attenuation relations are available for computing response spectra in western United States and eastern United States tectonic environments.

C21.1 SITE RESPONSE ANALYSIS

C21.1.1 Base Ground Motions. Ground motion acceleration histories that are representative of horizontal rock motions at the site are required as input to the soil model. Where a site-specific ground motion hazard analysis is not performed, the MCE response spectrum for Site Class B (rock) is defined using the general procedure described in Section 11.4.1. If the model is terminated in material of Site Class A, C, or D, the input MCE response spectrum is adjusted in accordance with Section 11.4.3. The United States Geological Survey national seismic hazard mapping project website (http://earthquake.cr.usgs.gov/research/hazmaps/) includes hazard deaggregation options that can be used to evaluate the predominant types of earthquake sources, magnitudes, and distances contributing to the probabilistic ground-motion hazard. Sources of recorded acceleration time histories include the databases of the Consortium of Organizations for Strong Motion Observation Systems (COSMOS) Virtual Data Center website (db.cosmos-eq.org) and the Pacific Earthquake Engineering Research Center (PEER) Strong Motion Data Base website (http://peer.berkeley.edu/products/strong_ground_motion_db.html/), and the United States National Center for Engineering

Strong Motion Data (NCESMD) website (http://www.strongmotioncenter.org). Ground motion acceleration histories at these sites generally were recorded at the ground surface and hence apply for an outcropping condition and should be specified as such in the input to the site response analysis code (see Kwok et al., 2007, for additional details).

C21.1.2 Site Condition Modeling. Modeling criteria are established by site-specific geotechnical investigations that should include: (a) borings with sampling, (b) standard penetration tests (SPTs), cone penetrometer tests (CPTs), and/or other subsurface investigative techniques, and (c) laboratory testing to establish the soil types, properties, and layering. The depth to rock or stiff soil material should be established from these investigations. Investigation should extend to bedrock or, for very deep soil profiles, to material in which the model will be terminated. While it is preferable to measure shear wave velocities in all soil layers, it is also possible to estimate shear wave velocities based on measurements available for similar soils in the local area or through correlations with soil types and properties. A number of such correlations are summarized by Kramer (1996).

Typically, a one-dimensional soil column extending from the ground surface to bedrock is adequate to capture first-order site response characteristics. For very deep soils, the model of the soil columns may extend to very stiff or very dense soils at depth in the column. Two- or three-dimensional models should be considered for critical projects when two- or three-dimensional wave propagation effects may be significant (for example, sloping ground sites). The soil layers in a one-dimensional model are characterized by their total unit weights and shear wave velocities from which low-strain (maximum) shear moduli may be obtained, and by relationships defining the nonlinear shear stress-strain behavior of the soils. The required relationships for analysis are often in the form of curves that describe the variation of soil shear modulus with shear strain (modulus reduction curves) and by curves that describe the variation of soil damping with shear strain (damping curves). In a two- or three-dimensional model, compression wave velocities or moduli or Poisson ratios also are required. In an analysis to estimate the effects of liquefaction on soil site response, the nonlinear soil model also must incorporate the buildup of soil pore water pressures and the consequent reductions of soil stiffness and strength. Typically, modulus reduction curves and damping curves are selected on the basis of published relationships for similar soils (for example, Vucetic and Dobry, 1991; Electric Power Research Institute, 1993; Darendeli, 2001; Menq, 2003; Zhang et al., 2005). Site-specific laboratory dynamic tests on soil samples to establish nonlinear soil characteristics can be considered where published relationships are judged to be inadequate for the types of soils present at the site. Shear and compression wave velocities and associated maximum moduli should be selected based on field tests to determine these parameters or, if such tests are not possible, on published relationships and experience for similar soils in the local area. The uncertainty in the selected maximum shear moduli, modulus reduction and damping curves, and other soil properties should be estimated (see Darendeli, 2001; and Zhang et al., 2008). Consideration of the range of stiffnesses prescribed in Section 12.13.3 (increasing and decreasing by 50 percent) is recommended.

C21.1.3 Site Response Analysis and Computed Results. Analytical methods may be equivalent linear or nonlinear. Frequently used computer programs for one-dimensional analysis include the equivalent linear program SHAKE (Schnabel et al., 1972; Idriss and Sun, 1992) and the nonlinear programs FLAC (Itasca, 2005), DESRA-2 (Lee and Finn, 1978), MARDES (Chang et al., 1991), SUMDES (Li et al., 1992), DMOD_2 (Matasovic, 2006), DEEPSOIL (Hashash and Park, 2001), TESS (Pyke, 2000), and OpenSees (Ragheb, 1994; Parra, 1996; Yang, 2000). If the soil response induces large strains in the soil (such as for high acceleration levels and soft soils), nonlinear programs may be preferable to equivalent linear programs. For analysis of liquefaction effects on site response, computer programs incorporating pore water pressure development (effective stress analyses) should be used (for example, FLAC, DESRA-2, SUMDES, D-MOD, TESS, DEEPSOIL, and OpenSees). Response spectra of output motions at the ground surface are calculated as the ratios of response spectra of ground-surface motions to input outcropping rock motions. Typically, an average of the response spectral ratio curves is obtained and multiplied by the input MCE response spectrum to obtain the MCE ground-surface response spectrum. Alternatively, the results of site-response analyses can be used as part of the PSHA using procedures described by Goulet et al. (2007) and programmed for use in OpenSHA (www.opensha.org; Field et al., 2005). Sensitivity analyses to evaluate effects of soil-property uncertainties should be conducted and considered in developing the final MCE response spectrum.

C21.2 GROUND MOTION HAZARD ANALYSIS

Uncertainties in the characterizations of the key seismic sources (tectonic provinces, zones of seismicity, and active faults), with respect to location, earthquake recurrence, and maximum earthquake magnitude, must be considered in the ground motion hazard analysis. Uncertainties in the ground-motion models are typically included by incorporating more than one ground-motion attenuation equation. However, these equations may underestimate the intermediate- and long-period motion from large earthquakes on nearby active faults due to directivity and directionality effects mentioned in C11.4.7. The probabilistic seismic hazard analysis code can be modified to account for these effects in a consistent probabilistic manner, or a deterministic adjustment can be made to the probabilistic MCE response spectrum using methods in Somerville et al. (1997) and Abrahamson (2000) or more recent procedures. If the deterministic adjustment is used, then judgment must be

exercised in selecting the parameters comprising these methods. The worst-case scenario yielding the maximum possible increase in motion from directivity/directionality effects is acknowledged to be conservative, but it offers an upper-bound solution to help gauge the appropriate level for the MCE response spectrum.

Site-response effects in PSHA generally should be evaluated by using the site term in the ground-motion prediction equations. This term is generally a scale factor or a function of V_{s30} = average shear-wave velocity in the upper 30 meters. Site-specific dynamic response analyses can also be performed as described in Section C21.1.

C21.2.1 Probabilistic MCE. PSHA methods are sufficient to define the MCE ground motion at all locations except those near highly active faults. Descriptions of current PSHA methods can be found in McGuire (2004).

C21.2.2 Deterministic MCE. Ground motions for the deterministic MCE shall be based on characteristic earthquakes on all known active faults in a region. The magnitude of a characteristic earthquake on a given fault should be a best estimate of the maximum magnitude capable for that fault but not less than the largest magnitude that has occurred historically on the fault. The maximum magnitude should be estimated considering all seismic-geologic evidence for the fault, including fault length and paleoseismic observations. For faults characterized as having more than a single segment, the potential for rupture of multiple segments in a single earthquake should be considered in assessing the characteristic maximum magnitude for the fault.

For consistency, the same attenuation equations used in the PSHA should be used in the DSHA. Adjustments for directivity/directional effects should also be made, when appropriate. In some cases, ground-motion simulation methods may be appropriate for the estimation of long-period motions at sites in deep sedimentary basins or from great ($M \geq 8$) or giant ($M \geq 9$) earthquakes, for which recorded ground-motion data are lacking.

As a point of clarification, the deterministic lower limit spectrum on the MCE (Figure 21.2-1) extends to zero period in the same manner as the design response spectrum of Figure 11.4-1. The spectrum in Figure 21.2-1 is simply a schematic illustrating the lower bounds for the constant spectral acceleration ($S_{aM} = 1.5F_a$) and constant spectral velocity ($S_{aM} = 0.6F_v/T$) portions of the spectrum. The transition in the deterministic lower limit spectrum from the $1.5F_a$ plateau to zero period occurs at a period (in seconds) of $0.08F_v/F_a$ which is derived in the same manner as T_0 in Section 11.4.5. From this period to zero period, where the ordinate is $0.6F_a$, the deterministic lower limit spectrum is a straight line, similar to the design response spectrum in the period band, 0 to T_0.

C21.3 DESIGN RESPONSE SPECTRUM

Eighty percent of the design response spectrum determined in accordance with Section 11.4.5 was established as the lower limit to prevent the possibility of site-specific studies generating unreasonably low ground motions from potential misapplication of site-specific procedures or misinterpretation or mistakes in the quantification of the basic inputs to these procedures. Even if site-specific studies were correctly performed and resulted in ground-motion response spectra less than the 80 percent lower limit, the uncertainty in the seismic potential and ground-motion attenuation across the United States was recognized in setting this limit. Under these circumstances, the allowance of up to a 20 percent reduction in the design response spectrum based on site-specific studies was considered reasonable.

C21.4 DESIGN ACCELERATION PARAMETERS

The 90 percent lower limit rule, which can affect the determination of S_{DS}, was inserted because it was recognized that site-specific studies could produce response spectra with ordinates at periods greater than 0.2 second that were significantly greater than those at 0.2 second. Similarly, the rule that requires that S_{D1} be taken as the larger of the spectral acceleration at a period of 1 second and two times the spectral acceleration at a period of 2 seconds accounts for the possibility that the assumed $1/T$ proportionality for the constant velocity portion of the design response spectrum begins at periods greater than 1 second or is actually $1/T^n$ (where $n < 1$). Thus, this rule leads to more accurate spectral ordinates at periods around 2 seconds and conservative estimates at shorter periods. However, the conservatism is unlikely to be excessive.

COMMENTARY TO CHAPTER 22, SEISMIC GROUND MOTION AND LONG-PERIOD TRANSITION MAPS

SEISMIC GROUND MOTION MAPS

ASCE/SEI 7-05 continues to use contour maps of spectral response acceleration (Figures 22-1 through 22-14). The spectral acceleration design maps were prepared by the U.S. Geological Survey (USGS) based on USGS probabilistic maps of the 48 conterminous states (2002), Alaska (1998), Hawaii (1998), and Puerto Rico/Virgin Islands (2003) with modifications based on the 1997 recommendations of the Building Seismic Safety Council. The maps of the 48 states and Puerto Rico/Virgin Islands have been updated from the 2002 edition of the standard but the maps of Alaska, Hawaii, Guam, and Tutuila are unchanged. The USGS also has developed a companion software program that calculates location-specific spectral values based on latitude and longitude or zip code; use of zip codes is discouraged in regions where ground-motion values vary substantially over a short distance. The calculated values are based on the data used to prepare the maps. The spectral values should be adjusted for Site Class effects using the Site Classification Procedure in Section 20 and the site coefficients in Section 11.4. Latitude and longitude for a given address can be found at a variety of websites. The companion software program may be accessed at the USGS website (http://earthquake.usgs.gov/designmaps). The software program should be used to establish spectral values for design because the maps found in ASCE/SEI 7-05 are too small to provide accurate spectral values for many sites.

LONG-PERIOD TRANSITION MAPS

The maps of the long-period transition period, T_L, (Figures 22-15 through 22-20) were introduced in ASCE/SEI 7-05. They were prepared by the USGS in response to BSSC recommendations and subsequently included in the 2003 edition of the *Provisions*. See Section C11.4.5 for a discussion of the technical basis of these maps. The value of T_L obtained from these maps is used in Equation 11.4-7 to determine values of S_a for periods greater than T_L.

The exception in Section 15.7.6.1, regarding the calculation of S_{ac}, the convective response spectral acceleration for tank response, is intended to provide the user the option of computing this acceleration with three different types of site-specific procedures: (a) the procedures in Chapter 21, provided they cover the natural period band containing T_c, the fundamental convective period of the tank-fluid system, (b) ground-motion simulation methods using seismological models, and (c) analysis of representative accelerogram data. Elaboration of these procedures is provided below.

With regard to the first procedure, attenuation equations have been developed for the western United States (Next Generation Attenuation, Power et al., 2006, 2008) and for the central and eastern United States (e.g., Somerville et al., 2001) that cover the period band, 0 to 10 seconds. Thus, for $T_c \leq 10$ seconds, the fundamental convective period range for nearly all storage tanks, these attenuation equations can be used in the same PSHA/DSHA procedures described in Chapter 21 to compute S_a (T_c). The 1.5 factor in Equation 15.7-11, which converts a 5 percent damped spectral acceleration to a 0.5 percent damped value, could then be applied to obtain S_{ac}. Alternatively, this factor could be established by statistical analysis of 0.5 percent damped and 5 percent damped response spectra of accelerograms representative of the ground motion expected at the site.

In some regions of the United States, such as Pacific Northwest and southern Alaska, where subduction-zone earthquakes dominate the ground-motion hazard, attenuation equations for these events only extend to periods between 3 and 5 s, depending on the equation. Thus, for tanks with T_c greater than these periods, other site-specific methods are required.

The second site-specific method to obtain S_a at long periods is simulation through the use of seismological models of fault rupture and wave propagation (Graves and Pitarka, 2004; Hartzell and Heaton, 1983; Hartzell et al., 1999; Liu et al., 2006; Zeng et al., 1994). These models could range from simple seismic source-theory and wave-propagation models, which currently form the basis for many of the attenuation equations used in the central and eastern United States for example, to more complex numerical models that incorporate finite fault rupture for scenario earthquakes and seismic wave propagation through 2-D or 3-D models of the regional geology, which may include basins. These models are particularly attractive for computing long-period ground motions from great earthquakes ($M_w \geq \sim 8$) because ground-motion data are limited for these events. Furthermore, the models are more accurate for predicting longer-period ground motions because: (a) seismographic recordings may be used to calibrate these models and (b) the general nature of the 2-D or 3-D regional geology is typically fairly well resolved at these periods and can be much simpler than would be required for accurate prediction of shorter period motions.

A third site-specific method is the analysis of the response spectra of representative accelerograms that have accurately recorded long-period motions to periods greater than T_c. As T_c increases, the number of qualified records decreases.

However, as digital accelerographs continue to replace analog accelerographs, more recordings with accurate long-period motions will become available. Nevertheless, a number of analog and digital recordings of large and great earthquakes are available that have accurate long-period motions to 8 seconds and beyond. Subsets of these records, representative of the earthquake(s) controlling the ground-motion hazard at a site, can be selected. The 0.5 percent damped response spectra of the records can be scaled using seismic source theory to adjust them to the magnitude and distance of the controlling earthquake. The levels of the scaled response spectra at periods around T_c can be used to determine S_{ac}. If the subset of representative records is limited, then this method should be used in conjunction with the aforementioned simulation methods.

PART 3, RESOURCE PAPERS (RP) ON SPECIAL TOPICS IN SEISMIC DESIGN

This part of the 2009 NEHRP Recommended Seismic Provisions consists of a series of resource papers that include:

- *Proposals for code and standard changes reflecting new and innovative concepts or technologies that are judged, at the time of publication of this edition of the Provisions, to require additional exposure to those who use codes and standards and to possibly require systematic trial use. Some of these potential future changes are formatted for direct adoption while others discuss only the thrust of the proposed change.*
- *Discussions of topics that historically have been difficult to adequately codify. These papers provide background information intended to stimulate further discussion and research and, eventually, code change proposals.*

Like Parts 1 and 2 of this volume, these resource papers have been approved for inclusion in this volume by both the 2009 Provisions Update Committee and the BSSC membership.

Comments and questions about the topics treated in these Part 3 resource papers should be addressed to:

Building Seismic Safety Council

Resource Paper 1

ALTERNATE MATERIALS, DESIGN, AND METHODS OF CONSTRUCTION

Early in its deliberations, the 2009 Provisions Update Committee (PUC) established Issue Team 1, Performance Criteria, to develop a proposal that would encourage the development of construction equivalent to that provided by prescriptive provisions but possibly offering economic, performance, or construction speed advantages. The PUC took this step in light of an ongoing FEMA-funded project to develop a recommended methodology for reliably quantifying building system performance and response parameters for use in seismic design, in response to growing interest in performance-based design and its use to develop alternate designs equivalent to prescriptive code provisions, and in recognition of the fact that a lack of guidance on methods of approval for such submittals might discourage the creation of needed review processes in some jurisdictions.

This paper was initially prepared by BSSC 2009 Issue Team 1 as a proposal for a Provisions Part 1 modification to Section 11.1.4 of ASCE/SEI 7-05. The voting by the BSSC member organizations, however, resulted in many comments about: use of the new methodology prior to completion of the FEMA project and/or prior to complete vetting of the project recommendations, approval methods for components and products on a smaller scale than full building systems, and the lack of specificity in the suggested approval processes. Although the issue team developed complete responses to these comments, the majority of the team recommended interim placement in Part 3 of the Provisions. Due to the high interest and need for guidance on approval of submittals under the Alternate Means section, it is recommended that this or a similar change be considered for inclusion in ASCE/SEI 7-05 as soon as possible.

PROPOSED CHANGE

Rearrange ASCE/SEI 7-05 Section 11.1.4.1 and add new Sec 11.1.4.2 as shown below (additions underlined).

11.1.4 Alternate Materials, Design, and Methods of Construction.

11.1.4.1 General. The provisions of this standard are not intended to prevent the use of any material, alternate design method, or alternate method of construction not specifically prescribed, provided that any such alternate has been approved and its use authorized by the authority having jurisdiction. The authority having jurisdiction may approve any such alternate, provided that the authority finds that the alternate is satisfactory and complies with the intent of the provisions of this standard, and that the alternate is, for the purpose intended, at least the equivalent of that prescribed in this standard in suitability, effectiveness, durability, and seismic resistance.

11.1.4.2 Approval of Proposals Under Sec 11.1.4. Nothing in this section shall limit the ability of the authority having jurisdiction to develop or accept general requirements for proposals under Section 11.1.4 or specific requirements for particular components or systems, such as acceptance of reports from evaluation services or other demonstration of equivalence as specified in Section 11.1.4.1. In the absence of such criteria, the approval process shall include the following elements:

11.1.4.2.1 Peer Review. Peer review of the preliminary submittal, final design, and/or construction documents.

11.1.4.2.2 Preliminary Submittal. A submittal of a detailed description and, if applicable, design criteria for the alternate material or method, for approval by the authority having jurisdiction, prior to application for a building permit.

11.1.4.2.3 Structural Design Criteria. For submittals requesting use of alternate materials, alternate design methods or alternate methods of construction for the complete seismic-force-resisting system, a structural design criteria shall be included based on the seismic performance for the Performance Category, as described in the 2006 International Code Council Performance Code, that is equivalent to the Occupancy Category of the building.

The design criteria submittal shall demonstrate how the required seismic performance will be met by generally following one of the two methods described below:

1. Nonlinear procedures described in ASCE/SEI 41-06, *Seismic Rehabilitation of Existing Buildings*.
2. Probabilistic nonlinear analysis methods of *Quantification of Building Seismic Performance Factor*, FEMA P-695. Using these methods, it shall be demonstrated that for the required performance objectives there is an acceptably low probability of not reaching the specified performance level, given the specified ground motion.

11.1.4.2.4 Nonstructural Design Criteria. For seismic protection of nonstructural components not part of a designated seismic system, the design shall demonstrate that the components and systems are capable of remaining secured to the structure and will not generate life-threatening debris under the Design Earthquake Ground Motion. For designated seismic systems and components of such systems, the design shall demonstrate that the components and systems will be capable of remaining functional following design level shaking. The procedures of Section 13.2.5 and 13.2.6 may be applied as satisfactory fulfillment of these requirements.

Resource Paper 2

NONLINEAR STATIC PROCEDURE

This resource paper was prepared by Technical Subcommittee 2, Design Criteria and Analysis and Advanced Technologies, as a replacement for the Appendix to Chapter 5 of the 2003 edition of the NEHRP Recommended Provisions. It revises the information on the nonlinear static procedure (NSP) to allow its use in design of regular buildings less than 40 feet in height. The principal value of this approach as currently presented is for the design of buildings that are controlled by drift limits. Such buildings can be designed to have sufficient stiffness without using the equivalent lateral force (ELF) procedure and to have sufficient strength without conducting detailed member evaluations ($R_d < R/\Omega_0$). In the future, the height limitation may be relaxed if, for example, the NSP is used in conjunction with a nonlinear dynamic analysis.

Because requirements for the nonlinear static procedure are now specified in ASCE/SEI 41-06, it is simpler to refer to that document than to write applicable requirements into the Provisions. Modifications to the ASCE/SEI 7-05 requirements are introduced here to maintain consistency with the nonlinear static procedure information presented in the 2003 Provisions.

The 40-foot height limit was selected based on the accuracy of response quantities determined for a three-story moment-frame structure; no height limit was identified in the FEMA-funded Applied Technology Council project on the evaluation of inelastic seismic analysis procedures (Improvement of Nonlinear Static Seismic Analysis Procedures, FEMA 440). Although higher modes will have a similar influence on ELF quantities, the higher base shear strengths and story shears of the ELF procedure will tend to result in smaller member ductility demands. Thus, precision in the NSP estimates is especially important when system strengths are lower than those resulting from use of the ELF approach, which evaluates member deformation demands in detail.

This resource paper simplifies the language used to establish whether lateral strength is nominally less than that required by the ELF procedure. This is now stated succinctly as $R_d > R/\Omega_o$. Section references have been harmonized with ASCE/SEI 7-05 section numbers. If adopted for ASCE/SEI 7-10 or subsequent editions, the chapter number assigned to the requirements portion of this paper will have to be substituted where "X" appears below.

REQUIREMENTS

X Nonlinear Static Procedure

X.1 Definitions

Target Displacement. An estimate of the maximum expected displacement of the control node, determined according to Section 3.3.3.3.2 of ASCE/SEI 41 Supplement1 using S_a defined as a design earthquake spectral response acceleration according to the 2009 *NEHRP Recommended Seismic Provisions* at the effective period.

X.2 Notation

Q_{Ei} Force in i^{th} member determined according to Section 12.15.8.
R_d The system strength ratio as determined by Equation X-1.
R_{max} The maximum strength ratio, defined by Equation 3-16 of ASCE/SEI 41 Supplement 1.
γ_i The deformations for member i.
Ω_0 See Section 11.3.

X.3 Applicability. Regular structures less than 40 feet in height in Occupancy Categories I and II may be designed using the nonlinear static procedure following the requirements of this chapter.

X.4 Seismic-force-resisting System. The seismic-force-resisting system shall conform to one of the types in Tables 12.2-1 and 15.4-1 and shall be in accordance with the seismic design category and height limitations indicated in these tables. The appropriate response modification coefficient, R, and system overstrength factor, Ω_0, identified in these tables shall be used, subject to the additional requirements of this chapter.

X.5 Modeling and Analysis. Modeling and analysis shall conform to Section 3.3.3 of ASCE/SEI 41 Supplement 1 except that: (a) S_a shall be defined as a design earthquake spectral response acceleration according to the *NEHRP Recommended Seismic Provisions* at the effective period and (b) the analysis shall be conducted for seismic actions occurring simultaneously with the effects of dead load in combination with not less than 25 percent of the required design live loads,

reduced as permitted for the area of a single floor. P-delta effects shall be included in the analysis model, and dead and live loads acting on the entire structure shall be represented in the model.

X.6 Maximum Strength Ratio. The system strength ratio, R_d, is given by Equation X-1 as follows:

$$R_d = \frac{S_a}{V_y / W} C_m \qquad \text{(X-1)}$$

where C_m, V_y, and W are as defined in Section 3.3.3.3.2 of ASCE/SEI 41 Supplement 1 and S_a is defined as a design earthquake spectral response acceleration according to the 2009 *NEHRP Recommended Seismic Provisions* at the effective period. Use of the nonlinear static procedure is not permitted when R_d exceeds R_{max}.

X.7 Story Drift. The design story drift, Δ, taken as the value obtained for each story at the step at which the target displacement is reached, shall not exceed the drift limit specified in Section 12.12.1 multiplied by $0.85R/C_d$.

X.8 Member Strength. In addition to satisfying the requirements of Section 12.15.9, member strengths also shall satisfy the requirements of Section 2.3 using $E = 0$, except that Section 12.4.3.2 shall apply when the effect of structural overstrength on the design seismic force must be considered. When the effect of structural overstrength is considered, the value of the individual member forces, Q_{Ei}, obtained from the analysis at the target displacement shall be taken in place of the quantity $\Omega_0 Q_E$.

X.9 Detailed Evaluation. Detailed evaluation satisfying Sections X.9.1and X.9.2 is required if R_d exceeds R/Ω_0.

X.9.1 Required Member Force and Deformation. For each nonlinear static analysis, the design response parameters, including the individual member forces, Q_{Ei}, and member deformations, γ_i, shall be taken as the values obtained from the analysis at the step at which the target displacement is reached.

X.9.2 Member Capacity. The adequacy of individual members and their connections to withstand the member forces, Q_{Ei}, and member deformations, γ_i, shall be evaluated based on laboratory test data for similar components. The effects of gravity and other loads on member deformation capacity shall be considered in these evaluations. The deformation of a member supporting gravity loads shall not exceed: (a) two-thirds of the deformation that results in loss of ability to support gravity loads and (b) two-thirds of the deformation at which the member strength has deteriorated to less than the 70 percent of the peak strength of the component model. The deformation of a member not required for gravity load support shall not exceed two-thirds of the value at which member strength has deteriorated to less than 70 percent of the peak strength of the component model. Alternatively, it shall be permissible to deem member deformation to be acceptable if the deformation does not exceed the value provided in ASCE/SEI 41 Supplement 1 for the Life Safety performance level.

Member forces shall be deemed acceptable if not in excess of expected capacities.

X.10 Design Review. A review of the design of the seismic-force-resisting system and the supporting structural analyses shall be performed by an independent team having experience in seismic analysis methods and the theory and application of nonlinear seismic analysis and structural behavior under earthquake loading. The team shall be composed of at least two members including at least one registered design professional. The design review shall include:

1. Review of any site-specific seismic criteria employed in the analysis including the development of site-specific spectra and
2. Review of the determination of the target displacement and effective yield strength of the structure.

For those structures with R_d exceeding R/Ω_0, the design review shall further include, but need not be limited to, the following:

1. Review of acceptance criteria used to demonstrate the adequacy of structural elements and systems to withstand the calculated force and deformation demands together with the laboratory and other data used to substantiate such criteria. Review of the acceptance criteria for nonlinear procedures given in ASCE/SEI 41 Supplement 1 shall be at the discretion of the design review team.
2. Review of the final design of the entire structural system and all supporting analyses.

The design review team shall issue a report that identifies, within the scope of the review, significant concerns and any departures from general conformance with the *NEHRP Recommended Provisions.*

COMMENTARY

This resource paper presents proposed requirements for nonlinear static analysis, a seismic analysis procedure also sometimes known as pushover analysis, for review and comment and for adoption into a subsequent edition of the *NEHRP Recommended Provisions*.

Although nonlinear static analysis has only recently been included in design provisions for new building construction, the procedure itself is not new and has been used for many years in both research and design applications. For example, nonlinear static analysis has been used for many years as a standard methodology in the design of the offshore platform structures for hydrodynamic effects and has been adopted recently in several standard methodologies for the seismic evaluation and rehabilitation of building structures, including the *Recommended Seismic Design Criteria for New Steel Moment-Frame Buildings* (FEMA 350, 2000), *Seismic Rehabilitation of Existing Buildings* (ASCE/SEI 41-06, 2007), and *Seismic Evaluation and Retrofit of Concrete Buildings* (Applied Technology Council, 1996). Nonlinear static analysis also forms the basis for earthquake loss estimation procedures contained in the earthquake module of the multihazard software application HAZUS-MH MR2 (FEMA, 2006) and its Advanced Engineering Building Module (FEMA, 2002). A critical review of and improvement to nonlinear static analysis methods, *Improvement of Nonlinear Static Seismic Analysis Procedures*, was published as FEMA 440 in 2005. Although it does not explicitly appear in the *Provisions*, the nonlinear static analysis methodology also forms the basis for the equivalent lateral force procedures contained in the provisions for base-isolated structures and structures with dampers.

One of the controversies surrounding the introduction of this methodology into the *Provisions* relates to the determination of the limit deformation (sometimes called a target displacement). Several methodologies for estimating the amount of deformation induced in a structure as a result of earthquake ground shaking have been proposed and are included in various adoptions of the procedure. The approach presented in this paper is based on statistical correlations of the displacements predicted by linear and nonlinear dynamic analyses of structures recommended in the FEMA 440 report (2005) on the evaluation of inelastic seismic analysis procedures.

A second controversy relates to the limited availability of consensus-based acceptance criteria to be used to determine the adequacy of a design once the forces and deformations produced by design earthquake ground shaking are estimated. It should be noted that this limitation applies equally to the nonlinear response history approach, which already has been adopted into building codes.

A third controversy relates to the effects of higher modes (or multi-degree-of-freedom effects for structures responding nonlinearly) on response quantities. FEMA 440 identifies significant disparities between response quantities determined by nonlinear static analysis and those determined by nonlinear dynamic analysis for all but low-rise structures; therefore, use of the nonlinear static procedure for the design of members proposed here is limited to structures 40 feet or less in height. This limitation has resulted in the nonlinear static procedure being located in Part 3 of the *Provisions*. The nonlinear static procedure may be used to ensure that structures designed according to the equivalent lateral force procedure achieve strengths comparable to code expectations. Interstory drifts are compared with tabulated allowable story drifts to maintain consistency with past practice, although it is recognized that larger interstory drifts should be anticipated due to higher mode or multi-degree-of-freedom effects.

Nonlinear static analysis provides a simplified method of directly evaluating nonlinear response of structures to strong earthquake ground shaking that can be an attractive alternative to the more complex procedures of nonlinear response history analysis. It may be useful for characterizing system strength and stiffness and for establishing that the structure develops a desirable inelastic mechanism.

Resource Paper 3

SEISMIC-RESPONSE-HISTORY ANALYSIS

This resource paper was developed by Technical Subcommittee 2, Design Criteria and Analysis and Advanced Technologies, as a replacement for ASCE/SEI 7-05 Chapter 16, Seismic Response-History Analysis. It reorganizes the chapter to eliminate redundancy as well as inconsistencies and duplication of ASCE/SEI 7-05 Chapter 12 analysis requirements. When response-history analyses (RHA) are used, they are commonly used as an maximum considered earthquake verification after a preliminary design has been completed. This paper adds a number of important requirements for RHA conducted at the risk-targeted maximum considered earthquake level. Feedback will be appreciated.

PROPOSED REPLACEMENT FOR ASCE/SEI 7-05 CHAPTER 16, SEISMIC-RESPONSE-HISTORY ANALYSIS

16.1 GENERAL REQUIREMENTS

A response-history analysis (RHA) shall consist of an analysis of a mathematical model of the structure to determine, through methods of numerical integration, its response to suites of ground motion acceleration histories. The analysis shall be performed in accordance with the requirements of this chapter. Structures with elements of the seismic-force-resisting system responding significantly beyond their elastic limit shall satisfy Section 16.3.12. When the analysis is used to validate a design that uses the exceptions in Section 16.1.1, the ground motions shall be scaled to the risk-targeted maximum considered earthquake (MCE_R) ground motion level in accordance with Section 16.2 and the acceptance criteria shall meet Section 16.4.

16.1.1 Design Requirements. The design of the structure shall meet all requirements for equivalent lateral force or modal response spectrum analysis in accordance with Section 12.6 except that specific exceptions to such requirements are permitted to be taken, provided the exceptions are:

1. Identified clearly in the documentation submitted for design review and
2. Justified through rational application of the RHA.

16.1.2 Level of Ground Motion. The analysis shall be based on the MCE_R ground motions defined in Section 11.4.

16.1.3 Occupancy Categories III and IV. For Occupancy Categories III and IV, the ground motion is in accordance with Section 16.1.2, but the acceptance criteria in accordance with Section 16.4 are more restrictive compared to values applicable to Occupancy Categories I and II. When alternative acceptance criteria are used, they shall be demonstrated to be consistent with the importance factor, *I*, in accordance with Section 11.5. Nonstructural elements shall be designed in accordance with Chapter 13 using I_p as required by Section 13.1.3.

16.2 GROUND MOTION

A suite of not less than seven appropriate ground motions shall be used in the analysis.

Appropriate ground motion acceleration histories shall be obtained from records of events having magnitudes, fault distances, and source mechanisms that are consistent with those that control the MCE_R. If a sufficient number of appropriate recorded ground motion records is not available, appropriate simulated or modified ground motion records are permitted to be used to as part of the total number required.

When applicable, the ground motion acceleration histories shall include near fault and directivity effects including direction of fault rupture and velocity pulses as appropriate.

16.2.1 Duration. Each response-history analysis shall be run for the full duration of the ground motion except that the first or last portion of the record is permitted to be truncated provided that the truncation does not significantly modify either the frequency content or the number of cycles of ground motion with an amplitude sufficient to induce nonlinear response.

16.2.2 Two-dimensional Analysis. When two-dimensional analyses are performed, each ground motion shall consist of a horizontal acceleration history. The ground motions shall be scaled such that the average value, over all ground motions, of the 5-percent-damped response spectra for the suite of motions is not less than the MCE_R response spectrum for the site for periods ranging from $0.2T$ to $1.5T$ where T is the natural period of the structure in the fundamental mode for the direction of response being analyzed.

16.2.3 Three-dimensional Analysis. When three-dimensional analysis is performed, ground motions shall consist of pairs of appropriate horizontal ground motion acceleration components. For each pair of horizontal ground motion components, a square root of the sum of the squares (SRSS) spectrum shall be constructed by taking the SRSS of the 5-percent-damped response spectra for the scaled components (for direct scaling, an identical scale factor is applied to both components of a pair). Each pair of motions shall be scaled such that for each period between $0.2T$ and $1.5T$, the average, over all component pairs, of the SRSS spectra does not fall below 1.3 times the corresponding ordinate of the MCE_R response spectrum by more than 10 percent.

16.3 MODELING AND ANALYSIS

Mathematical models shall conform to the requirements of Section 12.7. Design review requirements are described in Section 16.5.

16.3.1 Interaction of Elements. The analysis shall consider the interaction of all structural and nonstructural elements that can adversely affect the response of the structure to earthquake ground motions, including elements not designated as part of the seismic-force-resisting system.

16.3.2 Identification of Nonlinear Response. Documentation submitted for design review shall identify the elements in the seismic-force-resisting system (SFRS) designed for nonlinear seismic response. All other elements in the SFRS shall be demonstrated by analysis to remain essentially elastic (refer to Section 16.4.3).

16.3.3 Two-dimensional Analysis. A two-dimensional analysis model is permitted to be used if Section 12.7.3 does not require a three-dimensional model or if documentation submitted for design review demonstrates that the two-dimensional analysis captures all significant three-dimensional effects including plan torsion, non-orthogonal earthquake response, engagement of overturning resistance through flange effects or transverse coupling, and non-orthogonal effects on strong-column weak-beam behavior.

16.3.4 Direction of Loading. Two-dimensional modeling shall account for direction of loading effects in accordance with Section 12.5.

16.3.5 Diaphragm Modeling. Floor and roof diaphragms responding linearly shall be modeled according to Section 12.3.1.

Diaphragms responding beyond the linear range shall be modeled using nonlinear force-deformation relationships if required by Section 16.3.11

16.3.6 Seismic Mass. The masses used in the analytical model shall be as defined in Section 12.7.2. When modal computation techniques are used for response-history computation, Section 12.9.1 shall be satisfied and the results shall be multiplied by the ratio of the total mass to the mass participating in the modes included in the analysis.

16.3.7 Gravity Load. The modeling of and demands on elements in the analysis model shall be determined considering earthquake effects acting in the presence of expected gravity loads. For building structures with ordinary occupancies, expected gravity loads shall be taken as $1.0D + 0.5L$

For live loads subject to reduction on the basis of area in accordance with Section 4.8, the tributary area shall be permitted to be taken as the total floor area in the structure subject to that live load and K_{LL} shall be set to 1.0.

For other occupancies or when the expected gravity load is not well represented by $1.0D + 0.5L$ or is highly variable, the analysis shall be modified accordingly.

16.3.8 P-delta Effects. P-delta effects shall be included in the analysis using the gravity loads defined in Section 16.3.7.

16.3.9 Inherent Plan Torsion. Inherent plan torsion shall be included in accordance with Section 12.8.4.1.

16.3.10 Accidental Plan Torsion. If the accidental torsion requirements of Section 12.8.4.2 are included in the determination of the strength of the nonlinear elements of the structure and in the analysis used to meet the requirements of Section 16.1.1, inclusion of accidental torsion in the RHA is not required.

16.3.11 Nonlinear Modeling. The mathematical model shall directly account for the nonlinear hysteretic behavior of the members and connections that comprise the structural elements.

The hysteretic force-deformation behavior of elements shall be modeled consistent with applicable laboratory test data and shall account for all significant yielding, strength degradation, stiffness degradation, hysteretic pinching, and interaction effects indicated by such test data. Strength of elements shall be based on expected values considering material overstrength, strain hardening, and hysteretic strength degradation at the expected range of deformation. The behavior model shall not be extended to deformations beyond levels substantiated by test data.

Linear properties, consistent with the requirements of Section 12.7.3, are permitted to be used for those elements demonstrated by the analysis to remain within their linear range of response.

16.3.12 Stiffness. To the extent that such effects are significant for the MCE_R response, element properties shall account for the following:

1. Stiffness properties of reinforced concrete and reinforced masonry shall account for cracking and other phenomena that affect effective initial stiffness including strain penetration, bond slip, joint and panel zone deformation, and tension shift associated with shear cracking.
2. Stiffness properties of steel or other connected elements shall account for connection stiffness and, for moment frames, the effect of panel zone (beam-column joint) deformations.

16.3.13 Damping. The equivalent viscous damping level shall not exceed 5 percent of critical damping for any mode required to obtain the effective mass according to Section 12.7.2 unless substantiated. Documentation submitted for design review shall identify how damping effects are included in the RHA to account for energy dissipation that is not considered directly in the nonlinear analysis model.

16.4 ANALYSIS RESULTS

16.4.1 Design Values. The calculation of design values shall account for the signs of response parameters and the combinations of response parameters (e.g., axial force and bending moment) that can govern the design.

16.4.2 Analysis Results. The response parameters of interest shall be calculated for each ground motion used for the RHA. The peak value of each parameter shall be determined for each ground motion. The average of the peaks shall be used for checking acceptance criteria. When a combination of response parameters is important (e.g., for elements resisting both flexural and axial forces), these results shall be captured to be consistent with the acceptance criteria.

16.4.3 Acceptance Criteria for Ductile Behavior. Element response that satisfies the definition for deformation-controlled actions in Section 2.4.4.3 of ASCE/SEI 41 shall be evaluated on the basis of either nonlinear or linear behavior. If the calculated force in an element does not exceed 1.5 times its nominal strength, that element is permitted to be considered linear (essentially elastic).

16.4.3.1 Nonlinear Behavior of Ductile Elements. Member deformation shall not result in deterioration of its attainable member strength to less than 80 percent of the peak resistance. Deformation capacities shall be based on values tabulated in ASCE/SEI 41 or from laboratory test data for similar elements. When ASCE/SEI 41 is used, the following performance levels are to be used:

1. Collapse prevention for Occupancy Categories I and II,
2. Life safety for Occupancy Category IV, and
3. 80 percent of collapse prevention but not less than life safety for Occupancy Category III.

Documentation shall be submitted for design review to substantiate the adequacy of individual elements and their connections to withstand the deformation demands from the RHA.

16.4.3.2 Linear Behavior of Ductile Elements. Calculated force demands shall not exceed 150 percent of nominal capacities divided by the importance factor, *I*.

16.4.4 Acceptance Criteria for Nonductile Behavior. Any type of element response that does not satisfy the definition for deformation-controlled actions in Section 2.4.4.3 of ASCE/SEI 41 shall be evaluated on a linear basis. The demands from Section 16.4.2 shall not exceed the expected strength. Nominal strength is permitted to be used in lieu of expected strength.

16.4.5 Story Drift. The story drift ratio shall not exceed 1.5 times the limits of Section 12.12.1 for any story unless those elements not designated as part of the seismic-force-resisting system are capable of undergoing the calculated story drift for each RHA without collapse of the portion of the structure supported by those elements.

16.4.6 Stability. The structure shall be shown to be stable for the MCE_R ground motions.

16.5 Design Review. A design review of the seismic-force-resisting system, the structural analysis, and the documentation shall be performed by an independent team of registered design professionals in the appropriate disciplines and others experienced in seismic analysis methods and the theory and application of nonlinear seismic analysis and structural behavior under extreme cyclic loads. The design review shall include, but need not be limited to, the following:

1. Review of any site-specific seismic criteria employed in the analysis including the development of site-specific spectra and ground motion time histories.

2. Review of acceptance criteria used to demonstrate the adequacy of structural elements and systems to withstand the calculated force and deformation demands and laboratory and other data that substantiate these criteria.
3. Review of the preliminary design including the selection of structural system and the configuration of structural elements.
4. Review of the final design of the entire structural system and all supporting analyses.

Resource Paper 4

FOUNDATION GEOTECHNICAL ULTIMATE STRENGTH DESIGN AND FOUNDATION LOAD-DEFORMATION MODELING

(2003 *Provisions* Appendix to Chapter 7, Foundation Design Requirements)

This resource paper originally appeared as the appendix to Chapter 7, Foundation Design Requirements, of the 2003 NEHRP Recommended Provisions. It includes ultimate strength design (USD) procedures for the geotechnical design of foundations for trial use and evaluation by design professionals prior to adoption into a subsequent edition of the Provisions. Similarly, the resource paper presents criteria for the modeling of load-deformation characteristics of the foundation-soil system (foundation stiffness) for those analysis procedures in Chapter 5 of the 2003 Provisions that permit use of realistic assumptions for foundation stiffness rather than the assumption of a fixed base. Note that only format changes have been made and Provisions section numbers cited refer to the 2003 edition of the Provisions.

Practice for geotechnical foundation design has been based on allowable stresses with allowable foundation load capacities for dead plus live loads based on limiting long-term static settlements and providing a large factor of safety. In current practice, allowable soil stresses for dead plus live loads are typically increased by one-third for load combinations that include wind or seismic forces. The allowable stresses for dead plus live loads are often far below ultimate soil capacity. This resource paper's Provisions and the associated Commentary provide criteria and guidance for the direct use of ultimate foundation load capacity for load combinations that include seismic forces. The acceptance criteria cover both the analyses for fixed-base assumptions and analyses for linear and nonlinear modeling of foundation stiffness for flexible-base assumptions.

Although USD for foundations has not previously been included in design provisions for new buildings, the same basic principles used in this resource paper have been adapted to generate guidelines for the seismic evaluation and retrofit design of existing buildings (FEMA 273; FEMA 356; Applied Technology Council, 1996). The criteria and procedures presented herein for the nonlinear modeling of foundation stiffness combine a linear or multilinear stiffness and a limiting load capacity based on ultimate soil strength and are essentially the same as those presented in the publications cited above.

With respect to the adoption of USD procedures for geotechnical foundation design, the primary issue considered by the 2003 Provisions Update Committee and the BSSC member organizations was the impact of the proposed USD procedures on the size of foundations and the consequent effect on the potential for foundation rocking and building performance. A synopsis of two sets of design examples is presented at the end of this resource paper. The example results illustrate the expected effects of the methodology in that relative foundation sizes from USD vs. ASD are related to the factor of safety on load capacity under vertical dead plus live loads. When factors of safety are high, smaller foundations result from USD, but when factors of safety are low, it is possible that foundations may be larger using USD. Additional examples, including nonlinear dynamic analyses incorporating nonlinear load-deformation models for foundation soil stiffness and capacity, are warranted to further evaluate and possibly refine the methodologies and criteria presented in this paper. It is hoped that trial usage of the methodologies presented herein will allow the necessary consensus to be developed to permit later incorporation into the Provisions. Feedback will be appreciated.

APPENDIX TO 2003 *PROVISIONS* CHAPTER 7, FOUNDATION DESIGN REQUIREMENTS

A7.1 General

A7.1.1 Scope. This resource paper includes only those foundation requirements that are specifically related to seismic resistant construction. It assumes compliance with all other basic requirements which include, but are not limited to, requirements for the extent of the foundation investigation, fills to be present or to be placed in the area of the structure, slope stability, subsurface drainage, settlement control, and soil bearing and lateral soil pressure recommendations for loads acting without seismic forces.

A7.1.2 Definitions

Allowable foundation load capacity: See Section A7.2.2.

Ultimate foundation load capacity: See Section A7.2.2.

A7.1.3 Notation

Q_{as} Allowable foundation load capacity.

Q_{us} Ultimate foundation load capacity.

ϕ The strength reduction, capacity reduction, or resistance factor.

A7.2 General Design Requirements

The resisting capacities of the foundations, subjected to the load combinations prescribed elsewhere in these *Provisions*, shall meet the requirements of this resource paper.

A7.2.1 Foundation Components. The strength and detailing of foundation components under seismic loading conditions, including foundation elements and attachments of the foundation elements to the superstructure, shall comply with the requirements of Chapters 8, 9, 10, 11, or 12, unless otherwise specified in this chapter. The strength of foundation components shall not be less than that required for load combinations that do not include seismic load effects.

A7.2.2 Foundation Load Capacities. The vertical capacity of foundations (footings, piles, piers, mats or caissons) as limited by the soil shall be sufficient to support the structure for all prescribed load combinations without seismic forces, taking into account the settlement that the structure can withstand while providing an adequate factor of safety against failure. Such capacities are defined as allowable foundation load capacities, Q_{as}. For load combinations including seismic load effects as specified in Section 4.2.2, vertical, lateral, and rocking load capacities of foundations as limited by the soil shall be sufficient to resist loads with acceptable deformations, considering the short duration of loading, the dynamic properties of the soil, and the ultimate load capacities, Q_{us}, of the foundations under vertical, lateral, and rocking loading.

A7.2.2.1 Determination of Ultimate Foundation Load Capacities. Ultimate foundation load capacities shall be determined by a qualified geotechnical engineer based on geotechnical site investigations that include field and laboratory testing to determine soil classification and soil strength parameters, and/or capacities based on insitu testing of prototype foundations. For competent soils that do not undergo strength degradation under seismic loading, strength parameters for static loading conditions shall be used to compute ultimate load capacities for seismic design. For sensitive cohesive soils or saturated cohesionless soils, the potential for earthquake induced strength degradation shall be considered.

Ultimate foundation load capacities, Q_{us}, under vertical, lateral, and rocking loading shall be determined using accepted foundation design procedures and principles of plastic analysis. Calculated ultimate load capacities, Q_{us}, shall be best-estimated values using soil properties that are representative average values for individual foundations. Best-estimated values of Q_{us} shall be reduced by resistance factors (ϕ) to reflect uncertainties in site conditions and in the reliability of analysis methods. The factored foundation load capacity, ϕQ_{us}, shall then be used to check acceptance criteria, and as the foundation capacity in foundation nonlinear load-deformation models.

If ultimate foundation load capacities are determined based on geotechnical site investigations including laboratory or in-situ tests, ϕ factors equal to 0.8 for cohesive soils and 0.7 for cohesionless soils shall be used for vertical, lateral, and rocking resistance for all foundation types. If ultimate foundation load capacities are determined based on full-scale field-testing of prototype foundations, ϕ factors equal to 1.0 for cohesive soils and 0.9 for cohesionless soils are permitted.

A7.2.2.2 Acceptance Criteria. For linear analysis procedures (Sections 5.2, 5.3, and 5.4), factored foundation load capacities, ϕQ_{us}, shall not be exceeded for load combinations that include seismic load effects.

For the nonlinear response history procedure (Section 5.5) and the nonlinear static procedure (Appendix to Chapter 5), if the factored foundation load capacity, ϕQ_{us}, is reached during seismic loading, the potential significance of associated transient and permanent foundation displacements shall be evaluated. Foundation displacements are acceptable if they do not impair the continuing function of Seismic Use Group III structures or the life safety of any structure.

For nonlinear analysis procedures, an additional evaluation of structural behavior shall be performed to check potential changes in structural ductility demands due to higher than anticipated foundation capacity. For this additional evaluation, values of Q_{us} shall be increased by the factor $1/\phi$.

A7.2.3 Foundation Load-deformation Modeling. When permitted for the analysis procedures in Chapter 5 and the Appendix to Chapter 5, the load-deformation characteristics of the foundation-soil system (foundation stiffness), if included in the analysis, shall be modeled in accordance with the requirements of this section. For linear analysis methods, the linear load-deformation behavior of foundations shall be represented by an equivalent linear stiffness using soil properties that are compatible with the soil strain levels associated with the design earthquake motion. The strain-compatible shear modulus, G, and the associated strain-compatible shear wave velocity, v_S, needed for the evaluation of equivalent linear stiffness shall be determined using the criteria in Section 5.6.2.1.1 or based on a site-specific study. Parametric variations of not less than 50

percent increase and decrease in stiffness shall be incorporated in dynamic analyses unless smaller variations can be justified based on field measurements of dynamic soil properties or direct measurements of dynamic foundation stiffness.

For nonlinear analysis methods, the nonlinear load-deformation behavior of the foundation-soil system may be represented by a bilinear or multilinear curve having an initial equivalent linear stiffness and a limiting foundation capacity. The initial equivalent linear stiffness shall be determined as described above for linear analysis methods. The limiting foundation capacity shall be taken as the factored foundation load capacity, ϕQ_{us}. Parametric variations in analyses shall include: (1) a reduction in stiffness of 50 percent combined with a limiting foundation capacity, $\phi Q_{us,}$ and (2) an increase in stiffness of 50 percent combined with a limiting foundation capacity equal to Q_{us} increased by a factor $1/\phi$.

COMMENTARY

C-A7.2 General Design Requirements

C-A7.2.2 Foundation Load Capacities. In current geotechnical engineering practice, foundation design is based on allowable stresses, with allowable foundation load capacities, Q_{as}, for dead plus live loads based on limiting static settlements and providing a large factor of safety against exceeding ultimate capacities. In current practice, allowable soil stresses for dead plus live loads are increased by one-third for load combinations that include wind or seismic forces. The one-third increase is overly conservative if the allowable stresses for dead plus live loads are far below ultimate soil capacity. This resource paper provides guidance for the direct use of ultimate foundation load capacity, Q_{us}, for load combinations including seismic effects. It is required that foundations be capable of resisting loads with acceptable deformations considering the short duration of seismic loading, the dynamic properties of the soil, and the ultimate load capacities, Q_{us}, of the foundations under vertical, lateral, and rocking loading.

C-A7.2.2.1. Determination of Ultimate Foundation Load Capacities. For competent soils that are not expected to degrade in strength during seismic loading (e.g., due to partial or total liquefaction of cohesionless soils or strength reduction of sensitive clays), use of static soil strengths is recommended for determining ultimate foundation load capacities, Q_{us}. Use of static strengths is somewhat conservative for such soils because rate-of-loading effects tend to increase soil strengths for transient loading. Such rate effects are neglected because they may not result in significant strength increase for some soil types and are difficult to confidently estimate without special dynamic testing programs. The assessment of the potential for soil liquefaction or other mechanisms for reducing soil strengths is critical, because these effects may reduce soil strengths greatly below static strengths in susceptible soils.

The best-estimated ultimate vertical load capacity of footings, Q_{us}, should be determined using accepted foundation engineering practice. In the absence of moment loading, the ultimate vertical load capacity of a rectangular footing of width B and length L may be written as $Q_{us} = q_c BL$ where q_c = ultimate soil bearing pressure.

For rigid footings subject to moment and vertical load, contact stresses become concentrated at footing edges, particularly as footing uplift occurs. The ultimate moment capacity, M_{us}, of the footing as limited by the soil is dependent upon the ratio of the vertical load stress, q, to the ultimate soil bearing pressure q_c. Assuming that contact stresses are proportional to vertical displacements and remain elastic up to q_c, it can be shown that uplift will occur prior to plastic yielding of the soils when q/q_c is less than 0.5. If q/q_c is greater than 0.5, then the soil at the toe will yield prior to uplift. This is illustrated in Figure C-A7.2.2-1. In general the ultimate moment capacity of a rectangular footing may be expressed as:

$$M_{us} = \frac{LP}{2}\left(1 - \frac{q}{q_C}\right)$$

where P = vertical load, $q = P/BL$, B = footing width, and L = footing length in direction of rotation.

The ultimate lateral load capacity of a footing may be assumed equal to the sum of the best-estimated ultimate soil passive resistance against the vertical face of the footing plus the best-estimated ultimate soil friction force on the footing base. The determination of ultimate passive resistance should consider the potential contribution of friction on the face of the footing on the passive resistance.

For piles, the best-estimated ultimate vertical load capacity (for both axial compression and axial tensile loading) should be determined using accepted foundation engineering practice. When evaluating axial tensile load capacity, consideration should be given to the capability of pile cap and splice connections to take tensile loads.

The ultimate moment capacity of a pile group should be determined assuming a rigid pile cap, leading to an initial triangular distribution of axial pile loading from applied overturning moments. However, full axial capacity of piles may be mobilized when computing ultimate moment capacity, in a manner analogous to that described for a footing in Figure C-A7.2.2-1. The

ultimate lateral capacity of a pile group may be assumed equal to the best-estimated ultimate passive resistance acting against the edge of the pile cap and the additional passive resistance provided by piles.

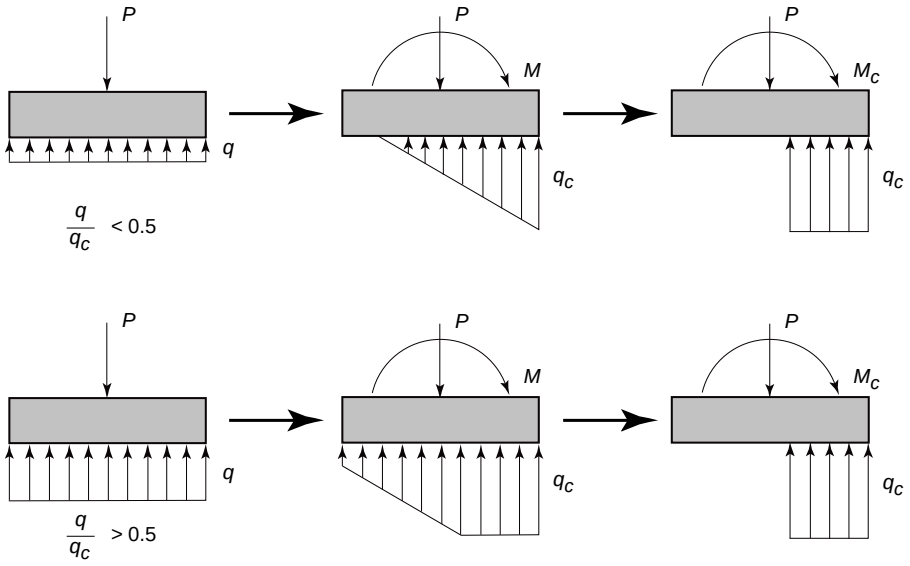

Figure C-A7.2.2-1.

Resistance factors, ϕ, are provided to factor ultimate foundation load capacities, Q_{us}, to reduced capacities, ϕQ_{us}, used to check foundation acceptance criteria. The values of ϕ recommended in the *Provisions* are higher than those recommended in some codes and specifications for long-term static loading. The development of resistance factors for static loading has been based on detailed reliability studies and on calibrations to give designs and factors of safety comparable to those given by allowable stress design. As indicated in the first paragraph of this section, mobilized strengths for seismic loading conditions are expected to be somewhat higher than the static strengths specified for use in obtaining values of Q_{us}, especially for cohesive soils. In the absence of any detailed reliability studies for seismic loading conditions, values of ϕ equal to 0.8 and 0.7 were selected for cohesive and cohesionless soils, respectively, when geotechnical site investigations, including laboratory or in-situ tests, are conducted, and values of ϕ equal to 1.0 and 0.9 were selected when full-scale field tests of prototype foundations are conducted. These values are comparable to the values of 0.8 (for soil strengths determined based on a comprehensive site soil investigation including soil sampling and testing) and 0.9 (for soil strengths determined by site loading testing using plate bearing or near full scale foundation element testing) recommended by the SEAOC Seismology Committee Ad Hoc Foundation Committee (2001).

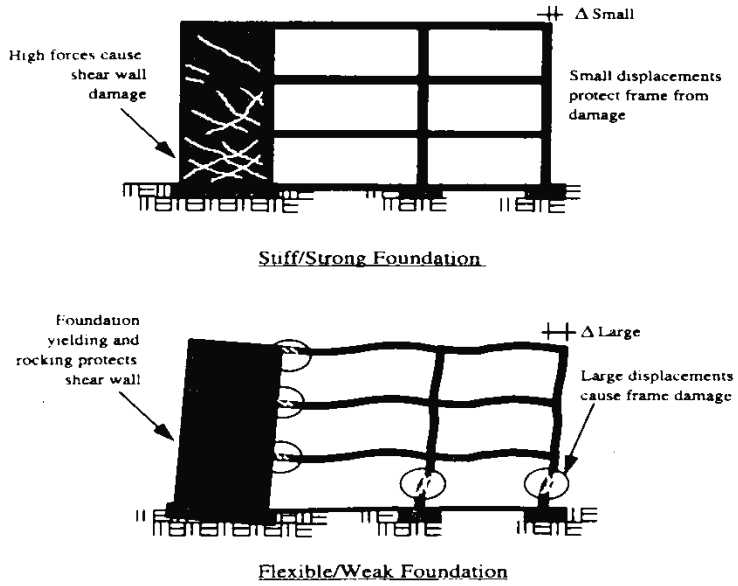
C-A7.2.2.2 Acceptance Criteria. The factored load capacity, ϕQ_{us}, provides the basis for the acceptance criteria, particularly for the linear analysis procedures. The mobilization of ultimate capacity in the nonlinear analysis procedures does not necessarily mean unacceptable performance as structural deformations due to foundation displacements may be tolerable, as discussed by Martin and Lam (2000). For the nonlinear analysis procedures, it is also prudent to evaluate structural behavior utilizing parametric increases in foundation load capacities above Q_{us} by a factor of $1/\phi$, to check potential changes in structural ductility demands.

C-A7.2.3 Foundation Load-deformation Modeling. Analysis methods described in Section 5.3 (response spectrum procedure) and Section 5.4 (linear response history procedure), permit the use of realistic assumptions for foundation stiffness, as opposed to the assumption of a fixed base. In addition, the nonlinear response history procedure (Section 5.5) and the nonlinear static procedure (Appendix to Chapter 5) permit the use of realistic assumptions for the stiffness and load-carrying characteristics of the foundations. Guidance for flexible foundation (non-fixed base) modeling for the above analysis procedures are described herein.

Foundation load-deformation behavior characterized by stiffness and load capacity may significantly influence the seismic performance of a structure, with respect to both load demands and distribution among structural elements (ATC 1996, NEHRP 1997a, 1997b). This is illustrated schematically in Figure C-A 7.2.3-1. While it is recognized that the load-deformation behavior of foundations is nonlinear, an equivalent elasto-plastic representation of load-deformation behavior is often assumed as illustrated in Figure C-A 7.2.3-2. To allow for variability and uncertainty in the selection of soil parameters

and analysis methods used to determine stiffness and capacity, a range of parameters for foundation modeling should be used to permit sensitivity evaluations.

Foundation stiffness and strength affect various structural components differently.



Stiff/strong is not always favorable; nor is flexible/weak always conservative.

Figure C-A7.2.3-1

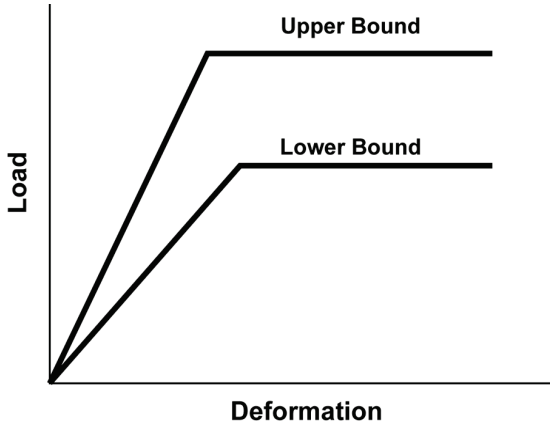


Figure CA7.2.3-2.

Consider the spread footing shown in Figure C-A 7.2.3-3 with an applied vertical load (*P*), lateral load (*H*), and moment (*M*). The soil characteristics might be modeled as two translational springs and a rotational spring, each characterized by a linear elastic-stiffness and a plastic capacity. The use of a Winkler spring model acting in conjunction with the foundation to eliminate the rotational spring may also be used, as shown in Figure C-A7.2.3-4. The Winkler model can capture more

accurately progressive mobilization of plastic capacity during rocking behavior. Note the lateral action is normally uncoupled from the vertical and rotational action. Many foundation systems are relatively stiff and strong in the horizontal direction, due to passive resistance against the face of footings or basement walls, and friction beneath footings and floor slabs. Comparisons of horizontal stiffness of the foundation and the structure can provide guidance on the need to include horizontal foundation stiffness in demand or capacity analyses. In general, foundation rocking has the most influence on structural response. Slender shear wall structures founded on strip footings, in particular, are most sensitive to the effects of foundation rocking.

Assuming a shallow footing foundation may be represented by an embedded rigid plate in an elastic half-space, classical elastic solutions may be used to compute the uncoupled elastic stiffness parameters. Representative solutions are described in *Commentary* to Section 5.6. Solutions developed by Gazetas (1991) are also often used, as described in ATC (1996). Dynamic soil properties (i.e. properties consistent with seismic wave velocities and associated moduli of the soils as opposed to static soil moduli) should be used in dynamic soil solutions. The effects of nonlinearity on dynamic soil properties should be incorporated using the reduction factors in Section 5.6.2.1.1 or based on a site-specific study.

In the case of pile groups, the uncoupled spring model shown in Figure C-A 7.2.3-3 also may be used, when the footing represents the pile cap. In the case of the vertical and rotational springs, it can be assumed that the contribution of the pile cap is relatively small compared to the contribution of the piles. In general, mobilization of passive pressures by either the pile caps or basement walls will control lateral spring stiffness. Hence, estimates of lateral spring stiffness can be computed using elastic solutions as for footings. In instances when piles may contribute significantly to lateral stiffness (i.e., very soft soils, battered piles), solutions using beam-column pile models are recommended.

Axial pile group stiffness spring values, k_{sv}, are generally in the range given by:

$$k_{sv} = \sum_{n=1}^{N} \frac{0.5AE}{L} \text{ to } \sum_{n=1}^{N} \frac{2AE}{L}$$

where A = cross-sectional area of a pile, E = modulus of elasticity of piles, L = Length of piles, and N = number of piles in group.

Values of axial stiffness depend on complex nonlinear interaction of the pile and soil (NEHRP, 1997b). For simplicity, best estimate values of *AE/L* and 1.5 *AE/L* are recommended for piles when axial capacity is primarily controlled by end bearing and side friction, respectively.

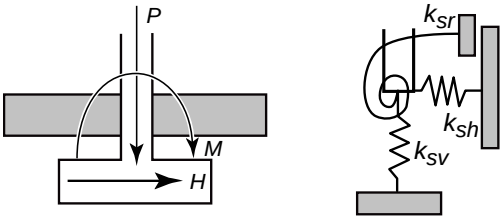

Figure C-A7.2.3-3.

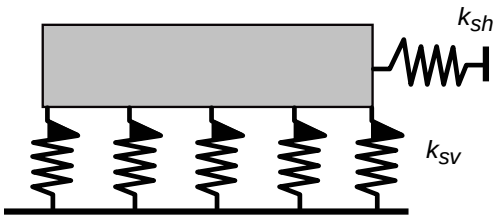

Figure C-A7.2.3-4.

The rocking spring stiffness values, k_{sr}, about each horizontal pile cap axis may be computed by assuming each axial pile spring acts as a discrete Winkler spring. The rotational spring constant (moment per unit rotation) is then given by:

$$k_{sr} = \sum_{n=1}^{N} k_{vn} S_n^2$$

where k_{vn} = axial stiffness of the n^{th} pile and S_n = distance between nth pile and axis of rotation. The effects of group action and the influence of pile batter are not accounted for in the above equations. These effects should be evaluated if judged significant.

Design Examples. In order to study and illustrate the effects of the change from allowable stress to ultimate strength design of foundations a series of examples were generated. The examples compared the size of foundations resulting from ultimate strength designs (USD) according to the new procedures with those that would be obtained from conventional allowable stress designs (ASD).

The examples were based upon a single six-story reinforced concrete building with shear walls and gravity frame (see Figure 7.2.3-5). One set of examples was for a shallow spread footing design beneath a shear wall. The other set applied to deep cast-in-drilled-hole (CIDH) piers placed beneath the same wall. For each set of examples, individual designs reflected a range of soil strengths and ASD factors of safety. The vertical loads were not changed, but two levels of seismic overturning demand were imposed.

While is not possible to generalize the results of these examples to apply universally, they are representative of the effects of the change to USD for a realistic case study. For the spread footing foundation the area of the footing for USD compared to that for ASD is controlled by the factor of safety applied to the soil strength for vertical loads. This reduction ranged from 0 to 20 percent for a low FOS (2) up to 25 to 40 percent for a high FOS (4). This is not surprising; when ASD uses a high factor of safety and is thus most conservative, USD results in a smaller footing size. However, the footing size cannot be smaller than that required for allowable stresses for static design under vertical dead plus live loads. For the pier example, the required length for USD was actually about 50 percent greater than for ASD for a low FOS (1.5) and up to 40 percent less for a high FOS (4).

Note: For a detailed description see *ATC 40 vol.2*

Resource Paper 5

ALTERNATIVE PROVISIONS FOR THE DESIGN OF PIPING SYSTEMS

(2003 *Provisions* Appendix to Chapter 6, Architectural, Mechanical, and Electrical Component Design Requirements)

Chapter 6, Architectural, Mechanical, and Electrical Component Design Requirements, of the 2003 NEHRP Recommended Provisions did not recognize discrete levels of performance that may be relevant to the seismic design of piping systems, particularly for essential facilities. This appendix was added to the 2003 Provisions to provide preliminary criteria for the establishment of such performance criteria and their use in the assessment and design of piping systems. The situation has not changed and this appendix and its commentary are reproduced here as a resource for use in the future. Note that only format changes have been made and Provisions section numbers cited refer to the 2003 edition of the Provisions. The performance criteria, from least restrictive to most severe, are: position retention, leak tightness, and operability. In particular, the interaction of systems and interface with the relevant piping design standards is addressed.

PROVISIONS

A6.1 Definitions

Leak Tightness: The condition of a piping system characterized by containment of contents, or maintenance of a vacuum, with no discernable leakage.

Operability: The condition of a piping system characterized by leak tightness as well as continued delivery, shutoff or throttle of pipe contents flow by means of unimpaired operation of equipment and components such as pumps, compressors and valves.

Position Retention: The condition of a piping system characterized by the absence of collapse or fall of any part of the system.

A6.2 Design Approach

The seismic design of piping systems is determined on the basis of Seismic Design Category, I_p, and pipe size, as provided in Table A6.2-1. For each case in Table A6.2-1, the procedure for seismic qualification is specified in Section A.6.5.

When $I_P = 1.0$, the piping system is not critical and is required to maintain position retention.

When $I_P = 1.5$, the piping system is critical and is required to exhibit leak tightness and may be required to maintain operability.

Table A6.2-1 Seismic Design Requirements

	$I_P = 1.0$		$I_P = 1.5$	
Seismic Design Category	**Pipe Size ≤ 4 inch (SI: 102 mm)**	**Pipe Size > 4 inch (SI: 102 mm)**	**Pipe Size ≤ 4 inch (SI: 102 mm)**	**Pipe Size > 4 inch (SI: 102 mm)**
B	Interactions (A6.5.2.1)	Interactions (A6.5.2.1)	Bracing (A6.5.2.2) Restraints (A6.5.2.3) Operability[a] (A6.5.2.4) Interactions (A6.5.2.1)	Bracing (A6.5.2.2) Restraints (A6.5.2.3) Operability[a] (A6.5.2.4) Interactions (A6.5.2.1)
C or D	Interactions (A6.5.2.1)	Interactions (A6.5.2.1)	Bracing (A6.5.2.2) Restraints (A6.5.2.3) Operability[a] (A6.5.2.4) Interactions (A6.5.4.2.1)	Analysis (A6.5.2.5) Restraints (A6.5.2.3) Operability[a] (A6.5.2.4) Interactions (A6.5.2.1)
E or F	Bracing (A6.5.2.2) Restraints (A6.5.2.3) Interactions (A6.5.2.1)	Bracing (A6.5.2.2) Restraints (A6.5.2.3) Operability[a] (A6.5.2.4) Interactions (A6.5.2.1)	Analysis (A6.5.2.5) Restraints (A6.5.2.3) Operability[a] (A6.5.2.4) Interactions (A6.5.2.1)	Analysis (A6.5.2.5) Restraints (A6.5.2.3) Operability[a] (A6.5.2.4) Interactions (A6.5.2.1)

[a] Leak tightness is the default requirement. Operability applies only when specified by design.

A6.3 System Coefficients

A6.3.1 Deformability. Piping systems shall be classified as either high-, limited-, or low-deformability systems. All materials in high-deformability piping systems shall have an elongation at rupture of at least 10 percent at the operating temperature, and pipes and pipe components used in high-deformability systems shall be joined by welding or by bolted flanges. Systems containing components with an elongation at rupture of less than 10 percent at the operating temperature, or having joints that rely only on friction, shall be classified as low-deformability systems. Systems that are neither high- nor low-deformability systems shall be classified as limited deformability systems. Systems with threaded connections shall be classified as limited- or low-deformability systems.

A6.3.2 Seismic Coefficients. The seismic coefficients a_P and R_P are specified in Table 6.4.1 for high-, limited-, and low-deformability piping systems.

A6.4 Seismic Demand

A6.4.1 Seismic demand on a piping system consists of applied forces and relative displacements.

A6.4.2 Seismic forces shall be determined as specified in Section 6.2.6.

A6.4.3 Seismic relative displacements at points of attachments of pipe restraints to the structure shall be determined as specified in Section 6.2.7.

A6.5 Seismic Qualification

A6.5.1 Elevator system piping shall satisfy the provisions of Section 6.4.9. ASME B31 pressure piping systems shall satisfy the provisions of the applicable ASME B31 code section. Fire sprinkler systems shall satisfy the provisions of Section A6.5.2.6.

A6.5.2 The seismic qualification of piping systems depends on the Design Approach selected in Section A6.2.

A6.5.2.1 When interactions are specified they shall be evaluated in accordance with Section 6.2.3.

A6.5.2.2 When bracing is specified, the pipe must be seismically restrained. Lateral restraints shall be provided (a) to limit the bending stress in the pipe to yield at the operating temperature and (b) to limit the rotations at articulated joints within the manufacturer limits. Unlike analysis (Section A6.5.2.5), bracing does not require a detailed analysis of the piping system; the distance between seismic restraints may be established based on beam approximations of the pipe spans. The effect of seismic restraints on operating loads (thermal expansion and contraction and weight) shall be considered.

A6.5.2.3 When restraints are specified, the pipe seismic restraints as well as their welds and anchorage attachment to the structure shall comply with the provisions of Chapters 8 to 12 of the 2003 *Provisions*. Supports shall be constructed so that support engagement is maintained considering both lateral and vertical seismic forces.

A6.5.2.4 When operability is specified, the equipment and components that must perform an active function that involves moving parts (such as pumps, compressors, fans and valve operators) shall comply with the requirements of Section2.4.5.

A6.5.2.5 When analysis is specified, the piping system shall be analyzed by static or dynamic methods. The maximum calculated elastic stress due to the earthquake loads and concurrent weight and pressure shall be limited to $1.5S_Y$ (where S_Y is the minimum specified material yield stress at normal operating temperature) and the rotations at articulated joints shall be within the manufacturer limits. The analysis shall include the effects of stress intensification factors as determined in the ASME B31 pressure piping code, and corrosion effects.

A6.5.2.6 Fire protection sprinkler systems shall meet the following requirements:

A6.5.2.6.1 Fire protection sprinkler systems in Seismic Design Categories A, B and C designed and constructed in accordance with NFPA-13 shall be deemed to satisfy the seismic force and relative displacement requirements of these *Provisions*.

A6.5.2.6.2 In Seismic Design Categories D, E and F, fire protection sprinkler systems designed and constructed in accordance with NFPA 13 shall also meet the following additional criteria:

1. The spacing of longitudinal sway bracing and transverse sway bracing specified in NFPA 13 Section 9.3.5 shall be reduced by multiplying the maximum brace spacing permitted in NFPA 13 Section 9.3.5 by $0.8W_p/F_p$.
2. The value of $0.8W_p/F_p$ shall not be taken as greater than 1.0.

COMMENTARY

C-A6.1 Seismic Interaction. There are two types of seismic interactions: system interactions and spatial interactions. A system interaction is a spurious or erroneous signal resulting in unanticipated operating conditions, such as the spurious start-up of a pump motor or the unintended closure of a valve. Spatial interactions are interactions caused by the failure of a structure or component in close proximity. Spatial interactions can in turn be further divided into falling interactions, swing interactions, and spray interactions. A falling interaction is an impact on a critical component due to the fall of overhead or adjacent equipment or structure. A swing interaction is an impact due to the swing or rocking of adjacent component or suspended system. A spray interaction is due to the leakage of overhead or adjacent piping or vessels.

Any interaction involves two components, a source, and a target. An interaction source is the component or structure that could fail and interact with the seismically designed component. An interaction target is a seismically qualified component that is being impacted, sprayed or spuriously activated. For an interaction to affect a seismically qualified component, it must be credible and significant. A credible interaction is one that can take place. For example, the fall of a ceiling panel located overhead from a motor control center is a credible interaction because the falling panel can reach and impact the motor control center. The target (the MCC) is said to be within the zone of influence of the source (the ceiling panel). A significant interaction is one that can result in damage to the target. For example, the fall of a light fixture on a 20-inch steel pipe may be credible (the light fixture being above the pipe) but may not be significant (the light fixture will not damage the steel pipe). In contrast, the overturning of a rack on an instrument panel is a significant interaction.

The process of considering seismic interactions begins with a interaction review. For new structures, this involves examination of the design drawings, to identify the interaction targets, and credible and significant sources of interaction. In many cases, the design documents may only locate components and systems in schematic terms. The actual location of, for example, piping and ductwork systems is determined in the field. In this case and when work is being performed on an existing structure, it is necessary to begin the interaction review with a walk-down, typically with a photographic record. Based on the assembled data, supporting calculations to document credible and significant sources of interactions can be prepared.

In practice, it is only necessary to document credible and significant sources of interaction. It is not necessary to list and evaluate every single overhead or adjacent component in the area around the target, only those that could interact and whose interaction could damage the target. Because only credible and significant sources of interaction are documented, an important aspect of the interaction review is engineering judgment. The spatial interaction review should therefore be performed by experienced seismic design engineers.

When system interactions are of importance, the written input of a system engineer is in order.

Resource Paper 6

OTHER NONBUILDING STRUCTURES

(2003 *Provisions* Appendix to Chapter 14, Nonbuilding Structure Design Requirements)

This appendix first appeared in the 2000 NEHRP Recommended Seismic Provisions and was revised for inclusion in the 2003 Provisions. It is intended to serve as a resource document for future voluntary standards and model code development and to encourage development of up-to-date consensus standards for electrical transmission, substation, and distribution structures, telecommunications towers, and buried structures as well as performance criteria for tanks and vessels. The guidance presented reflects current industry design practice for these types of nonbuilding structures. Feedback will be appreciated. Note that only format changes have been made and Provisions section numbers cited refer to the 2003 edition of the Provisions.

PROVISIONS

A14.1 General

A14.1.1 Scope. This paper includes design requirements for electrical transmission, substation, and distribution structures, telecommunications towers, and buried structures and performance criteria for tanks and vessels.

A14.1.2 References

IEEE 693 Institute of Electrical and Electronics Engineers, *Recommended Practices for Seismic Design of Substations*, Power Engineering Society, Piscataway, New Jersey, 1997.

A14.1.3 Definitions

Base shear: See Section 4.1.3.

Buried structures: Subgrade structures such as tanks, tunnels, and pipes.

Dead load: See Section 4.1.3.

Registered design professional: See Section 2.1.3.

Seismic Use Group: See Section 1.1.4.

Structure: See Section 1.1.4.

A14.1.4 Notation

C_d See Section 4.1.4.
C_S See Section 5.1.3.
I See Section 1.1.5.
R See Section 4.1.4.
S_{D1} See Section 3.1.4.
S_{DS} See Section 3.1.4.
T See Section 4.1.4.
V See Section 5.1.3.
W See Section 1.1.5.

A14.2 Design Requirements

A14.2.1 Buried Structures. Buried structures that are assigned to Seismic Use Group II or III, or warrant special seismic design as determined by the registered design professional, shall be identified in the geotechnical report. Such buried structures shall be designed to resist minimum seismic lateral forces and expected differential displacements determined from a properly substantiated analysis using approved procedures.

A14.3 Performance Criteria for Tanks and Vessels

Tanks and vessels shall be designed to meet the minimum post-earthquake performance criteria as specified in Table A14.3-1. These criteria depend on the Seismic Use Group and content-related hazards of the tanks and vessels being considered.

Table A14.3-1 Performance Criteria for Tanks and Vessels

Performance Category [a]	Minimum Post-earthquake Performance
I	The structure shall be permitted to fail if the resulting spill does not pose a threat to the public or to adjoining Category I, II or III structures.
II	The structure shall be permitted to sustain localized damage, including minor leaks, if (a) such damage remains localized and does not propagate; and (b) the resulting leakage does not pose a threat to the public or to adjoining Category I, II or III structures.
III	The structure shall be permitted to sustain minor damage, and its operational systems or components (valves and controls) shall be permitted to become inoperative, if (a) the structure retains its ability to contain 100 percent of its contents; and (b) the damage is not accompanied by and does not lead to leakage.
IV[b]	The structure shall be permitted to sustain minor damage provided that (a) it shall retain its ability to contain 100 percent of its contents without leakage; and (b) its operational systems or components shall remain fully operational.

[a] Performance Categories I, II, and III correspond to the Seismic Use Groups defined in Section 1.2 and tabulated in Table 14.2-1.
[b] For tanks and vessels in Performance Category IV, an Importance Factor, *I,* of 1.0 shall be used.

COMMENTARY

C-A14.1 General

C-A14.2.1 Buried Structures. This section is included for the following reasons:

1. The material may serve as a starting point for continued development.
2. The comments stimulated by consideration of this section will provide valuable input so that this section may be further developed and then incorporated in the *Provisions* in the future.
3. It was determined by TS 13 and the Provisions Update Committee that it would be premature to incorporate this section into the *Provisions* for the 2000 edition.
4. Accepted industry standards are in the process of incorporating seismic design methodology reflecting the *Provisions*.

It is not the intent of the Provisions Update Committee to discourage incorporation of this section into a building code or to minimize the importance of this section. Placing this section in the appendix indicates only that this section requires further development.

Seismic forces on buried structures may include forces due to: soil displacement, seismic lateral earth pressure, buoyant forces related to liquefaction, permanent ground displacements from slope instability, lateral spread movement, fault movement, or dynamic ground displacement caused by dynamic strains from wave propagation. Identification of appropriate seismic loading conditions is dependent upon subsurface soil conditions and the configuration of the buried structure. Conditions related to permanent ground movement can often be avoided by careful site selection for isolated buried structures such as tanks and vaults. Relocation is often impractical for long buried structures such as tunnels and pipelines.

Wave propagation strains are a significant seismic force condition for buried structures if local site conditions (for instance, deep surface soil deposits with low shear wave velocities) can support the propagation of large amplitude seismic waves. Wave propagation strains tend to be most pronounced at the junctions of dissimilar buried structures (such as a pipeline connecting with a building) or at the interfaces of different geologic materials (such as a pipeline passing from rock to soft soil).

Loading conditions related to liquefaction require detailed subsurface information that can be used to assess the potential for liquefaction and, for long buried structures, the length of structure exposed to liquefaction effects. In addition, the assessment of liquefaction requires specifying an earthquake magnitude that is consistent with the definition of ground shaking. It is recommended that one refer to Chapter 7 of this C*ommentary* for additional guidance in determining liquefaction potential and seismic magnitude. Providing detailed structural design procedures in this area is beyond the scope of this document.

Loading conditions related to lateral spread movement and slope instability can be defined in terms of lateral soil pressures or prescribed ground displacements. In both cases, sufficient subsurface investigation in the vicinity of the buried structure is necessary to estimate the amount of movement, the direction of movement relative to the buried structure, and the portion of the buried structure exposed to the loading conditions. Definition of lateral spread loading conditions requires special geotechnical expertise and specific procedures in this area are beyond the scope of this document.

Defining the loading conditions for fault movement requires specific location of the fault and an estimate of the earthquake magnitude on the fault that is consistent with the ground shaking hazard in the *Provisions*. Identification of the fault location should be based on past earthquake movements, trenching studies, information from boring logs, or other accepted fault identification techniques. Defining fault movement conditions requires special seismological expertise. Additional guidance can be found in the Chapter 7 *Commentary*.

It may not be practically feasible to design a buried structure to resist the effects of permanent ground deformation. Alternative approaches in such cases may include relocation to avoid the condition, ground improvements to reduce the loads, or implementing special procedures or design features to minimize the impact of damage (such as remote controlled or automatic isolation valves that provide the ability to rapidly bypass damage or post-earthquake procedures to expedite repair). The goal of providing procedures or design features as an alternative to designing for the seismic loadings is to change the hazard and function classification of the buried structure such that it is not classified as Seismic Use Group II or III.

It is recommended that one refer to the Chapter 7 C*ommentary* for additional guidance in determining liquefaction potential and determining seismic magnitude.

Buried structures are subgrade structures such as tanks, tunnels, and pipes. Buried structures that are designated as Seismic Use Group II or III, or are of such a size or length to warrant special seismic design as determined by the registered design professional, must be identified in the geotechnical report.

Buried structures must be designed to resist minimum seismic lateral forces determined from a substantiated analysis using approved procedures. Flexible couplings must be provided for buried structures requiring special seismic considerations when changes in the support system, configuration, or soil condition occur.

The requirement for and value of flexible couplings should be determined by the "properly substantiated analysis and approved procedures." It is assumed that the need for flexible couplings refers to buried piping or conduits. The prior wording of Section A14.2.3 was far too broad in requiring flexible couplings when changes in the support system, configuration or soil condition occur. These broad requirements could result in flexible couplings installed at locations where permanent ground displacement is expected or at transitions between aboveground supported pipe and buried pipe. As currently available flexible couplings are not generally designed to match the ultimate strength properties of the piping or conduit, the prior requirements potentially introduce a weak point in the piping or conduit system. The original focus of the prior requirements was penetrations of buried service lines into a building or other structure. Properly designed flexible couplings can be an effective means to limit forces at connections to buried structures. However, special care is needed to make sure the design loads and displacements are adequately specified. There are several other alternative to providing sufficient flexibility at connections to buried structures that are more robust in terms of margin above their design levels.

Resource Paper 7

SPECIAL REQUIREMENTS FOR SEISMIC DESIGN OF STRUCTURAL GLUED LAMINATED TIMBER (Glulam) ARCH MEMBERS AND THEIR CONNECTIONS IN THREE-HINGE ARCH SYSTEMS

Glulam arch structures are used with some regularity in churches and other public buildings and assembly areas; however, ASCE/SEI 7-05 does not provide guidance regarding the seismic design of these systems. The design recommendations reflected in this resource paper were drafted by BSSC Technical Subcommittee 7, Design of Wood, with input from the American Institute of Timber Construction (AITC). This paper provides seismic design coefficients for two classes of one-story three-hinge arch systems: a special glulam arch and a glulam arch not specifically detailed for seismic resistance.

For special glulam arch systems, required detailing enables limited inelastic behavior in connections through either wood bearing or fastener yielding. This is accomplished by requiring design of wood members at connections for the lesser of overstrength forces or the forces that can be developed in the connections. Use of glulam arch systems not specifically detailed for seismic resistance is limited to Seismic Design Categories A, B, and C. This limit is analogous to the approach taken for steel systems not specifically detailed for seismic resistance and wood shear wall systems with other than wood structural panel. The value of R = 2.0 is based on a relative comparison of R for special systems. The assumed system overstrength for both systems is Ω_0=2.5.

To facilitate eventual code/standard adoption of the guidance provided in this paper, requirements are presented first followed by a commentary section.

PROPOSED REQUIREMENTS FOR ONE-STORY THREE-HINGE ARCH SYSTEMS

1. Scope. These provisions are intended for use in the design and detailing of structural glued laminated timber (glulam) arch members and connections that are part of the seismic-force-resisting system in one-story three-hinge arch systems. Seismic design coefficients for these systems shall be as specified in the applicable building code or, in the absence of such information, shall be as indicated in Table 1.

Glulam arch systems not specifically detailed for seismic resistance shall comply with recommended detailing in AITC 104-2003, *Typical Construction Details* and the requirements of the 2005 *National Design Specification® for Wood Construction* (*NDS®*) including Appendix E, ASCE/SEI 7-05, *Minimum Design Loads for Buildings and Other Structures* and the applicable building code.

Special glulam arch systems shall meet the requirements for glulam arch systems not specifically designed for seismic resistance. In addition, special glulam arch systems shall meet the requirements of Sections 1.1 through 1.7 below.

Table 1 Seismic Design Coefficients for One-Story Glulam Arch Systems

Seismic-Force-Resisting System	R	Ω_0	C_d
Special glulam arch	2.5	2.5	2.5
Glulam arch not specifically detailed for seismic resistance[a]	2.0	2.5	2.0

[a] Limited to Seismic Design Categories A, B, and C only.

1.1 Connection Requirements. Connections that are part of the special glulam arch seismic-force-resisting system shall be in accordance with requirements of NDS Chapter 10 for mechanical connections and the additional requirements of this section.

1.1.1 Arch Base. Arch base connections shall utilize a steel shoe assembly in accordance with AITC 104. Timber rivets or dowel-type fasteners such as thru-bolts or lag screws shall attach the arch to the shoe. Dowel-type fasteners shall be chosen such that the expected yield mode is Mode III or Mode IV as defined in the NDS. Timber rivet connections shall be designed to ensure that the expected strength limit state is characterized by rivet capacity.

1.1.2 Arch Peak. Connection of the arch at the peak shall utilize shear plates, bolts, steel dowels, or metal side plates or combination thereof in accordance with AITC 104.

1.2 Nominal Connection Capacity. The nominal capacity of a connection shall be determined in accordance with the following:

1. For dowel type fasteners -- n x $Z(K_F)(\lambda)(C_M)(C_t)(C_{eg})$ where n is the number of fasteners; Z is the reference lateral design value for a single fastener; and K_F, λ, C_M, C_t, and C_{eg} are adjustment factors specified in the NDS for format conversion, time effect, wet service, temperature and end grain, respectively.
2. For timber rivets: (P_r or Q_r) x $(K_F)(\lambda)(C_M)(C_t)(C_{st})$ where P_r is parallel to grain reference rivet capacity; Q_r is perpendicular to grain reference rivet capacity; and K_F, λ, C_M, C_t, and C_{st} are adjustment factors specified in the NDS for format conversion, time effect, wet service, temperature and metal side plate, respectively.
3. For split ring and shear plate connectors -- n x P x $(K_F)(\lambda)(C_M)(C_t)(C_d)(C_{st})$ or n x Q x $(K_F)(l)(C_M)(C_t)(C_d)$ where n is the number of fasteners; P is the reference design value parallel to the grain for a single split ring connector unit or shear plate unit; Q is the reference design value perpendicular to grain for a single split ring connector unit or shear plate unit; and K_F, λ, C_M, C_t, C_d, and C_{st} are adjustment factors specified in the NDS for format conversion, time effect, wet service, temperature, penetration and metal side plate, respectively.

1.3 Member Requirements. Arch members that are part of the special glulam arch seismic-force-resisting system shall meet requirements of the NDS and the requirements of this section.

1.3.1 Slenderness. The ratio of tangent point depth to breadth (d_t/b) shall not exceed 6 based on actual dimensions when one edge of the arch is braced by decking fastened directly to the arch or braced at frequent intervals as by girts or roof purlins. When such lateral bracing is not present, d_t/b shall not exceed 5.

1.3.2 End Grain Bearing. At the arch base, end grain bearing shall be on a metal plate with sufficient strength and stiffness to distribute the applied load. At moment splices, end grain bearing shall be on a metal plate when $f_c > (0.75)(F_c^*)$ as required in accordance with NDS Section 3.10.1.3.

1.3.3 Compression Perpendicular to Grain. Compression perpendicular to grain induced at the arch base shall be by a metal plate with sufficient strength and stiffness to distribute the applied load.

1.4 Member Resistance.

1.4.1 Moment, Tension, Compression, and Shear. The arch member for special glulam arch systems shall be designed to resist moment, tension, compression, shear, and applicable combinations of these induced by seismic forces determined in accordance with the load combinations of ASCE/SEI 7-05 Section 12.4.3.2 (load combinations with overstrength) but need not exceed forces resulting from strength at connections determined in accordance with Section 1.4.2a.

1.4.2 Member Resistance at Connections. The arch member for special glulam arch systems shall be designed for limit states of net section tension rupture, row tear-out, group tear-out as defined in NDS Appendix E, and shear in accordance with NDS Section 3.4.3.3 due to the seismic forces as determined by the lesser of:

1. The nominal connection capacity determined in accordance with Section 1.2 for load resistance factor design (LRFD) or the nominal connection capacity determined in accordance with Section 1.2 divided by 1.35 for allowable stress design (ASD).
2. The required capacity resulting from load combinations of ASCE/SEI 7-05 Section 12.4.3.2 (load combinations with overstrength).

1.5 Transfer of Forces to the Arch Members. The diaphragm, members, and connections shall be sized to transfer out-of-plane wall and roof forces into the arch.

1.6 End Fixity. In accordance with assumed pinned behavior of a three-hinge arch, determination of reaction and arch member forces is based on assumed idealized pin behavior at the arch peak and base. Actual detailing may introduce partial moment fixity at reactions, and consideration shall be given to the effect of such fixity on member and connection response.

1.7 Arch Moment Splice. Arch moment splices shall utilize a metal bearing plate (when required), metal side plates, shear plates, bolts, steel dowels, timber rivets, or combination thereof in accordance with AITC 104. Design forces for determining the size and number of fasteners shall be based on load combinations of ASCE/SEI 7-05 Section 12.4.3.2 (load combinations with overstrength) but need not exceed the member design force based on forces resulting from strength at connections (see Section 1.4.1 and 1.4.2a).

COMMENTARY FOR ONE-STORY THREE-HINGE ARCH SYSTEMS

C1 Scope. Special provisions are provided for the design of arch members and connections to resist seismic forces as part of a three-hinge arch system (see Figure C1.0). Such systems typically employ glued laminated timber Tudor arch members and are commonly used in church construction and other facilities intended for public assembly. Common features of these systems are the presence of 2x and 3x tongue and groove roof decking with wood structural panel overlay, longitudinal and transverse walls of light frame construction, or longitudinal and transverse masonry walls. Transverse end walls may or may not be designed as shear walls.

Special requirements apply to typical construction details used for over 50 years in three-hinged arch systems as outlined in AITC 104, *Typical Construction Details.* Typical arch base details in AITC 104 are generally expected to produce good performance characteristics of connection yielding by either wood bearing or a combination of wood bearing and fastener yielding and will limit occurrence strength limit states of row tear-out, group tear-out, and net section tension rupture prior to connection yielding. The design requirements in this white paper utilize standard details that have been used successfully and that encourages a combination of wood bearing and metal fastener yielding modes at the base.

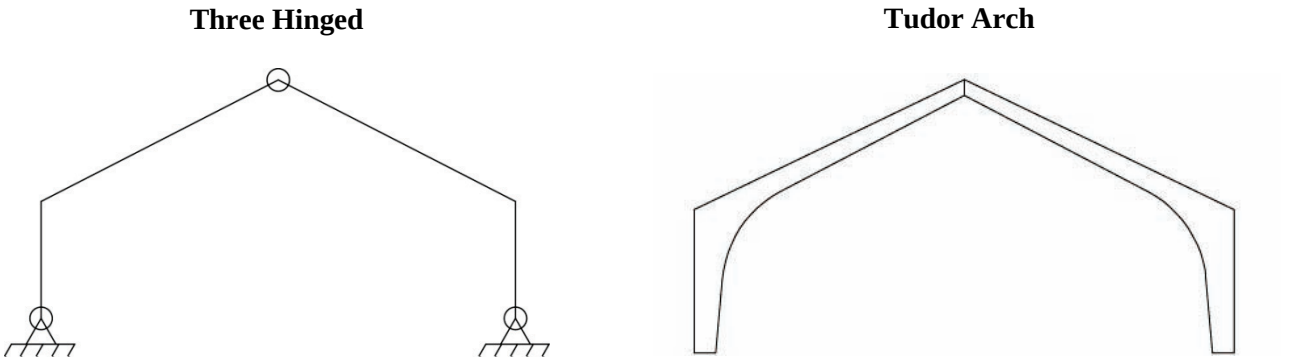

Figure C1.0 Three-hinge arch and Tudor arch configurations.

C1.1 Connection Requirements for Special Glulam Arch Systems. The ordinary load combinations (load combinations without overstrength) of ASCE/SEI 7-05 are used to determine the size and number of fasteners in arch member connections at the base. Determination of the size and number of fasteners is not subject to special load combinations (load combinations with overstrength forces) to enable limited inelastic behavior of dowel-type fasteners (either by wood bearing or fastener bending) when coupled with the wood member strength requirements of Section 1.4. This approach recognizes that wood connection strength is typically governed by wood failure mechanisms, not failure of the metal fasteners. For a given wood member cross-section, determination of the size and number of fasteners based on the overstrength load combinations may not be beneficial to overall connection performance due to an increased number of fasteners and a reduction in wood member net section to accommodate the fasteners.

C1.1.1 Arch Base. The connection at the arch base utilizes a metal shoe (see Figure C1.1.1) and typically employs a thru-bolt loaded in double shear. Placement of the bolt(s) is an important consideration. In-service drying of the member causes shrinkage which must be accounted for in the detailing of the connection to prevent splitting due to the development of tension perpendicular to grain stresses.

It is recommended that the bolt(s) be placed within 6 inches of the back of the arch if standard size holes are used. Where bolt(s) are placed farther than this from the back of the arch to resist the required loads, the designer should provide detailing to allow the wood to shrink without pulling away from the bearing seat. This may be accomplished through the use of slotted holes or oversized holes in the arch member. It is recognized that some movement of the arch at the base will occur before the bolt is engaged. This practice is used to prevent wood splitting due to occurrence of dimensional change under gravity loads. In some situations a bearing seat is also used at the inside face of the arch. In such a case, the bolt(s) is generally placed at the geometric center of the section with the hole(s) detailed to accommodate shrinkage.

Timber rivets as well as lag screws installed at each side of the arch base are expected to produce comparable performance provided that the controlling yield mechanism is based on dowel yielding or rivet capacity.

Under outward loads, the bending yield capacity of the plate at the back of the metal shoe will typically determine the size of the bearing area (i.e., the plate will yield before the wood reaches its design compression perpendicular to grain stress).

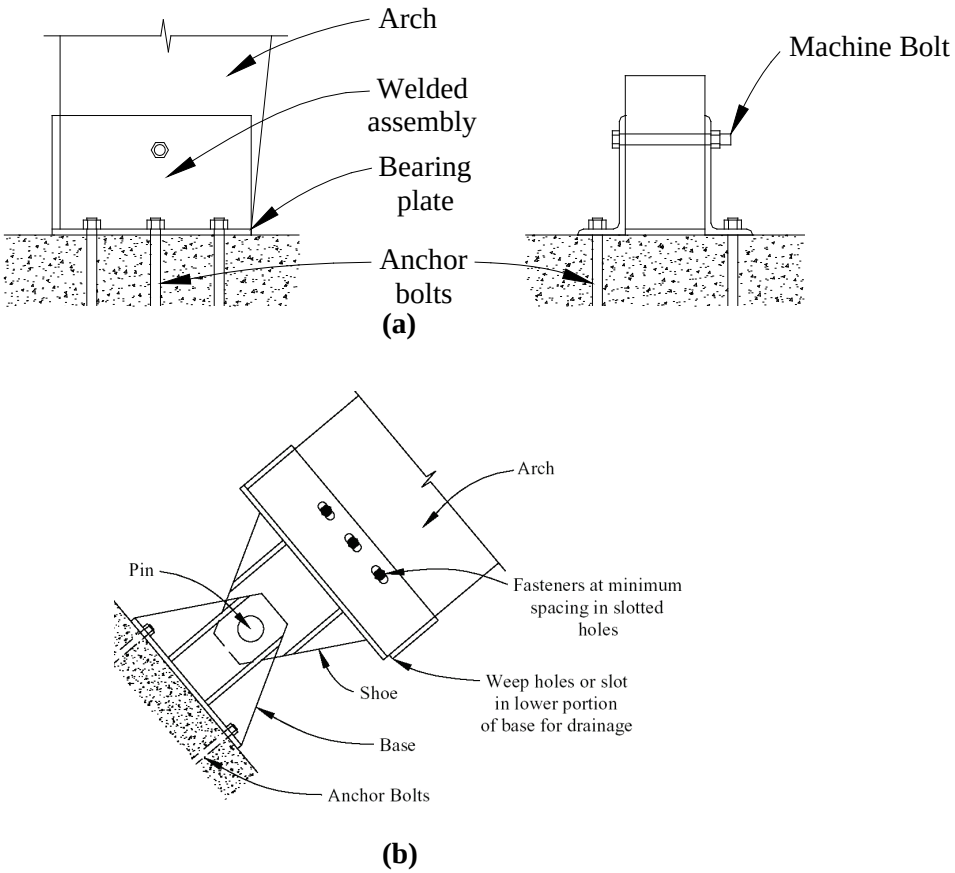

Figure C1.1.1 (a) Typical arch base with thru-bolt and (b) arch base with true hinge.

C1.1.2 Arch Peak. The connection at the peak typically employs use of a shear plate or plates with thru-bolt(s) and is typically pre-fabricated in a manufacturing facility to establish proper fit and alignment. For arches with slopes of 3:12 or more, typical connections employ shear plates and bolts or a combination of shear plates and bolts and dowels to transfer both horizontal and vertical forces. For low pitch (low slope) arches, steel side plates on each face are used in combination with shear plates. Figure C1.1.2 shows one example of a peak connection.

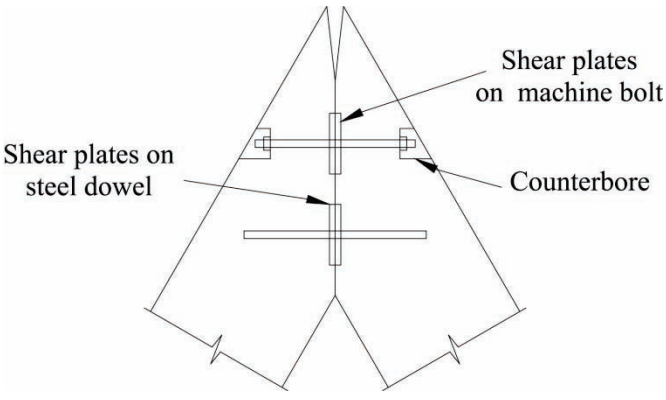

Figure C1.1.2 Typical arch peak connection detail.

The bevel cuts shown at the top of the arch peak connection are used to minimize wood crushing and permit rotation due to downward deflection of the peak connection of deep members. They are not required for all designs but should be considered by the designer where significant rotation is expected. Bevel cuts generally are not used on the bottom side of the connection.

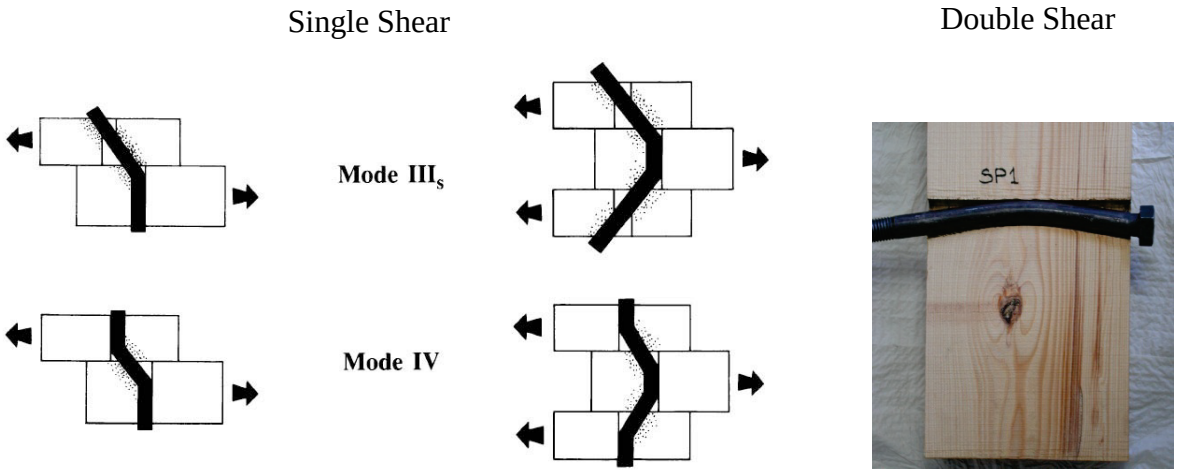
C1.2 Nominal Connection Capacity. Determination of nominal capacity does not include adjustment factors for group action and geometry to more conservatively estimate nominal connection capacity. These factors are 1.0 or less in value and address wood strength limit states that are to be checked explicitly per Appendix E and the shear provisions of the NDS.

C1.3 Member Requirements. Prescriptive limits on *d/b* match those in the NDS for arches.

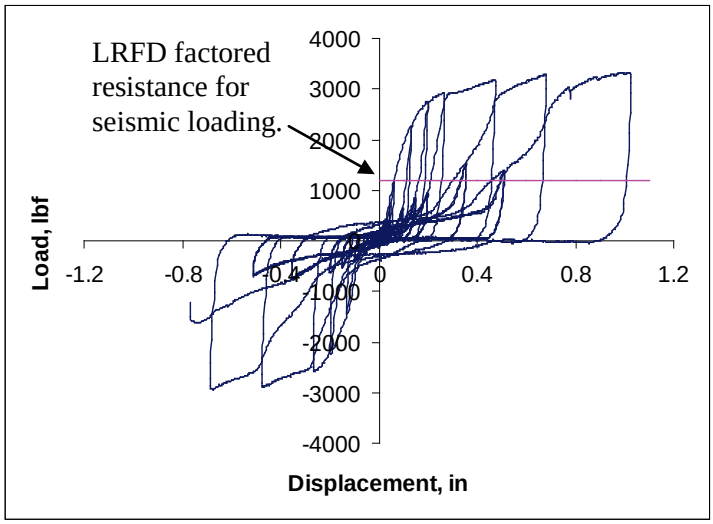
C1.3.2 End Grain Bearing. Consistent with typical construction details used for these systems, a metal plate with sufficient strength and stiffness to distribute the applied load is used at the base (see Figure C1.1.1) regardless of the level of stress in end grain bearing. This bearing plate also prevents direct contact between the arch and the concrete, thus preventing moisture from wicking into the arch from the concrete.

C1.3.3 Compression Perpendicular to Grain. Compression stress perpendicular to the grain in the arch member at the base should be through bearing on a metal plate with sufficient strength and stiffness to distribute the applied load.

C1.4 Member Resistance. The requirements of Section 1.4 are intended provide excess capacity in the member relative to connections because little or no inelastic deformation is expected from the arch member itself except in bearing modes. Limited inelastic deformation can occur through wood bearing and fastener yielding in the connection region at the base (see Figure C1.3.3a and b for examples of Mode III and Mode IV yielding and Figure C1.3.3c for cyclic behavior of a bolted steel side plate to wood connection).



(a) **(b)**



(c)

Figure C1.3.3 (a) Mode III and Mode IV yielding for single and double shear connections, (b) Mode IV yielding from a double shear connection test, and (c) cyclic curve for single shear bolted connection - Mode IIIs (3/8 inch diameter bolt, 4x6 wood member, ¼ inch steel side plate).

C1.4.1 Moment, Tension, Compression, and Shear. Arch member design strength must equal or exceed the force based on the overstrength load combinations of ASCE/SEI 7-05 but need not exceed nominal forces developed by connections in accordance with Section 1.4.2a. Design for bending, tension, compression and shear, per Section 1.4.1, is based on applicable net section or net bearing areas in accordance with the NDS. Member design at connections, including provisions for shear at connections at member ends and local stresses in fastener groups, is in accordance Section 1.4.2.

C1.4.2 Member Resistance at Connections. This section requires member design at connections for forces that can be developed in the connections or the ASCE/SEI 7-05 overstrength load combinations to increase capacity based on wood strength limit states relative to connection capacity and to provide for limited inelastic behavior at base and peak connections by either wood bearing or fastener yielding or a combination thereof.

In Section 1.4.2, required design wood strength at connections is taken as the lesser of: (a) the nominal strength of the connection for LRFD or the nominal strength divided by 1.35 for ASD or (b) the force based on the ASCE/SEI 7-05 overstrength load combinations. Case b generally will apply when loads other than seismic control the size and number of fasteners in the arch base. When the connection has design strength in excess of that needed to resist seismic forces (e.g., forces from wind exceed calculated seismic forces), it is necessary only to ensure that the wood member has sufficient design strength to resist loads from special load combinations, not the expected strength of the fasteners.

For ASD, wood strength limit states are checked using the nominal strength of the connection divided by a factor of 1.35. The 1.35 factor is specified to provide for consistent design whether provisions of ASD or LRFD are used. For member design (except compression perpendicular to grain) and connection design, the ratio of the LRFD adjusted design value (10 minute basis) to the ASD adjusted design value (10 minute basis) is 2.16/1.6 = 1.35. The factor of 2.16 is the constant in the format conversion factor, K_F, and adjusts the ASD reference design values (10 year basis) to LRFD design values (10 minute basis) and 1.6 is the load duration factor, C_D, which adjusts the ASD reference design values (10 year basis) to the ASD design values at a 10 minute basis.

C1.5 Transfer of Forces to the Arch Members. Adequate transfer of in-plane diaphragm forces and out-of plane wall and roof forces can be addressed by use of the NDS for wood member and connection resistance and the provisions of ASCE/SEI 7. For anchorage of concrete or masonry structural walls, see ASCE/SEI 7 Sections 12.11 and 12.14.7.5; for bearing walls and shear walls, see ASCE/SEI 7 Section 12.14.7.6; and for nonstructural components, see ASCE/SEI 7 Section 12.14.7.7.

C1.6 End Fixity. Three-hinge arch systems are designed assuming pin behavior when typical construction details of AITC 104 are used; however, it is recognized that limited moment fixity is introduced at the arch base and arch peak connection regions by the presence of connectors and the bearing of the member cross section. For example, at the arch base, rotation about the inside face of the arch at the base coupled with the presence of connections in the arch shoe will provide moment fixity beyond the assumed condition of an ideally pinned joint. The intent of Section 1.6 is to consider the effect of such end fixity as the arch resists anticipated loading.

It is difficult to generate precise estimates of anticipated deformations that may be detrimental to overall connection and member performance. Their effect at the base connection is mitigated through: (a) the use of dowel fasteners in yielding mode, (b) increased strength of dowel fasteners loaded parallel to grain when compared to the same fastener loaded perpendicular to grain, (c) the presence of localized bearing deformations about the arch base and surrounding the dowel, and (d) dowel placement. At the arch peak, tapering of the arch member minimizes fixity created by wood bearing as the arch deforms (see Figure C1.1.2).

Limited cyclic data for single shear, single bolt connections consisting of a steel side plate and a wood main member indicate an average displacement of 0.8 inch at maximum load (see Anderson). For the particular connection tested, the ratio of average maximum strength to LRFD factored resistance was approximately 2.6. Displacement at maximum load and ratio of maximum load to the LRFD factored resistance will vary by connection configuration.

C1.7 Arch Moment Splice. Large arches may employ arch moment splices in locations of reduced moment to facilitate shipping. Like the connection at the peak, these connections are typically prefabricated in a manufacturing facility to establish proper fit and alignment. Compression stress in the moment splice region is resisted by end grain bearing on a metal bearing plate between the connected members. Tension is taken across the splice by steel straps and shear plates, shear is taken by shear plates in end grain, and side plates are used to hold sides and tops of members in position.

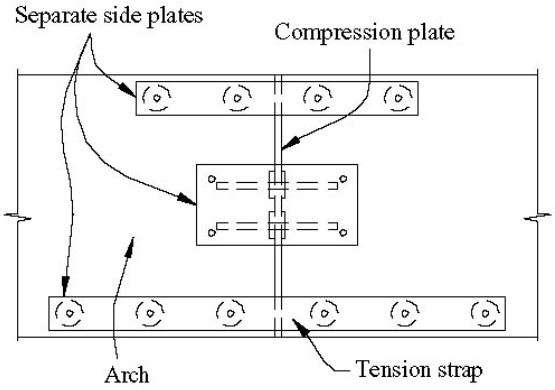


Figure C1.1.3 Typical arch moment splice.

APPROPRIATE SEISMIC LOAD COMBINATIONS FOR BASE PLATES, ANCHORAGES, AND FOUNDATIONS

The suitability of existing load combinations has been increasingly questioned as building code provisions have shifted from an allowable stress design (ASD) basis towards a strength or load and resistance factor design (LRFD) basis. Foundation design requirements remain grounded in ASD because consensus is lacking on how to convert these requirements to an ultimate strength basis. Disagreement also exists concerning which requirements for base plates and anchorage are appropriate in that building designers are inclined to specify use of the special seismic load combination for these elements whereas designers of nonbuilding structures tend to rely on inelastic behavior and, to some extent, uplift or sliding. This resource paper presents the findings of a study conducted to determine appropriate load conditions for base plates, anchorages (via anchor bolts, anchor rods, or other), and foundations (either shallow or deep).

CONTROLLING BEHAVIOR OF STRUCTURAL COMPONENTS IN SERIES

The system created when a structural element is attached to a base plate, anchorage, and foundation is a "series" combination of structure elements as shown in Figure 1. In the simplest sense, a series combination can be conceptualized as a chain of components in which the maximum strength and deformation capacity of the combination is controlled by whichever component is the weakest in the series.

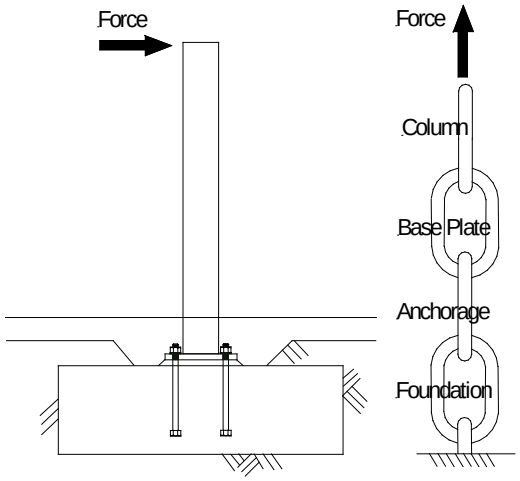

Figure 1 Structural elements in series (column, base plate, anchorage, foundation, and soil).

In actuality, each component has different strength and deformation capacities. Figure 2 illustrates the strength and deformation capacities of three imaginary components. System 1 is a flexible ductile element; System 2 is a rigid and weaker but ductile element; and System 3 is a rigid and brittle but strong element.

If these elements are connected into a series, the combined strength and deformation capacity of the system would be determined by summation of the individual displacements of each element at any given force level (Figure 3). This type of combination is referred to as a force-dependent structural system.

For the example shown in Figure 2, the combined strength and ductility capacity of the structural system is entirely controlled by System 2, because both the yield and ultimate strength of System 2 is less than the yield strength of either System 1 or System 3. For purposes of discussion, the behavior of System 1 might be imagined as that of a building structural element, System 2 might be the rocking behavior of a shallow foundation, and System 3 might be that of a low-ductility base plate and anchorage. The low ductility of System 3 is not a problem because this element always remains elastic; however, the low strength of System 2 may be a problem because it prevents the relatively good ductility of System 1 from being utilized.

In order to transition the controlling behavior and mechanism from System 2 to that of System 1, the required strength of System 2 needs to be increased until the ultimate strength of System 1 is less than that of System 2 as shown in Figure 3. This demonstrates that appropriate scaling of the seismic component in load combinations is a necessary factor in controlling structural behavior.

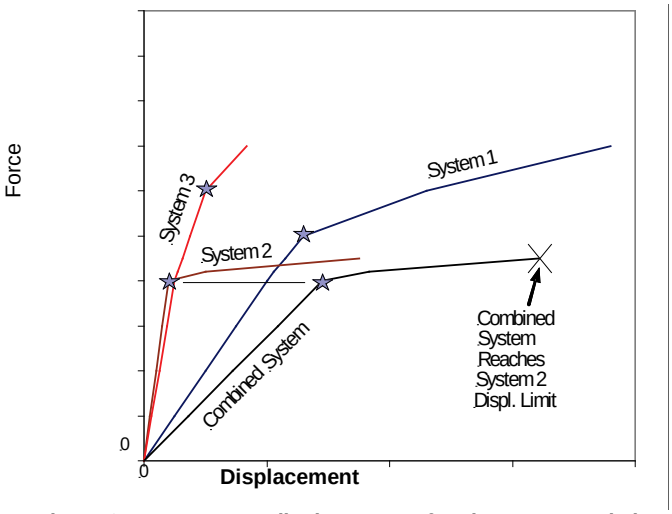

Figure 2 Force versus displacement of series-connected elements.

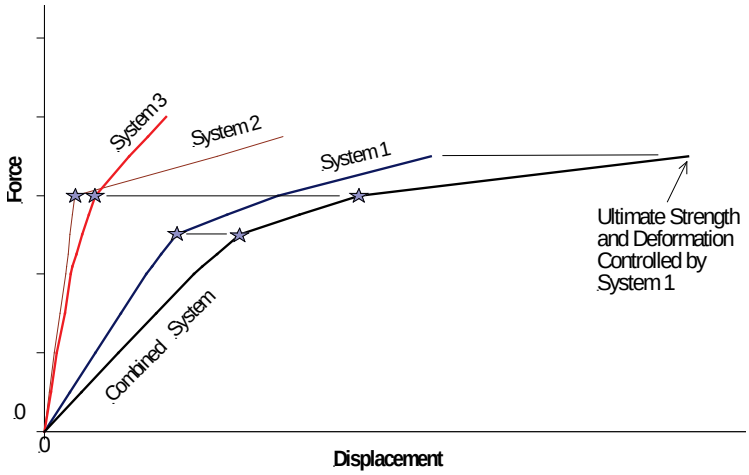

Figure 3 Using load factors to increase required strength of System 2 causes behavior to be controlled by System 1.

Base Plates and Anchorages. Base plates and anchorages are commonly used for: steel structures; light-frame structures; large nonbuilding structures such as tanks, vessels, and signs; equipment attachments; and nonstructural component attachments. Design standards and ductility requirements vary considerably for these items. Table 1 summarizes some of the broad variety of criteria currently used to define the seismic strength requirements and permitted capacity values for various types of structural elements that typically use some form of anchor rods/bolts and base plates or anchorages.

Current design standards for steel buildings specify use of the special load combination for base plates and anchor rods[1] for steel columns unless the provisions of ASCE/SEI 7-05 Table 12.2-1 System (H) are permitted. When anchor rods may be needed to attach elements other than columns, increased strength requirements are not currently required.

When anchor bolts are required for light-frame construction, current design standards generally do not require any different strength requirements than for the attached structural component.

Designers of some types of nonbuilding structure have shown a preference for using foundation anchor bolts as a yield mechanism to provide structural ductility. For example, ASCE/SEI 7-05 Section 15.7.5 and API standards require that the vertical vessel structures typically found in oil refineries, which do not have significant ductility, be intentionally designed to create a plastic mechanism of tensile yielding in the anchor bolts used to attach the vessel to its foundation. The anchor bolts

[1] AISC has introduced the term "anchor rod" to describe a bolt that attaches steel to concrete, but other standards groups continue to use the term "anchor bolt." This paper uses the term "anchor rod" when specifically referring to AISC standards and the term "anchor bolt" with respect to anchorage in general.

are specified to use ductile material and to be installed in a manner that facilitates tensile yielding over a significant length of the bolt. The anchorage used to attach the anchor bolts to the vessel as well as the vessel itself is then designed to mobilize the full strength of the anchor bolts.

Table 1 Summary of Selected Criteria

	System Type	R_{max}	Element	Required Seismic Load Effect	Design Criteria	Average Anchor or Attachment Strength Relative to Supported Item
Steel Buildings	High seismic; SDC D-F (AISC definition)	SPSW[f] R = 7	Attachments	E	AISC Seismic	Same
			Anchorage	Uncertain	ACI D3.3 w/AISC modifications	Same
		Other system types, R_{max} = 8	Base plate	E_m	AISC Seismic	Same
			Anchorage	E_m	ACI D3.3 w/AISC modifications	Same
	Low seismic; SDC A-C (AISC definition)	Systems with > 3	(Same as high-seismic SDC D-F requirements)			
		Systems with $R \leq 3.0$	Base plate	E	AISC 360	Same or weaker[b]
			Anchorage	E	ACI D3.3	Same or weaker[b]
Light-Frame Buildings	Shear wall	7.0	Uplift devices	E/1.4	ICC-ES	Varies
			Uplift anchorage	E	ACI D3.3, SDC C-F	Stronger[a]
				E	ACI D3.3, SDC A-B	Same
			Shear anchorage	E	ACI D3.3, SDC C-F	Stronger[a]
				E	ACI D3.3, SDC A-B	Same
Nonbuilding Structures	Having building-like structural systems	8.0	Same as steel buildings including high and low seismic categorization			
	Other types	3.5	Base plate and attachments	E	AISC 360[e]	Same
			Anchorage	E	ACI D3.3, SDC C-F other industry standards may govern	Stronger[a]
				E	ACI D3.3, SDC A-B	Same
Nonstructural Components	Supports and attachments for ductwork or welded piping	R_p = 10.0[d] max	Base plate and attachments	E or E/1.4	Generally from ICC-ES ESRs	Same
	Supports and attachments for other components	R_p = 6.0 max	Base plate and attachments	E or E/1.4	Generally from ICC-ES ESRs	Same
	Anchors seismically-qualified or per ACI D3.3)	R_p = 6.0 max	Anchorage per ASCE 13.4	E	ICC-ES AC193, AC308	?
					ACI D3.3, SDC C-F	Stronger[a]
					ACI D3.3, SDC A-B	Same
	Other nonductile anchors	R_p = 1.5	Anchorage per ASCE 13.4	$(1.5/R_p)\,E$	ICC-ES AC193, AC308	Stronger

[a] Presumed stronger because ACI D3.3 applies a 0.75 strength reduction factor to the anchor strength.
[b] Weaker when supported item strength is determined by drift or other considerations.
[c] ASD strengths determined using ICC-ES reports are based on tests.
[d] Welded piping with R_p=12 is effectively only R_p=10 because of the $F_{p\,min}$ requirement.
[e] API and AWWA requires anchorage to be designed for yield load of anchor.
[f] SPSW = steel plate shear walls.

Nonstructural components such as fan motors, piping systems, and building facades often have cast-in or post-installed anchors with limited or no ductility for support. In some instances, the anchorage or bracket used to attach the component to the anchor is the element most capable of providing some degree of ductility in the attachment. In many cases, imposed displacements are the controlling factor in the anchorage design.

There is too much variety in structure and attachment types to define any single target behavior about which load combinations might be developed. Considering the wide variety of structures and components that utilize base plates and anchorages, there exist valid justifications to define ductility requirements for the structural element, the base plate/anchorage, or the anchor bolt. Recommended future code development should instead target rational rules within the three basic arenas of yield mechanisms. For each situation, specific design and detailing rules are appropriate to include in conjunction with the intended yield mechanism.

For the anchor rod/bolt as a yield mechanism:

1. Design the base plate/anchorage to resist the actual (not specified) tensile strength of the anchor bolt.
2. Design the foundation anchorage to resist the actual tensile strength of the anchor bolt.
3. Use ductile steel for the anchor bolt and nuts capable of developing the anchor bolt strength.
4. In the case of cast-in and post-installed grouted anchors, consider de-bonding the anchor bolt from the concrete over a significant length (inelastic length) to permit development of meaningful displacements.
5. Either use continuously threaded rod to ensure uniform yielding over the inelastic length of the anchor bolt or ensure that the rod material has sufficient tensile strength relative to its yield strength that the rod is fully yielded before tension fracture occurs. Upset threads are not considered necessary for anchors resisting seismic loads.
6. Consider use of nuts on both sides of the base plate so that progressive elongation of the anchor bolt is reduced and cyclic reversals have a chance to cycle rod in compression (however, anchor bolts are not recommended for direct transfer of shear forces).
7. Provide adequate stretch length in the yielding section of anchor bolts to accommodate maximum expected inelastic displacements and rotations.

For the anchorage/base plate as a yield mechanism:

1. Design the anchor bolt, particularly if nonductile (e.g., an expansion bolt), to be stronger (elastic strength) than the yield strength of the anchorage assembly and with adequate displacement capacity to accommodate maximum joint movements.
2. Qualify post-installed anchor bolts by appropriate testing to confirm adequate strength and ductility characteristics under anticipated design conditions.
3. Although using an anchorage or base plate as the intended yield mechanism may be successful at protecting a nonductile anchor bolt from failure, the total work performed in a small anchorage may not provide adequate hysteresis to reduce global structural seismic behavior.

For an unyielding anchorage/anchor bolt assembly:

1. Utilize the design requirements for the non-ductile structural elements that currently exist.
2. Ensure that the load-amplification provisions for the anchor bolt/rod and base plate which are expected to remain elastic do not overlap.

FOUNDATIONS

A geotechnical engineer tends to define the ultimate strength of a foundation at a point when either an unstable soil movement is imminent or a limiting value of displacement is reached. A structural engineer tends to define the ultimate strength of a foundation at a point when either the occurrence of an unstable mechanism within the structure is imminent (such as rocking) or a structural capacity is reached. In other words, the geotechnical engineer assumes that the soil will fail before the structure, and the structural engineer assumes that soil behavior can be simplified to the extent of being a simple fluid or force; neither assumption is correct.

In conventional design, the geotechnical engineers need to define soil strength values for both seismic and long-term load conditions early in the design process when the size, shape, and ultimate loading on the foundations are, at best, only rough estimates. Unless ultimate foundation strengths can be re-evaluated by the geotechnical engineer at a later design stage when the sizes, shapes, and loading of foundations are relatively definite, the geotechnical engineer typically will maintain some degree of conservatism with respect to potential geotechnical mechanisms.

The traditional practice of arbitrarily defining a one-third increase in permitted long-term soil pressures for seismic loading does not adequately reflect what is necessary to transition from ASD to an ultimate strength design. While the one-third increase might be suitable for checking stresses for a 100-year wind event, it is not suitable for determining adequacy for a limit-state seismic event. It is therefore necessary to separately define design limit values for limit-state and long-term load conditions.

Table 1804.2 of the 2006 *International Building Code* (IBC) reproduced below requires substantial revision as part of any change to strength design procedures.

2006 IBC Table 1804.2 Allowable Foundation and Bearing Pressure

CLASS OF MATERIALS	Allowable Foundation Pressure (psf)[d]	Lateral Bearing (psf/ft below natural grade)$_d$	Lateral Sliding	
			Coefficient of friction[a]	Resistance (psf)[b]
1. Crystalline bedrock	12,000	1,200	0.70	--
2. Sedimentary and foliated rock	4,000	400	0.35	--
3. Sandy gravel and/or gravel (GW and GP)	3,000	200	0.35	--
4. Sand, silty sand, clayey sand, silty gravel and clayey gravel (SW, SP, SM, SC, GM, and GC)	2,000	150	0.25	--
5. Clay, sandy clay, silty clay, clayey silt, silt and sandy silt (CL, ML, MH and CH)	1,500[c]	100	--	130

[a]Coefficient to be multiplied by the dead load.
[b]Lateral sliding resistance value to be multiplied by the contact area as limited by Section 1804.3.
[c]Where the building official determines that in-place soils with an allowable bearing capacity of less than 1,500 psf are likely to be present at the site, the allowable bearing capacity shall be determined by a soils investigation.
[d]An increase of one-third is permitted when using the alternate load combinations in Section 1605.3.2 that include wind or earthquake loads.

Performance Statement for Soil Limit-State Condition. In order to define the soil and foundation strength values associated with limit-state design, a definitive performance statement for structural and geotechnical conditions at the limit state needs to be developed.

When structural actions result in repeated cycles of loading at or near the limit-state soil pressure, some degree of progressive foundation settlement is expected to occur due to compaction and local shear movements of soil materials beneath the foundation as shown in Figure 4. The total and differential settlements resulting from repeated cycles of loading should be considered in the light of the performance-based design criteria. Large total settlement may not be detrimental if the differential settlements between adjacent foundations are within acceptable limits.

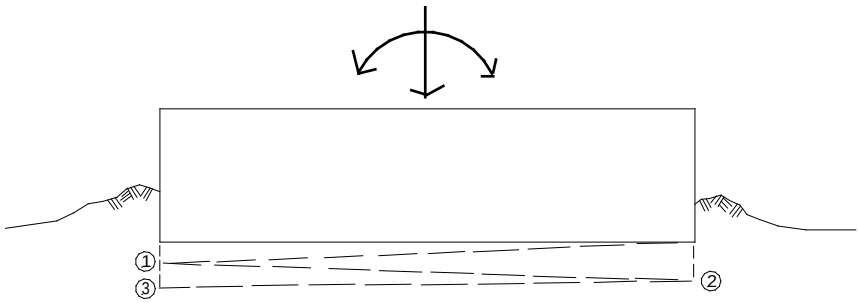

Figure 4 Progressive settlement during repeated cycling.

Rotational mechanisms of foundations due to soil shear failures as shown in Figure 5 should not be permitted. Maximum structure overturning moments should maintain a factor of safety against soil shear failure mechanisms of at least 2; otherwise foundations should be interconnected by grade beams so that the resulting soil loading will be primarily direct compression.

Lateral sliding of buildings and other structures may be resisted by both friction and passive soil pressure. Lateral displacement or sliding of foundations during the design event may be permissible; however, structural stability must be maintained.

Strength and Overstrength of Shallow Foundations. Past and current code provisions for both shallow and deep foundations have been based on allowable strength design methodology. FEMA 450-1 includes an appendix that has proposed a new strength design methodology. An evaluation of foundation design provisions must address both methodologies.

Selected 2006 IBC sections relative to seismic load combination requirements for shallow foundations are:

1. Section 1605.2.1 – permits use of strength load combinations in conjunction with the maximum 25 percent reduction in overturning moment permitted in ASCE/SEI 7 Section 12.13.4.
2. Section 1605.3.1 – permits use of ASD load combinations [$D + H + F + 0.7E$] and [$0.6D + 0.7E + H$].
3. Section 1605.3.2 – permits use of alternative ASD load combinations [$D + L + S$ + E/1.4] and [$0.9D + E$/1.4] without the overturning reduction permitted by ASCE/SEI 7-05 Section 12.13.4.
4. Table 1804.2, Footnote d, permits a one-third increase in allowable soil pressures when using the alternate load combinations that include seismic loads.

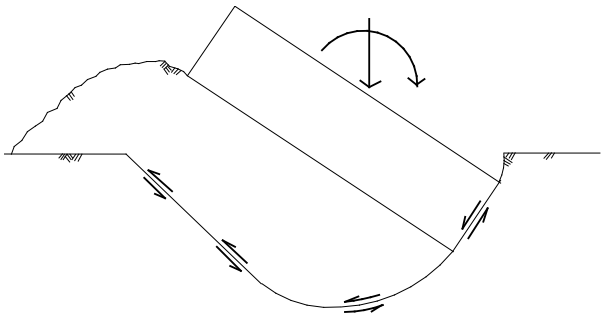

Figure 5 Foundation rotational mechanism within soil.

Proposed new IBC Table (expected to follow existing Table 1804.2) Limit-state Foundation and Bearing Pressure (for use with Section xxx, Load Conditions)

Class of Materials	Ultimate Foundation Pressure (psf)	Lateral Bearing (psf/ft below natural grade)	Lateral Sliding	
			Coefficient of friction	Resistance (psf)
1. Crystalline bedrock	24,000	2,500	0.70	--
2. Sedimentary and foliated rock	10,000	1,000	0.35	--
3. Sandy gravel and/or gravel (GW and GP)	8,000	600	0.35	--
4. Sand, silty sand, clayey sand, silty gravel and clayey gravel (SW, SP, SM, SC, GM, and GC)	6,000	500	0.25	--
5. Clay, sandy clay, silty clay, clayey silt, silt and sandy silt (CL, ML, MH and CH)	4,500	300	--	400

The load combinations defined in Section 1605.3.2, in combination with the one-third increase permitted in Table 1804.2 are commonly used in current practice.

An unusual additional load combination provision is found in ACI 318 Section 15.2.2: "Base area of footing or number and arrangement of piles shall be determined from unfactored forces and moments transmitted by footing to soil or piles and permissible soil pressure of permissible pile capacity determined through principles of soil mechanics." Although ACI 318, Section 21.10 (seismic foundation requirements), does not override this section, it does conflict with IBC Section 1605, which would govern over the ACI provision.

Traditionally, the structural design of shallow foundations assumes that soil pressure beneath the foundations can be treated as a linearly-varying pressure across the length of the foundation, forming a pressure diagram which, depending upon the degree of eccentricity, $e = M/P$, can be described as either trapezoidal or triangular in shape. The 2003 *NEHRP Recommended Provisions* (FEMA 450) introduced a foundation strength design approach that permits a Whitney stress-block approach to be used to simulate an ultimate soil pressure condition to be used to design shallow foundations. Appendix 1 of this paper presents a summary of Equations 1 and 2, which describe the ASD load limits of simple rectangular-in-plan foundations. It also includes an Equation 3 that describes the strength limits for the strength design approach introduced in 2003 Provisions and now described in Resource Paper 4 of this volume. Using Equations 1 through 3, simple load vs. moment interaction curves can be developed for any rectangular foundation shape.

Figure 6 presents an example interaction curve for a 10-foot square foundation with an allowable long-term soil pressure of 3 ksf and an assumed ultimate soil strength of 9 ksf. In the figure:

1. The radial line occurs at $e = L/6$, the transition from trapezoidal to triangular soil pressure distribution.
2. Line 1 represents an interaction curve using ASD design assumptions with an allowable soil pressure of 3 ksf.

3. Line 2 represents the effect of a 33 percent allowable increase in soil pressure for temporary load conditions to 4 ksf.
4. Line 3 represents the effect of using IBC Section 1605.3.2 to design foundations (the reduction of $E/1.4$ is represented as an increase in allowable soil pressure by a factor of 1.4).
5. Line 4 represents the interaction curve at the ultimate soil pressure of 9 ksf using traditional triangular/trapezoidal soil pressure distribution (i.e., the ultimate soil pressure occurs only at the extreme edge of the foundation).
6. Line 5 represents the interaction curve at the ultimate soil pressure of 9 ksf using a equal-pressure soil distribution.

The overstrength of the traditional ASD design approach can be expressed as the ratio between the presumed ultimate (Line 5) and the design-level (Line 3) interaction curves. The amount of overstrength that results using the ASD design approach is not constant; it varies significantly depending on how much vertical load is on the foundation. Let us define P as the actual vertical load on a foundation and P' as the theoretical maximum permitted vertical load capacity of a concentrically loaded foundation (equal to the maximum permitted soil pressure times the total footing area). For more lightly loaded foundations (having $P/P' < 0.5$), the amount of overstrength present varies significantly to the extent that when a foundation is at $P/P' = 0$ (such as when a foundation is loaded in direct uplift), the effective factor of safety present is 1.0 (i.e., no overstrength).

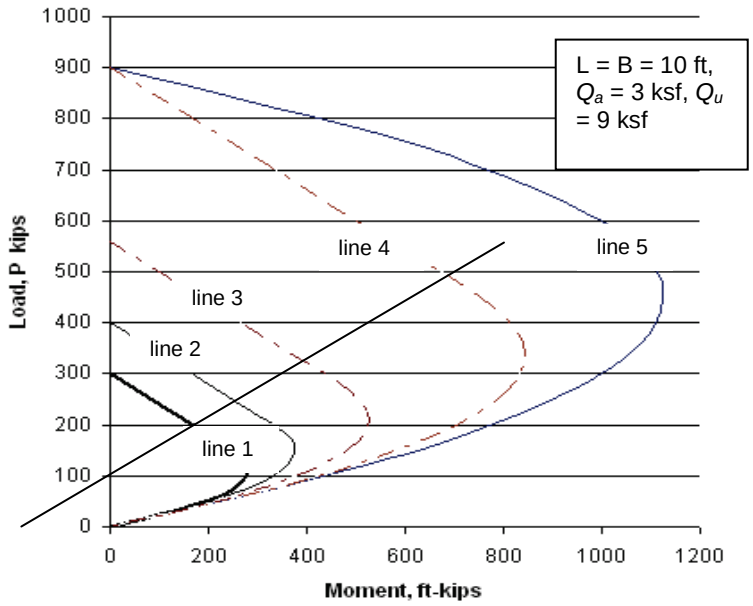

Figure 6 Example interaction curve for a shallow foundation.

Although the foundation strength design approach defined in the FEMA 450 Appendix to Chapter 7, introduced in 2003 Provisions and now described in Resource Paper 4 of this volume, defines procedures that can be used to determine an ultimate strength design such as shown in Line 5 of Figure 6, it is silent regarding which strength load combinations to use for design. The available alternatives are either the ASCE/SEI 7 seismic load combinations defined in Section 12.4.2.3 or the special load combinations defined in Section 12.4.3.2.

The basic strength load combinations are not generally appropriate for use in conjunction with ultimate foundation strength values. Using load combinations incorporating $1.0E$ together with the ultimate foundation strength means that the design procedure permits no overstrength to be present at all in the design (i.e., that foundation failure will always be the dominant controlling mechanism in any structure). It also means that the expected ductility capacity of the resulting foundation mechanism must equal or exceed the value of R used in the design (whereas for the building structure the expected ductility demand is $R_d = R / R_O$. If the special load combination is used in conjunction with ultimate foundation strength values, foundation rocking or sliding mechanisms are unlikely to be a controlling or participating mechanism in the structure response. While this might be an acceptable or desired characteristic for structures using high-R systems or for essential facilities, it is probably an undesirable characteristic for ordinary-use structures using moderate- or low-R systems. Because modest levels of foundation nonlinearity generally are considered to be acceptable for ordinary structures using moderate- or low-R systems, the use of the special load combinations would prevent such action and would result in an increase in their expected construction cost.

Strength of Deep Foundations. Although the ultimate strength of a deep foundation cannot be simplified in the same manner as a shallow foundation, simplified methods can be used to predict ultimate strength values with a slight resemblance to reality. Geotechnical engineers can determine allowable ultimate and long-term load capacities of assumed pile groups, translate that into individual-pile ultimate and long-term load values for the structural engineer, and the structural engineer then can translate those back into predicted ultimate and long-term pier or pile-group capacities that may or may not resemble the values originally determined by the geotechnical engineer.

Appendix 2 of this paper presents two examples of how a structural engineer might estimate the ultimate strength of a pile group based on individual-pile capacities. Both of these approaches are vast oversimplifications of the actual interaction and response that occurs between the structure and soil of a deep foundation, but they are both simple enough for practicing engineers to adopt as design practice. The first example is a modification of a current common design practice for multi-pile foundations that assumes the ultimate strength point is reached when the outermost pile reaches a defined ultimate strength. The second example is a plastic-analysis approach that assumes all piles in a pile group are eventually able to reach their defined ultimate strengths. The plastic analysis approach likely overestimates the strength that a multi-pile group is capable of developing; however, the 0.7 φ factor will provide significant compensation when using either approach. Further, both approaches require that the pile cap structure have sufficient strength to accommodate the full expected strength of the foundation capacity that is used, but many engineers probably would prefer the more conventional linear-strain approach in order to reduce the required strength of pile caps.

More accurate methods to predict the ultimate strength of deep foundations include field testing of individual piles, reduced-scale testing of pile groups, and prediction of strength and deformation states of both foundation and soil through complex models of the combined foundation and surrounding soil. Analysis of soil seismic behavior in this manner should include the strain-dependent strength of the soil materials due to both foundation loading and ongoing seismic deformations.

Overstrength of Deep Foundations. Deep foundations are significantly different from shallow foundations in that deep foundations can have tensile strength, overturning strength with low gravity loads, and element overstrength properties similar to superstructure elements. Deep foundations therefore might be capable of internally developing overstrength values in the range of tabulated Ω_0 values provided that adequate ductility is present in the piles. Thus, for deep foundation, there is no clear need for specifying a special or increased load combination in order to offset a lack of overstrength in the foundation system as there is for lightly loaded shallow foundation systems. However, earthquake damage in deep foundations is difficult to detect and is probably frequently overlooked in post-earthquake damage investigations and, even if detected, it is very costly to repair. This might justify an increase in deep foundation strength for higher Seismic Design Category structures since foundations for these structures might be expected to experience more than one damaging earthquake during the foundation's service life and the potential loss-of-use and repair costs are less acceptable.

Recommendations for Foundations. Foundation design including soil pressures for either shallow or deep foundation systems might utilize ultimate strength design load combinations in which the value of *E* is as shown in Tables 2 and 3.

Table 2 Buildings and Building-like Nonbuilding Structures

***R* Value from ASCE/SEI 7 Table 12.2-1,12.14-1, or 15.4-1**	**Fixed-Base Analysis**	**Including Foundation Deformations per ASCE/SEI41**
For $R \geq 5$	2.0 *E*	1.5 *E*
R 3 to < 5	1.5 *E*	1.0 *E*
$R \leq 3$	1.0 *E*	1.0 *E*

Table 3 Nonbuilding Structures Not Similar to Buildings

***R* Value from ASCE/SEI 7 Table 15.4-2**	**Fixed-Base Analysis**	**Including Foundation Deformations per ASCE/SEI 41**
$R > 3$	1.5 *E*	1.0 *E*
$R \leq 3$	1.0 *E*	1.0 *E*

It is likely that this scaling would apply to the full value of $E = E_h + E_v$ used in design with no other reduction permitted; however, it is recognized that the full effects of design including redundancy factors, importance factors, and the vertical seismic component have not been studied in depth and that the results of such an in-depth study might warrant further changes. These load factor scaling factors were selected in conjunction with the foundation-soil strength values (including phi-factors) presented in this paper. Inherently, the load factor of 2.0*E* is intended to result in a structure in which inelastic response is preferred in the portions of the structure that are above the foundation and base plate while the load factor of 1.0*E* was selected with the intent that some inelastic response might be preferred in the foundation of light structures. The load

factor of 1.5*E* was selected as a value that would provide for inelastic response in the foundation, in the supported structure, or in both elements.

It is recognized that simple rules often yield imperfect results and that some structural systems might be identified that defy the logic of this reasoning. For instance, foundations beneath shear panels of light-frame buildings would be required to be designed using 2.0*E* suggesting that the foundations beneath these elements should remain relatively elastic while many engineers might argue that a load factor of 1.5*E* might be more appropriate. However, until a more rational means of determining *R* values prevails, this relatively simple table was judged to be generally effective in providing the preferred inelastic behavior distribution.

No distinction was made between the load factor recommendations for deep and shallow foundations because the load factors recommended appear likely to result in at least as much successful behavior for deep as opposed to shallow foundations.

Common ASD methods currently used for seismic design can be approximately matched with the ultimate foundation strengths discussed herein by dividing calculated ultimate foundation strengths by a factor of safety of 3.0 and using the earthquake forces recommended above reduced by a factor of 1.4.

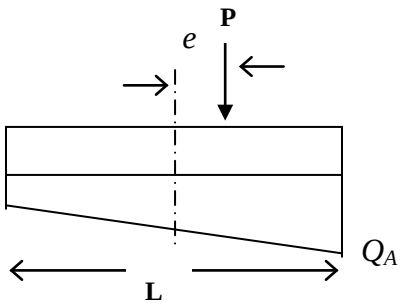
Appendix 1, DERIVATION OF SHALLOW FOUNDATION EQUATIONS



Traditional ASD Design – Full Contact

Given: P = vertical load
M = overturning moment
L = length of rectangular footing
B = width of rectangular footing
$e = M/P$ = eccentricity of loading
Q_A = maximum ASD allowable soil pressure

From the standard ending stress equation:

$\sigma = P/A \pm M/S$, the maximum soil pressure, Q_A will be:

$$Q_A = \frac{P}{BL} + \frac{6M}{BL^2} = \frac{P}{BL}\left(1 + \frac{6e}{L}\right)$$

Rearranging,

$$e = \frac{L}{6}\left(\frac{Q_A}{P}BL - 1\right)$$

Introduce the term: $P' = Q_A BL$ so that we can substitute $BL = P'/Q_A$ resulting in

$$\frac{e}{L} = \frac{1}{6}\left(\frac{P}{P''} - 1\right) \qquad (1)$$

Traditional ASD Design – Partial Contact

For $e \geq L/6$, the soil pressure is assumed as a triangular distribution.

$$Q_A = \frac{2P}{3B\left(L/2 - e\right)}$$

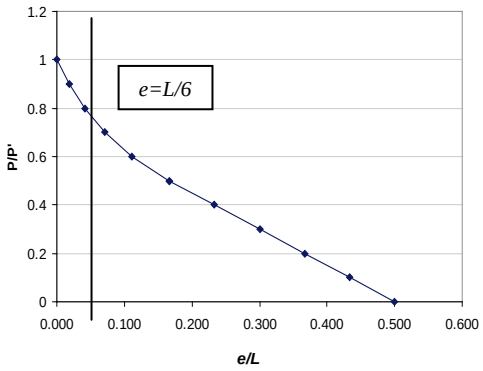
Rearranging,

$$e = \frac{L}{2} - \frac{2}{3}\frac{P}{Q_A B}$$

Substituting $Q_A B = P'/L$,

$$\frac{e}{L} = \frac{1}{2}\left[1 - \frac{4}{3}\left(\frac{P}{P'}\right)\right] \qquad (2)$$

At the transition point between Equations 1 and 2, $e = L/6$ and $P/P' = 1/2$. The following is a graph of Equations 1 and 2:

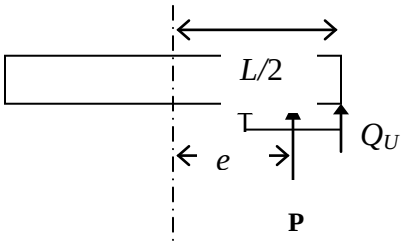


Simplified Ultimate Strength Design Method

A simplified ultimate strength design approach, based on the Whitney Stress Block Method, follows:

Define (in addition to terms used above):

Q_U = Ultimate Soil Pressure



For an assumed rectangular soil pressure distribution;

$$Q_U = \frac{P}{2B\left(L/2 - e\right)}$$

Substituting $B = \frac{P'}{LQ_A}$:

$$\frac{e}{L} = \frac{1}{2}\left[1 - \left(\frac{Q_A}{Q_U}\right)\left(\frac{P}{P'}\right)\right] \qquad (3)$$

Graphing this equation against the ASD equations:

Resource Paper 9

SEISMIC DESIGN USING TARGET DRIFT, DUCTILITY, AND PLASTIC MECHANISMS AS PERFORMANCE CRITERIA

Traditional seismic design methods operate in the elastic domain and use a response modification coefficient in conjunction with a period of vibration to establish required member strengths. This resource paper presents a design approach that establishes the base shear required to limit ductility and drift demands based on an estimate of the yield displacement and uses a plastic mechanism analysis to establish required member strengths. It is suggested as an alternative to the equivalent lateral force procedure and is presented in Part 3 of the 2009 NEHRP Recommended Seismic Provisions in order to expose the approach to the design community and to elicit feedback from members of that community.

BACKGROUND

Traditional seismic design methods operate in the elastic domain and use a response modification coefficient in conjunction with a period of vibration to establish required member strengths. The design approach presented here is an alternative to the equivalent lateral force (ELF) procedure. Several recent developments are combined to achieve simplicity and transparency in the design process. Unique features of this design approach are:

1. An estimate of the yield displacement in a first-mode pushover analysis is used as an initial basis for proportioning the seismic-force-resisting system in a manner analogous to the way that an estimated period is used in current code approaches. This approach reduces the need for iterations in proportioning the structural system.
2. Equivalent-single-degree-of-freedom (ESDOF) systems are used explicitly for determining the required base shear strength; estimates of modal parameters are used in preliminary design.
3. The required base shear strength is determined using a representation of inelastic spectra known as yield point spectra (YPS). The elastic portion of the YPS is given by smoothed elastic design spectra defined in the 2009 *NEHRP Recommended Seismic Provisions*; inelastic portions are derived on the basis of coefficient relationships that were recommended in a 2005 report published by the Federal Emergency Management Agency, *Improvement of Nonlinear Static Seismic Analysis Procedures* (FEMA 440).
4. An improved lateral force distribution is used which results in a more uniform distribution of peak interstory drifts over the height of the structure as well as a reduction in column design moments relative to those obtained with the current ELF procedure.
5. A plastic mechanism analysis is used to determine required member strengths given the required base shear strength. The analysis assists the engineer in visualizing the intended mechanism, makes preliminary sizing of designated yielding members very simple, and helps ensure that an intended mechanism actually develops.

System ductility demands are a measure of damage to structural components. Values of system ductility corresponding to currently recognized seismic-force-resisting systems are suggested for use with this approach. Interstory drift is a measure of damage to nonstructural components. Relationships between interstory drift and roof drift are suggested as a basis for complying with currently recognized allowable story drift limits. System ductility and roof drift limits are explicitly considered when establishing the required base shear strength, in order to limit damage to structural and nonstructural components.

In many cases, the estimate of the yield displacement will be sufficiently accurate that no iteration of the preliminary design will be needed.

Figure 1 illustrates how system ductility and roof drift limits define regions where the yield points of single-degree-of-freedom (SDOF) and equivalent SDOF (or ESDOF) systems either satisfy the ductility and drift limits or fail to satisfy one or both of these limits. For a given yield displacement, satisfaction of both limits requires that the larger of the associated yield strengths be provided. Because a change in strength is usually achieved by changing the amount of structural material, the stiffness changes as well. Thus, the period of vibration is a consequence of the strength provided to satisfy drift and ductility limits, and an estimate of the yield displacement is used as a starting point rather than an estimate of the period. The admissible design region shown in Figure 1 was derived for a particular performance objective; when multiple performance objectives must be considered, each may further constrain the admissible design region. Details of the construction and interpretation of YPS are provided in the appendix to this paper.

Because the lateral force distribution results in more uniform peak interstory drifts over the height of the structure, those structures for which interstory drift is the controlling design parameter can be allowed to achieve larger peak roof drifts relative to those obtained with current code approaches. As a result, structures that are slightly more flexible (longer period) than obtained with current code approaches may be found to be acceptable.

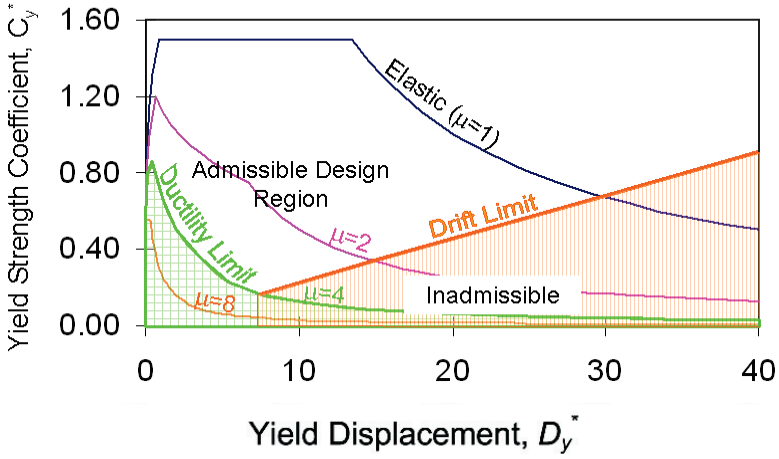

Figure 1 Limits on ductility and drift demands are used to establish admissible and inadmissible design regions. SDOF and ESDOF oscillators that have yield points located within the admissible design region satisfy the ductility and drift limits shown.

Because the design is based on estimates of relatively stable parameters (yield displacement, first-mode participation factor, and first-mode mass coefficient) as well as the use of a plastic mechanism, little or no iteration in member sizes is required in typical cases. In some cases, by ensuring compatibility of the modal parameters obtained for the elastic model with the values assumed in the design, one can avoid nonlinear static (pushover) analysis. Schematic design, system selection, and even preliminary optimization can be done using only pencil and paper, avoiding the effort of developing detailed computer models.

The design approach presented here focuses on steel and reinforced concrete structural systems that do not have flexible diaphragms. Reinforced concrete design examples are provided herein; examples of the design of steel moment resistant frames using YPS are provided by Black and Aschheim (2000). Estimated values provided for initial proportioning presume fairly typical spatial distributions of lateral stiffness, strength, and mass; departures from typical distributions will increase the likelihood that design iterations will be needed. Systems with torsional irregularities and other important considerations (e.g., P-delta effects) addressed in Chapter 12 of the 2003 *NEHRP Recommended Provisions* are not addressed here nor are structural systems composed of materials other than steel and reinforced concrete and those using base-isolation or supplemental damping.

OVERVIEW OF DESIGN APPROACH

The design process is illustrated in Figure 2 and is described in detail in the sections that follow. An overview of the process and logic follows.

A structural system having a defined and desirable plastic mechanism is selected by the engineer. The required base shear strength, V_y, of this mechanism is determined to limit the peak roof displacement to an acceptable value considering interstory drift and system ductility limits. V_y is determined based on the corresponding ESDOF system using YPS. Estimates of the yield displacement, D_y, first-mode participation factor, Γ_1, and first-mode mass coefficient, α_1, are based on the type of structural system and number of stories. The base shear, V_y, is distributed over the height of the structure using an improved lateral force distribution. A simple plastic mechanism analysis is used to proportion the designated yielding members of the seismic-force-resisting system. A mathematical model of the structure is prepared and the calculated modal properties are used to assess the validity of the estimates D_y, Γ_1, and α_1 and whether changes to the design base shear might be needed. The preceding steps establish the strength of the intended mechanism. Force-protected members then can be proportioned to ensure that the intended mechanism can develop, considering amplification due to higher modes and material overstrength.

DESIRABLE INELASTIC MECHANISMS

Current seismic design philosophies presume the development of desirable inelastic mechanisms with the concentration of inelastic deformation demands occurring at locations detailed for ductile response. Figure 3 illustrates desired mechanisms applicable to several common structural types. Once selected, the desired mechanism is used to determine the required strengths of the yielding portions of the seismic force-resisting system using a virtual work analysis.

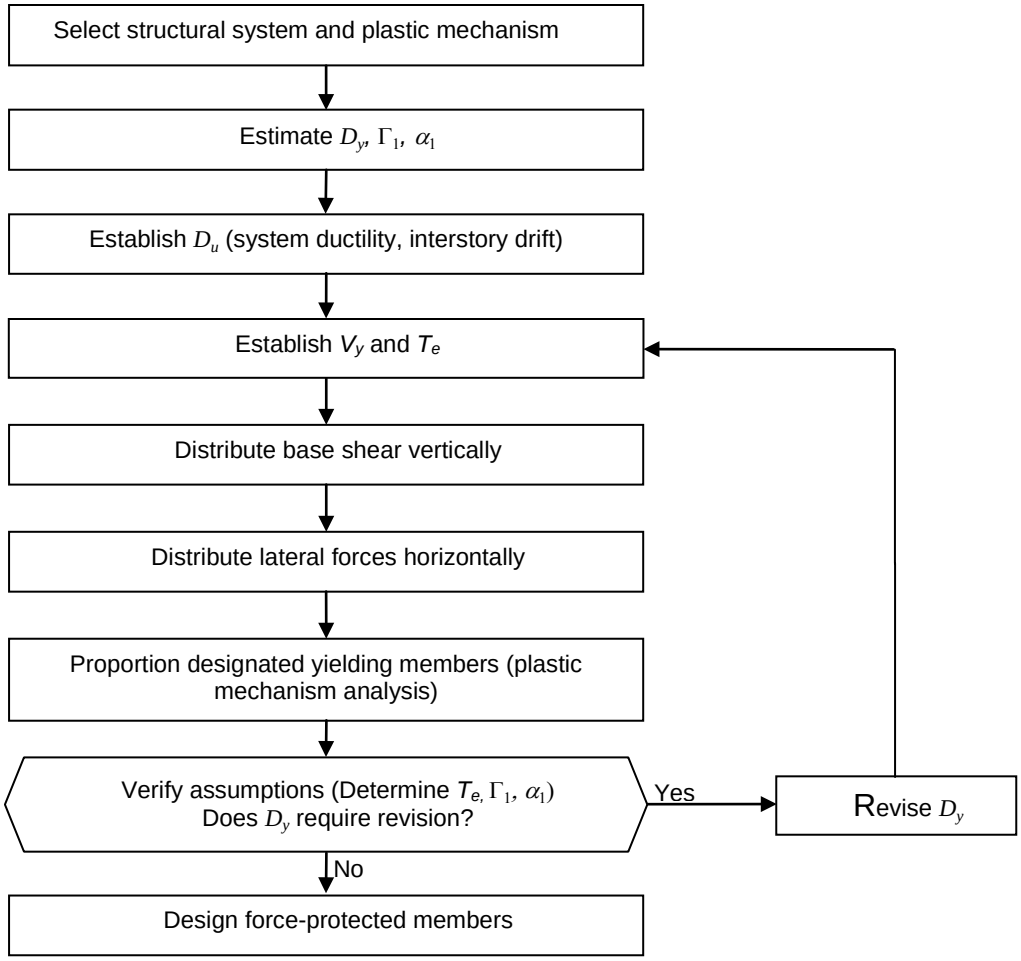

Figure 2 Steps in the design process.

ESTIMATES OF YIELD DISPLACEMENT

Nonlinear static or "pushover" analyses subject a model of a structure that includes nonlinear member force-deformation relationships to progressively increasing lateral forces. Of particular interest is the plot of base shear as a function of roof displacement obtained when lateral forces are proportional to the first mode (i.e., lateral force $F_{i,1}$ at the i^{th} floor level is proportional to the mode shape amplitude $\phi_{i,1}$ and weight, w_i). Such a plot is shown in Figure 4 for a four-story steel moment frame. The figure also shows a bilinear curve that has been fitted to approximately represent the initial stiffness and post-yield stiffness of the capacity curve. The breakpoint of the bilinear curve is known as the yield point, which defines the yield strength, V_y, and yield displacement, D_y.

Experience generally confirms the kinematic expectation that for any given structural system (distribution of mass, stiffness, and member depths), the yield displacement, D_y, determined in a pushover analysis varies with the yield strength of the steel members or reinforcement but is nearly independent of the strength of the system – that is, changes in strength achieved by increasing steel section weights or reinforcement percentages while maintaining member depths generally have a negligible influence on D_y (Priestley and Kowalsky, 1998; Priestley, 2000). Furthermore, the yield drift ratio (D_y normalized by the height of the structure) is nearly invariant with changes in the number of stories for a given structural system (e.g., Aschheim, 2000; Paulay, 2002). Thus, it is feasible to provide estimates of yield drift ratio to be used in design. The yield drift ratio

estimates can be used in much the same way that conventional seismic design approaches make use of period estimates. Periods of vibration, however, may vary significantly during design iterations whereas the yield displacement is fairly stable.

Estimates of the drift ratio at yield, D_y/h, for steel buildings using Grade 50 steel and for reinforced concrete buildings using Grade 60 reinforcement are given in Table 1.

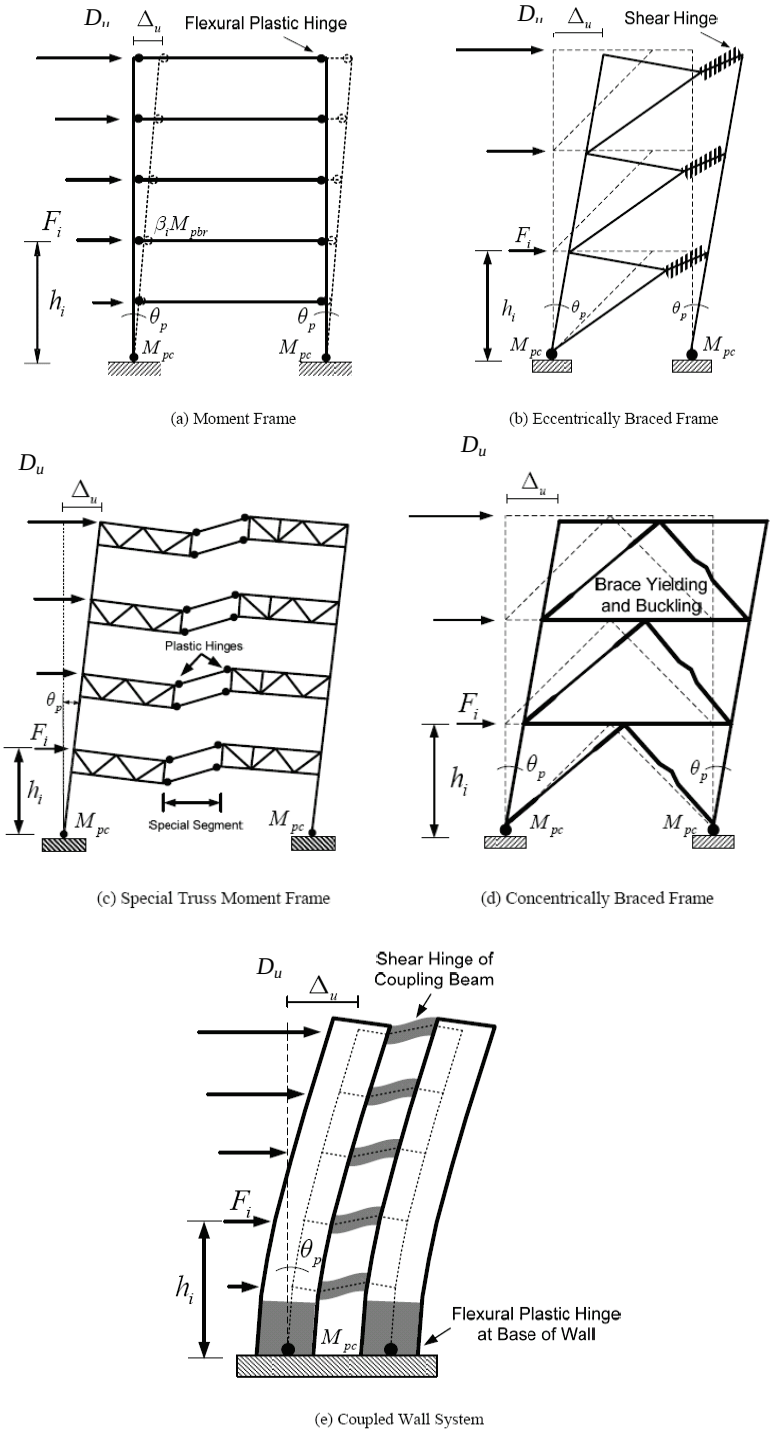

Figure 3 Desirable inelastic mechanisms.

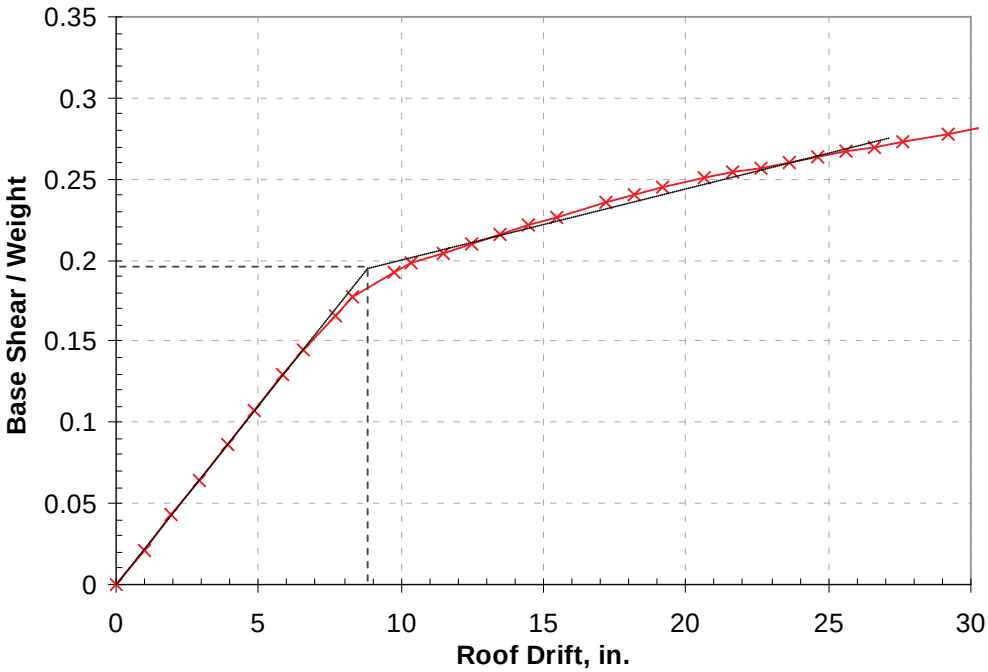

Figure 4 Capacity curve obtained from a nonlinear static (pushover) analysis.

Table 1 Yield Drift Ratio Estimates

Seismic-Force-Resisting System	Estimated Yield Drift Ratio, %
Reinforced Concrete Buildings	
Moment Frames	0.5 – 0.6
Cantilever Shear Walls[a]	0.10 h / l_w
Steel Buildings	
Moment Frames	1 – 1.2
Special Truss Moment Frames	0.75
Concentrically Braced Frames	0.3
Eccentrically Braced Frames	0.5
Buckling Restrained Braced Frames	0.3 – 0.5

[a] Expression is based on Tjhin et al. (2002).

Thus, the yield displacement for a building whose roof is at height h above the base is given as:

$$D_y = \left(\frac{D_y}{h} \right) h \qquad (1)$$

These drift ratios are considered suitable for preliminary design purposes; however, more refined estimates may be available in specific cases. The influence of foundation flexibility on the yield displacement and required strength determination also may be addressed as described in the appendix to this paper.

DETERMINATION OF PEAK DISPLACEMENT FOR DESIGN

Peak displacement response is limited to prevent excessive interstory drift and system ductility demands as a means of protecting nonstructural elements and the seismic-force-resisting system from excessive damage.

While the influence of higher modes (or MDOF effects in the case of inelastic response) on peak roof displacement generally is small, higher modes may play a more prominent role in peak interstory drift demands, particularly for systems that deform in a "shear" mode (e.g., moment-resistant frames). In the equivalent lateral force procedure, limits on allowable story drift are compared with story drifts determined from an elastic analysis using statically applied lateral forces. Larger interstory drifts can be expected during dynamic response. Thus, a *Provisions*-compatible design approach would compare interstory drifts under a static quasi-first-mode pattern of lateral forces with tabulated allowable story drifts.

Values of a coefficient, $\alpha_{3,stat}$, are given in Table 2 for different structural systems as a function of the number of stories. This coefficient is an estimate of the ratio of the maximum interstory drift ratio over the height of the building to the average roof drift ratio under first-mode lateral forces. Thus, for design purposes, compliance with allowable story drifts is approximately (and constructively) achieved by limiting the peak roof drift to:

$$D_{u,\Delta} = \frac{\Delta_a}{h_{sx} \cdot \alpha_{3,stat}} h \qquad (2)$$

where Δ_a is the allowable story drift from Table 12.12-1 of the 2003 *NEHRP Recommended Seismic Provisions*, h is the height of the roof level above the base, and h_{sx} is the parameter appearing in this table.

Table 2 Parameter Estimates

Number of Stories	Moment-Resistant Frames				Dual Shear Wall-Moment Frame Systems				Slender Cantilevered Shear Walls and Braced Frames			
	Γ_1	α_1	$h_{eff,1}/h$	$\alpha_{3,stat}$	Γ_1	α_1	$h_{eff,1}/h$	$\alpha_{3,stat}$	Γ_1	α_1	$h_{eff,1}/h$	$\alpha_{3,stat}$
1	1.00	1.00	1.00	1.00	1.00	1.00	1.00	1.00	1.00	1.00	1.00	1.00
2	1.21	0.94	0.79	1.19	1.24	0.89	0.81	1.00	1.24	0.76	0.86	1.38
3	1.27	0.90	0.73	1.23	1.33	0.85	0.75	1.00	1.35	0.70	0.81	1.49
5	1.32	0.86	0.70	1.26	1.40	0.82	0.71	1.00	1.46	0.66	0.78	1.58
10	1.35	0.82	0.67	1.28	1.45	0.79	0.69	1.00	1.54	0.63	0.75	1.64
≥ 20	1.37	0.80	0.66	1.29	1.48	0.77	0.68	1.00	1.59	0.62	0.74	1.67

Figure 5 conceptually illustrates the capacity curve and peak roof displacement for a structure responding in the first mode.

The coefficient Ω represents the true overstrength in contrast to the Ω_0 parameter specified in the 2003 *Provisions*. Coefficients C_1, C_2, α_1, and Γ_1 are defined below. Relative to the effective yield point shown in Figure 5, the system displacement ductility, μ, is:

$$\mu = \frac{D_{u,\mu}}{D_y} = \frac{C_1 C_2 \Gamma_1 S_d}{\Gamma_1 S_d \left(\frac{\Omega I}{\alpha_1 R} \right)} = C_1 C_2 \alpha_1 \frac{R}{\Omega I} \qquad (3)$$

Thus, an inference about the true overstrength coefficient, Ω, makes it possible to establish system ductility limits that are consistent with the R and Ω_0 values given in the *Provisions*.

System ductility limits (μ_c) were derived assuming $\Omega = \Omega_0$ for structures of ordinary importance ($I = 1.0$) assuming $C_1 = C_2 = 1.0$ and taking $\alpha_1 = 0.90$ for moment-resistant frames, 0.80 for eccentrically braced frames, and 0.65 for cantilever shear walls and concentrically braced frames. These values correspond approximately to the point at which ductility limits would be expected to control rather than drift. For structures with shorter periods, the consideration of short-period displacement amplification vis-à-vis the C_1 and C_2 coefficients in this design approach will result in better control of system ductility response than is achieved with the equivalent lateral force procedure because the latter uses period-independent R factors. System ductility limits derived with this approach are given in Table 3 and reflect ductility demands relative to the effective yield displacement, considering overstrength for design-level ground motions.

Modification of the system ductilities given in Table 3 for building importance is appropriate. Consequently, the design ductility limit, μ_d, is given as $\mu_d = \mu_c / I$ and

$$D_{u,\mu} = \mu_d \cdot D_y \qquad (4)$$

Since either the drift limit or the ductility limit may be more restrictive, the target roof displacement used for design is given as:

$$D_u = \min(D_{u,\Delta}, D_{u,\mu}) \qquad (5)$$

Consequently, the target ductility demand (considering interstory drift and system ductility limits) is given as:

$$\mu_t = \frac{D_u}{D_y} \tag{6}$$

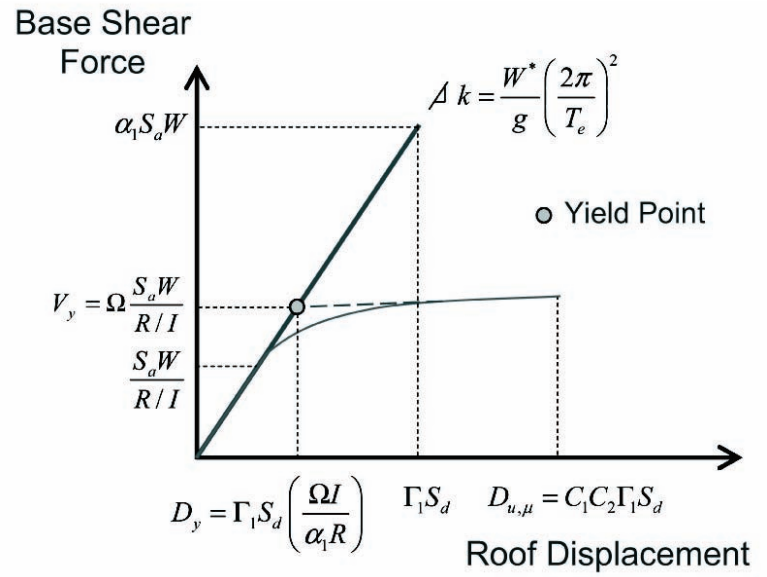

Figure 5 Response of elastic and yielding MDOF systems in the first mode. The "yield point" identifies the change in slope of a bilinear curve that is fitted to the capacity curve over the applicable range of displacement response. Ω represents the actual overstrength factor, not the value Ω_0 provided in the 2003 *NEHRP Recommended Seismic Provisions*.

Table 3 System Ductility, μ_1, for Buildings of Ordinary Importance at Design Basis Level (2/3 of MCE Level per the 2003 *Provisions*)

Eccentrically Braced Frames Non-moment-resisting beam-column connections With moment-resisting beam-column connections		2.8 2.6	

EQUIVALENT SDOF RELATIONSHIPS FOR MDOF SYSTEMS

Because the contribution of higher modes to roof displacement tends to be small, the required base shear strength to limit drift response is based on an equivalent SDOF model that reflects first-mode contributions. Thus, this section presents established relationships that allow MDOF properties to be mapped to ESDOF properties and vice versa.

An ESDOF system can be determined having seismic weight W^* and force and displacement quantities equal to those of the MDOF system divided by the first-mode participation factor, Γ_1. Since the roof drift at yield, D_y, can be estimated as indicated above, the yield drift of the ESDOF oscillator can be estimated as:

$$D_y^* = \frac{D_y}{\Gamma_1} \tag{7}$$

where the asterisk (*) signifies a property of the ESDOF system. Estimates of Γ_1 are provided in Table 2.

Once a detailed mathematical model of the structure has been created, a precise value of Γ_1 can be computed. To do so, a modal analysis is performed and values of the first-mode shape $\phi_{i,1}$ at each level, *i*, are stored in a vector $\boldsymbol{\phi}_1$, normalized such that the amplitude of the roof displacement equals 1. Weights w_i at each level, *i*, are stored in a diagonal matrix **W.** Then, Γ_1 may be determined as:

$$\Gamma_1 = \frac{\boldsymbol{\varphi}_1^T \mathbf{W1}}{\boldsymbol{\varphi}_1^T \mathbf{W} \boldsymbol{\varphi}_1} \tag{8}$$

where **1** = a vector of length *n* in which all entries are ones. Given the estimate of D_y^* from Equation 7, the strength of the ESDOF oscillator to limit its ductility demand to μ_t may be determined using YPS as $V_y^* = C_y^* W^*$. Since

$$V_y^* = \frac{V_y}{\Gamma_1}, \tag{9}$$

the required base shear strength for the MDOF system may be determined as:

$$V_y = V_y^* \cdot \Gamma_1 \tag{10}$$

However, knowing that $W^* = \boldsymbol{\phi}_1{}^T \mathbf{W1}$,

$$V_y = C_y W = V_y^* \cdot \Gamma_1 = C_y^* \cdot W^* \cdot \Gamma_1 = C_y^* \boldsymbol{\varphi}^T \mathbf{W1} \left(\frac{W}{\mathbf{1}^T \mathbf{W1}} \right) \Gamma_1 = \tag{11}$$

$$C_y^* \Gamma_1 \left(\frac{\boldsymbol{\varphi}^T \mathbf{W1}}{\mathbf{1}^T \mathbf{W1}} \right) W = C_y^* \alpha_1 W$$

since $W = \mathbf{1}^T \mathbf{W1}$ and the first-mode mass coefficient, $\alpha_{1,}$ can be defined in terms of weights as:

$$\alpha_1 = \frac{\boldsymbol{\varphi}_1^T \mathbf{W1}}{\boldsymbol{\varphi}_1^T \mathbf{W} \boldsymbol{\varphi}_1} \cdot \frac{\boldsymbol{\varphi}_1^T \mathbf{W1}}{\mathbf{1}^T \mathbf{W1}} = \Gamma_1 \cdot \frac{\boldsymbol{\varphi}_1^T \mathbf{W1}}{\mathbf{1}^T \mathbf{W1}} \tag{12}$$

Equation 11 can be used to derive an expression that is quite simple to use in practice. Since the yield strength coefficient, C_y^*, can be determined directly from the design YPS, the base shear coefficient of the MDOF system can be determined simply as:

$$C_y = \alpha_1 C_y^* \tag{13}$$

Thus, the design base shear is given as:

$$V_y = C_y W \tag{14}$$

An initial estimate of α_1 may be obtained from Table 2, while a more precise value can be computed using Equation 12 after a detailed model of the structure has been developed and evaluated to determine the first-mode shape.

The period of vibration depends on the amount of strength provided to ensure the ESDOF oscillator has a ductility demand not exceeding μ_t. Having established the yield displacement, D_y^*, and the yield strength coefficient, C_y^*, of the ESDOF oscillator, the corresponding period of vibration, T^*, is given by:

$$T^* = 2\pi \sqrt{\frac{D_y^*}{C_y^* g}} \tag{15}$$

This period can be used in determining the lateral force distribution to be used in design and can be compared to the fundamental period of vibration determined for a detailed model of the structure, which may be affected by inaccuracy in the estimates of D_y, α_1, and Γ_1.

BASE SHEAR STRENGTH DETERMINATION

The response of inelastic oscillators has been the subject of academic inquiry since perhaps 1960. Peak displacement and peak ductility responses have been related to the peak response of companion elastic oscillators having the same initial stiffness. In recent work by the Applied Technology Council, the peak displacement of the SDOF oscillator is estimated as the product of the peak displacement of the companion elastic oscillator, S_d, and coefficients C_1 and C_2 that account separately for the effects of strength and degradation of strength and stiffness (FEMA 440, 2005). Since $S_d = S_a(T_e/2\pi)^2 g$, the peak displacement of the yielding oscillator, D_u^*, may be expressed as:

$$D_\mu^* = C_1 C_2 S_a \left(\frac{T_e}{2\pi}\right)^2 g \qquad (16)$$

The effect of yield strength less than that required for elastic response on peak displacement response is represented by the coefficient, C_1, which is evaluated as:

$$C_1 = 1 + \frac{R^* - 1}{aT_e^2} \qquad (17)$$

where R^* = the ratio of the strength required for elastic response and the yield strength of the inelastic oscillator, T_e = period of vibration in seconds, and a is a parameter that varies with Site Class where a can be taken equal to 130 for Site Classes A and B, 90 for Site Class C, and 60 for Site Classes D, E, and F.

The effect of cyclic degradation of stiffness and strength on peak displacement response is represented by the coefficient C_2. For T_e less than 0.7 sec, this coefficient is estimated by

$$C_2 = 1 + \frac{1}{800}\left(\frac{R^* - 1}{T_e}\right)^2 \qquad (18)$$

For periods greater than 0.7 sec, C_2 may be taken equal to one. According to FEMA 440, the value of T_e used in Equations 17 and 18 need not be taken less than 0.2 sec.

YPS developed for a particular site by applying the above relationships to a design spectrum determined according to 11.4.5 are presented in Figure 6. The appendix of this paper presents background on the YPS representation of seismic demands.

Having determined D_y^* and μ_t, the required C_y^* can be determined by interpolation between the curves of constant μ shown in the YPS. For example, for D_y^* = 12 in. and μ_t = 1.7 chosen somewhat arbitrarily, Figure 6 illustrates that the required ESDOF base shear coefficient, C_y^*, is approximately 0.37. The expected peak displacement of the ESDOF system is $D_u^* = \mu D_y^* = 1.7(12 \text{ in.}) = 20.4$ in. Using Equation 15, the period of vibration of the ESDOF oscillator is:

$$T^* = 2\pi\sqrt{\frac{D_y^*}{C_y^* g}} = 2\pi\sqrt{\frac{12 \text{ in}}{0.37 \cdot 386.1 \text{ in/sec}^2}} = 1.82 \text{ sec}$$

Having estimated α_1 and Γ_1, the peak roof displacement and required base shear strength at yield for the multi-degree-of-freedom system can be estimated as $D_u = \mu_t D_y = \mu_t(\Gamma_1 D_y^*)$ and $V_y = C_y^*(\alpha_1 W)$, respectively.

Note that it is not necessary to construct admissible design regions when working with a specific value of D_y^*; whether drift or ductility limits control will be apparent in the determination of μ_t.

DISTRIBUTION OF LATERAL FORCES FOR DESIGN

Because dynamic response indicates story shears in multistory buildings differ significantly from those associated with the equivalent lateral force procedure of the *Provisions*. a new lateral force distribution has been recommended (Chao et al., 2007). This lateral force distribution more closely corresponds to the peak shears observed in nonlinear dynamic response. This distribution is characterized by the parameter β_i. In this paper, β_i is used to represent the ratio of the story shear, V_i, just below Level i, and the base shear, V_y, corresponding to the effective yield strength, as follows:

$$\beta_i = \frac{V_i}{V_y} = \left(\frac{\sum_{j=i}^{n} w_j h_j}{\sum_{j=1}^{n} w_j h_j} \right)^{\frac{\alpha}{T_e^{0.2}}} \quad (19)$$

where story weights, w_j, and story heights, h_j, are defined as w_i and h_i, respectively, in the *Provisions*, V_y = effective yield strength, and $\alpha = 0.75$. Thus, the equivalent lateral force applied at Level *i*, $F_{i,\beta}$, is given by:

$$F_{i,\beta} = (\beta_i - \beta_{i+1}) \cdot V_y \quad (20)$$

where $\beta_{n+1} = 0$.

The intended mechanism may yield in response to the overturning moments or the story shears developed by the lateral forces and deformations. Many systems (e.g., moment frames and shear walls) yield in response to the overturning moments (associated with the lateral forces acting above the base of the structure) developed during response. Other systems (e.g., braced frames) yield in response to the story shears developed by the lateral forces.

The $F_{i,\beta}$ distribution of forces generally increases the story shears in the upper stories relative to the first-mode distribution of forces and many code force distributions.

The design base shear at yield determined in Equation 14 on the basis of the first-mode is adequate to limit roof displacement response of the MDOF system. Higher mode (or MDOF) effects have a relatively minor contribution to displacement response but can have a significant contribution to interstory drifts and story shears and lead to design forces represented by the $F_{i,\beta}$ distribution.

For those systems that yield in response to overturning moments, distribution of the base shear determined on the basis of first-mode response over the height of the structure according to the $F_{i,\beta}$ distribution generally will increase the overturning resistance of the structure above that required to limit displacement response. For this reason, the base shear used in conjunction with Equations 19 and 20 must be modified for those systems that yield in response to the overturning moments (e.g., moment frames and shear walls). The modified base shear is given by $V_y \cdot (h_{eff,1}/h_{eff,\beta})$ where V_y is determined using Equation 14, $h_{eff,1}$ is the height of the resultant of the first-mode forces, and $h_{eff,\beta}$ is the height of the resultant of the β_i lateral forces. Table 2 provides estimates of $h_{eff,1}/h$.

MECHANISM-BASED DETERMINATION OF MEMBER STRENGTHS

A plastic mechanism analysis may be used to determine member strengths as described by Goel and Chao (2007). As shown in Figure 3, the vertical distribution of story strengths (or plastic hinge strengths) may be made proportional to β_i. Doing so appears to promote a number of desirable effects, including limiting the column moments obtained in a static (design) analysis during the development of a mechanism (by providing inflection points within each story) and making the distribution of peak interstory drifts observed in nonlinear dynamic analyses more uniform over the height of the structure than is obtained with conventional designs (e.g., Goel et al., 2007).

Thus, with reference to Figure 3, a virtual work analysis may be used to determine member strengths required to provide the seismic-force-resisting system with the required base shear strength. For example, considering a moment frame, the reference plastic moment strength, M_{pbr}, may be determined by Equation 21 if beam plastic hinge strengths at the i^{th} level are assigned the value $\beta_i \cdot M_{pbr}$. Equating external work and internal work leads to:

$$\sum_{i=1}^{n} F_{i,\beta} h_i \theta_p = V_y h_{eff,\beta} \theta_p = 2M_{pc}\theta_p + \sum_{i=1}^{n} \beta_i M_{pbr} \theta_p \quad (21)$$

which may be solved for M_{pbr} once the column plastic hinge strengths at the base of the frame have been established. The column plastic hinge strengths should be established to provide a sufficient margin against the development of a weak-story mechanism. For example, using a factor of 1.1, the column plastic hinge strengths for a one-bay frame would be determined as:

$$M_{pc} = 1.1 \frac{V_b \cdot h_1}{4} \quad (22)$$

based on the intention that a weak-story mechanism at this location be avoided. Equation 21 may then be solved for the M_{pbr}; beam plastic moments at each level are determined as $\beta_i \cdot M_{pbr}$.

DESIGN VALIDATION/REFINEMENT

After members have been sized, a mathematical model of the structure can be developed and evaluated. A nonlinear static (pushover) analysis in the first mode may be performed to evaluate the yield point of the MDOF system and establish a more accurate ESDOF system for use in estimating the expected peak displacement and corresponding system ductility demands. However, nonlinear static analysis can be avoided entirely for structural systems that do not soften or crack prior to the onset of yield—in such cases, elastic analysis results may be used to validate the performance of a preliminary design and to identify refinements when necessary.

As illustrated in Figure 5, the yield point may be estimated based on the actual stiffness and strength provided to the structure. The strength of the system is the design base shear at yield (Equation 14) or the plastic strength obtained in a mechanism analysis under the $F_{i,\beta}$ force distribution modified by ($h_{eff,1}/h_{eff,\beta}$). The first-mode period, T_e, reflects the actual initial stiffness, and this period can be obtained from an eigenvalue analysis of the elastic model (provided that softening or cracking of the structure does not occur prior to the onset of yield). An improved estimate of the yield displacement of the MDOF model can be determined for such systems. Because the initial stiffness of the capacity curve is given by $(W^*/g)(2\pi/T_e)^2$, the improved estimate of the yield displacement is given by:

$$D_y' = \frac{V_y}{W^* / g}\left(\frac{T_e}{2\pi}\right)^2 \qquad (23)$$

where $W^* = \boldsymbol{\phi}_1^T \mathbf{W1}$ should be computed using the first-mode shape obtained for the mathematical model of the structure (with entries normalized such that the roof displacement amplitude equals one). Since the modal parameter Γ_1 can be determined for the mathematical model, the yield point of the ESDOF oscillator (D_y'/Γ_1, V_y/Γ_1) can be plotted on the YPS in order to make a more precise estimate of the ductility demand and peak roof displacement. If these values are within the design limits, the design is considered acceptable. If it should be necessary to reduce the ductility demand, revision of the required strength may be determined based on the improved estimate of yield displacement (D_y'/Γ_1) and using modal parameters determined for the first-mode properties of the mathematical model.

With some experience, however, comparison of T_e with the period of the ESDOF system, T^*, can provide a sufficient basis for evaluating the adequacy of the preliminary design. As indicated by Equation 15, a longer period indicates the yield point has shifted to the right leading to lower ductility demands but higher drifts for a given strength (consider Figures 1 and 6). In contrast, a shorter period indicates the yield point has shifted to the left leading to higher ductility demands but lower drifts for a given strength. Provided that the estimates of α_1 and Γ_1 are reasonably accurate, comparison of periods may be sufficient to assess whether refinement of the preliminary design is needed.

Softening and/or cracking prior to yielding would be anticipated for reinforced concrete systems. If these effects are represented in the mathematical model of the structure (for example, due to gravity loads pre-compressing reinforced concrete members that may have been modeled with zero tensile strength), then the initial period of the model cannot characterize the effective stiffness or period at yield. In such cases, the fundamental period of vibration determined at small displacements, T_1, should be modified to obtain an effective period of vibration (T_e) associated with the effective yield point observed in a nonlinear static (pushover) analysis using first-mode lateral forces.

Estimation of the effective period, T_e, is illustrated in the reinforced concrete wall example below.

DESIGN OF CAPACITY-PROTECTED MEMBERS

This paper focuses on the design of the designated yielding members of the seismic-force-resisting system. Force-protected members or actions include axial forces in collectors and the shears in slender structural walls. Amplification due to higher modes (or MDOF effects) and member overstrength should be considered for the design of members (or actions) that must remain elastic to ensure development of the intended mechanism.

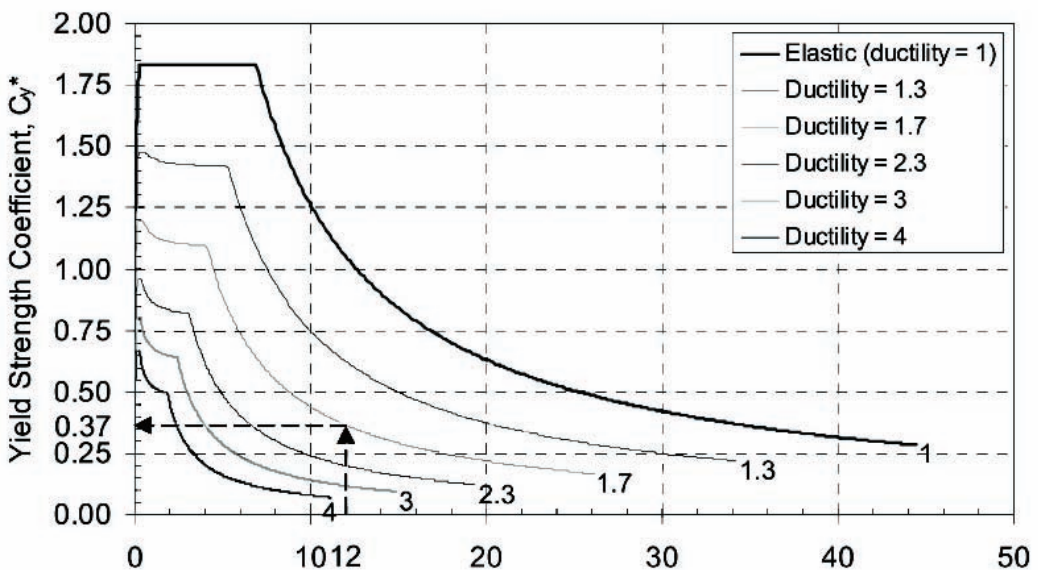

Figure 6 Yield point spectra.

REINFORCED CONCRETE WALL BUILDING EXAMPLE 1

A special reinforced concrete structural wall system was designed to provide lateral force resistance to a six-story reinforced concrete building. Four 20-foot long walls (labeled W1 in the plan of Figure 7) were designed. Story heights of 12 feet and dead loads of 175 psf were assumed; design live loads were 50 psf. Lumped masses at the floors and roofs were assumed uniform over the height of the building. Full dead load plus 20 percent of the live load was assumed present during seismic loading. For purposes of defining site seismicity, the example building was assumed to be located in Sacramento, California (in the 95837 Zip Code) on Site Class D soils according to the 2003 *NEHRP Recommended Seismic Provisions*.

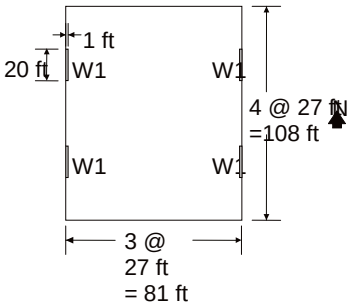

Figure 7 Reinforced concrete wall building plan.

The preliminary design was developed as follows:

1. Based on Table 1, the yield drift ratio was estimated as $0.10(h/l_w) = 0.10(72 \text{ ft})/(20 \text{ ft}) = 0.36$ percent. Therefore, the yield drift (at the roof level, corresponding to effective yield in a first-mode pushover analysis) is estimated as $D_y = (0.36\%)(h) = (0.0036)(72 \text{ ft})(12 \text{ in./ft}) = 3.11$ in.

2. From Table 2, the first-mode participation factor, Γ_1, is estimated to be 1.47. Therefore, the yield drift of the "equivalent" SDOF oscillator is estimated as $D_y^* = D_y/\Gamma_1 = 3.11/1.47 = 2.12$ in.

3. A limit on displacement ductility is established by considering drift and system ductility limits.

   From Table 3, the allowable system ductility for a special reinforced concrete cantilever shear wall system is 1.6. Therefore, the peak displacement limit based on the allowable ductility is $D_{u,\mu} = 1.6(3.11 \text{ in.}) = 4.98$ in.

The allowable story drift, obtained from Table 4.5-1 of the 2003 *NEHRP Recommended Provisions*, is $0.020h_{sx}$ = 0.020(12 ft)(12 in./ft) = 2.88 in. Table 2 provides an estimate of $\alpha_{3,stat}$ = 1.59. Therefore, the roof drift limit associated with the allowable story drift is approximately (0.020/1.59)(72 ft)(12 in./ft) = 10.87 in.

The more restrictive of the two roof displacement limits governs the design. In this case, $D_{u,\mu}$ = 4.98 in., and $\mu_t = D_{u,\mu}/D_y$ = (4.98 in.)/(3.11 in.) = 1.6.

4. To determine the required yield strength coefficient, YPS are prepared for the design basis ground motion (Figure 8). For D_y^* =2.12 in. and μ_t = 1.6, the minimum base shear coefficient (at yield) is given by C_y^* = 0.19. Using α_1 = 0.65 from Table 2, the required base shear strength coefficient (at yield) for the MDOF system is given by $C_y = \alpha_1 C_y^*$ = 0.65(0.19) = 0.124.

   The expected fundamental period of vibration of the building, based on the assumed yield displacement and modal parameters α_1 and Γ_1, is $T_e = 2\pi(D_y^*/(C_y^* g))^{0.5} = 2\pi\,[2.12 \text{ in.}/(0.19 \cdot 386.1 \text{ in./sec}^2)]^{0.5}$ = 1.07 sec.

5. Since there are four walls, the base shear strength (at yield) required for each wall for response in the first mode is given by $V_y = C_y \cdot W/4$ = 0.124(2296 kips) = 285 kips.

6. Because the $F_{i,\beta}$ distribution of lateral forces has a resultant that generally acts at a location that differs from that of the first-mode distribution, the base shear is adjusted so that the flexural strength of the wall is equal to the product of V_y (= 285 kips) and the height of the resultant of the first-mode lateral forces. The $F_{i,\beta}$ distribution is determined using T = 1.07 sec as given in Table 4. The effective height of the resultant lateral force is given by $h_{eff,\beta} = \Sigma F_i h_i / \Sigma F_i$ = 15,909 k-ft/285 kips = 56.41 ft. Then, $h_{eff,\beta}/h$ = 56.41 ft / 72 ft = 0.784. Since the first mode is estimated to have $h_{eff,1}/h$ = 0.77, the adjusted base shear is V_y = (285 kips)(0.77/0.784) = 280 kips.

7. The wall is designed using the β_i distribution (Table 4) of lateral forces for a base shear of 280 kips. The required strength at the base of the wall is M_n = (280 kips)(0.784)(72 ft)(12 in/ft) = 190,000 kip-in. The wall shown in Figure 9 has a nominal strength of 197,000 kip-in when subjected to a compressive force associated with its tributary gravity load, using Grade 60 reinforcement and f'_c = 5 ksi.

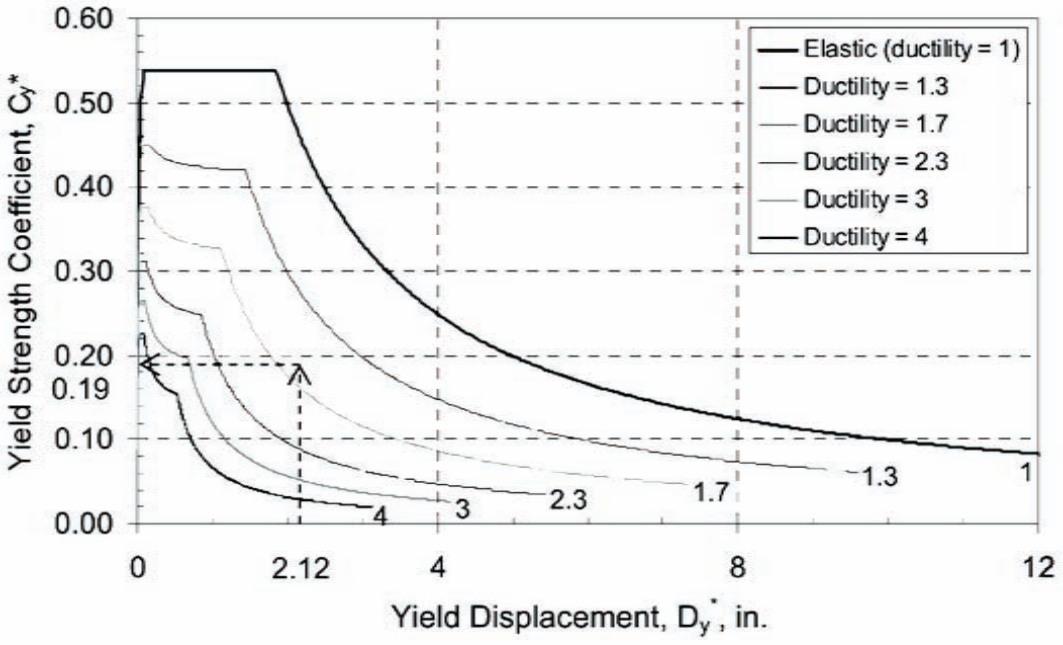

Figure 8 YPS used in the wall building example.

				Σ	4.652	1.000	285.0	15,909

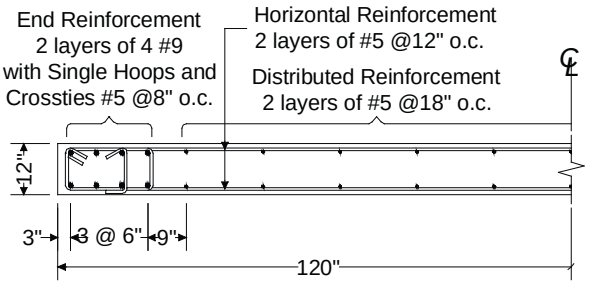

Figure 9 Section at the base of the reinforced concrete wall.

To further substantiate the design approach, a first-mode pushover analysis of the wall was conducted. The wall was modeled in Drain-2DX (Prakash et al., 1993) using a fiber element. Materials were modeled using their nominal strengths; strain hardening of reinforcement was included in the model. Modal properties used to establish the lateral force distribution for the pushover analysis are based on initial (uncracked) properties. The resulting capacity curve is shown in Figure 10. A bilinear curve was fitted to the capacity curve. The yield point (D_y, V_y) is given by (3.08 in, 288 kips), which is very close to the estimate of (3.11, 280 kips) that was used as a basis for the design.

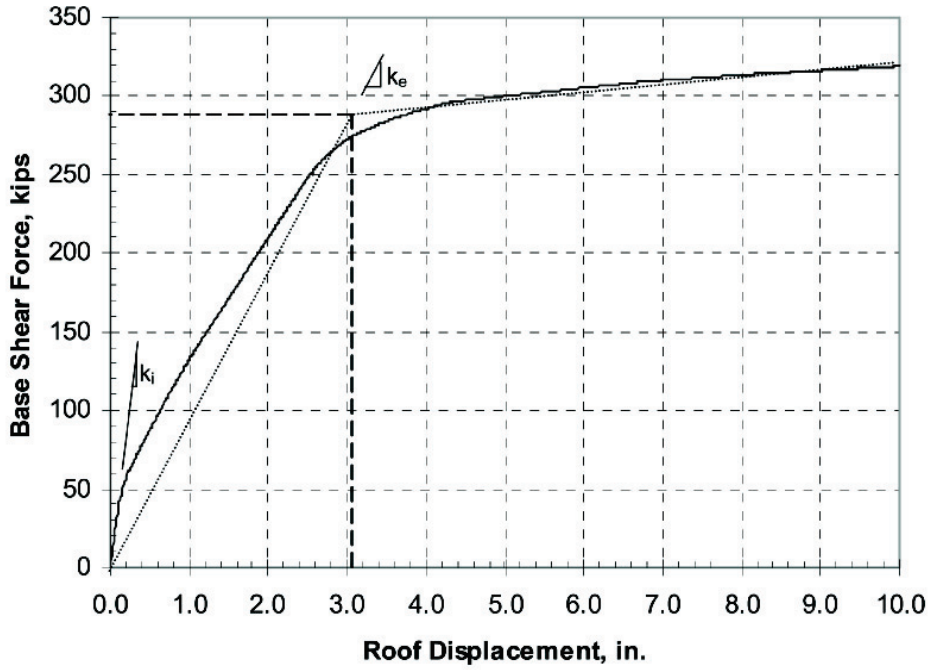

Figure 10 Capacity curve obtained in the pushover analysis of a wall.

The first-mode mass participation factor, based on uncracked sections, is 0.667, and the actual $h_{eff,1}/h$ is 0.806. The initial period based on uncracked sections, $T_{1,}$ is 0.524 sec. The effective period may be determined as $T_e = T_i(k_i/k_e)^{0.5} = 0.524(385/93.5)^{0.5} = 1.06$ sec where $k_e = V_y/D_y = 288$ kips/3.08 in = 93.5 k/in. Because 1.06 sec is approximately equal to the ESDOF period (1.07 sec), the initial design is deemed adequate.

REINFORCED CONCRETE FRAME BUILDING EXAMPLE 2

A six-story special reinforced concrete moment frame was designed for a building having the same nominal floor plan and loading as the reinforced concrete wall example. Figure 11 shows a plan view. Story heights of 12 feet and dead and live loads of 175 and 50 psf, respectively, were assumed. This example building was also located in Sacramento, California, on Site Class D soils.

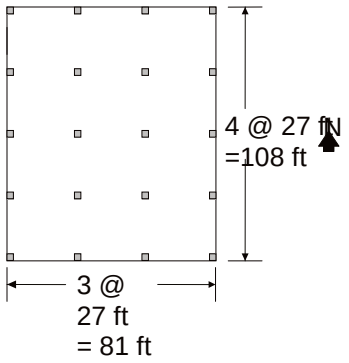

Figure 11 Plan view of reinforced concrete frame building.

The preliminary design was developed as follows:

1. Assuming from Table 1 that the yield drift ratio of the reinforced concrete moment frame is approximately 0.55 percent, the yield drift (at the roof level, corresponding to effective yield in a first-mode pushover analysis) was estimated as $D_y = (0.55\%)(h) = (0.0055)(72 \text{ ft})(12 \text{ in./ft}) = 4.75$ in.
2. From Table 2 the first-mode participation factor, Γ_1, was estimated to be 1.33. Therefore, the yield drift of the "equivalent" SDOF oscillator was estimated as $D_y^* = D_y/\Gamma_1 = 4.75/1.33 = 3.57$ in.
3. A limit on displacement ductility was established by considering drift and system ductility limits. From Table 3, the allowable system ductility for a special reinforced concrete moment frame is 2.4. Therefore, the peak displacement limit based on the allowable ductility is $D_{u,\mu} = 2.4(4.75 \text{ in.}) = 11.4$ in. The allowable story drift, obtained from Table 4.5-1 of the 2003 *NEHRP Recommended Provisions*, is $0.020h_{sx} = 0.020(12 \text{ ft})(12 \text{ in/ft}) = 2.88$ in. Table 2 provides an estimate of $\alpha_{3,stat} = 1.26$. Therefore, the roof drift limit associated with the allowable story drift is approximately (0.020/1.26)(72 ft)(12 in./ft) = 13.71 in. The more restrictive of the two roof displacement limits governs the design. In this case, $D_{u,\mu} = 11.4$ in., and $\mu_t = D_u/D_y = (11.4 \text{ in.})/(4.75 \text{ in.}) = 2.4$.
4. To determine the required yield strength coefficient, YPS were prepared for the design basis ground motion (Figure 12). For $D_y^* = 3.57$ in. and $\mu_t = 2.4$, the minimum base shear coefficient (at yield) is given by $C_y^* = 0.048$. Using $\alpha_1 = 0.85$ from Table 2, the required base shear strength coefficient (at yield) for the MDOF system was determined to be $C_y = \alpha_1 C_y^* = 0.85(0.048) = 0.0408$. The expected period of vibration is $T_e = 2\pi[D_y^*/(C_y^* g)]^{0.5} = 2\pi[3.57 \text{ in.}/(0.048 \cdot 386.1 \text{ in./sec}^2)]^{0.5} = 2.76$ sec.
5. If four separate moment frames provide resistance to lateral forces, the base shear strength (at yield) required for each frame for response in the first mode is given by $V_y = C_y \cdot W/4 = 0.0408(2296 \text{ kips}) = 93.7$ kips.
6. Because the $F_{i,\beta}$ distribution of lateral forces has a resultant that generally acts at a location that differs from that of the first-mode distribution, the base shear was adjusted so that the strength of the mechanism under the lateral forces corresponds to the overturning moment generated by the first-mode lateral forces over the height of the structure. The $F_{i,\beta}$ distribution was determined using $T_e = 2.76$ sec as given in Table 5. The effective height of the resultant lateral force is given by $h_{eff,\beta} = \Sigma F_i h_i/\Sigma F_i = 5433$ k-ft/93.7 kips = 57.98 ft for a period of 2.76 sec. Then, $h_{eff,\beta}/h = 57.98 \text{ ft} / 72 \text{ ft} = 0.805$. Since the first mode is estimated to have $h_{eff,1}/h = 0.69$, the adjusted base shear is $V_y = (93.7 \text{ kips})(0.69/0.805) = 80.3$ kips.

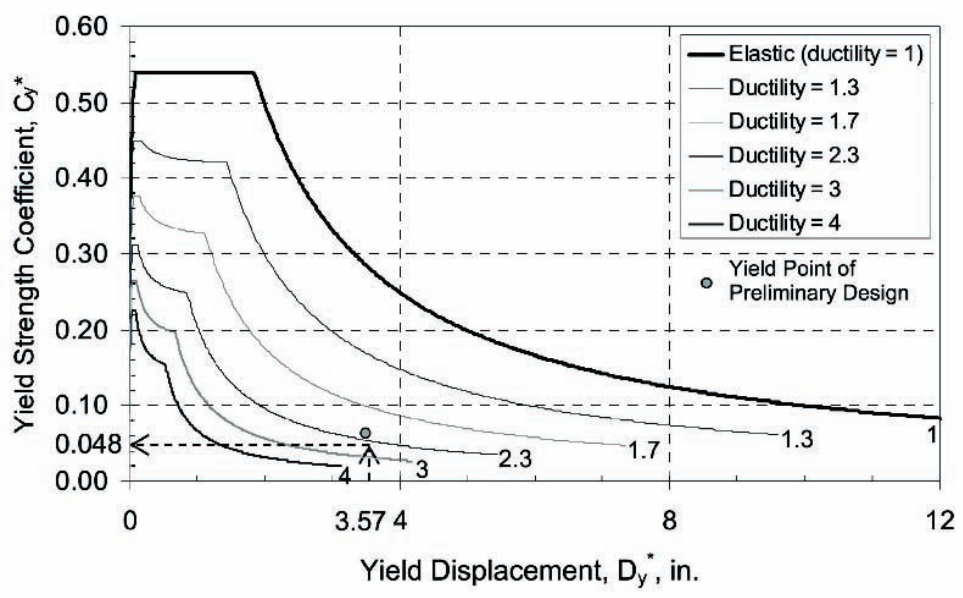

Figure 12 YPS used in the reinforced concrete frame example.

Table 5 Lateral Force Distribution for Reinforced Concrete Frame Example

Level	h_i (ft)	w_i (kips)	$w_i h_i$ (k-ft)	$\Sigma w_i h_i$ (k-ft)	$\beta_i = V_i/V_y$	$F_{i,\beta}/V_y$	$F_{i,\beta}$ (kips)	$F_{i,\beta} \cdot h_i$ (k-ft)

2	24	383	9,185	91,848	0.971	0.061	5.68	136
1	12	383	4,592	96,440	1.000	0.029	2.76	33
				Σ	4.832	1.000	93.70	5433

7. The frame was designed using the $F_{i,\beta}$ distribution (Table 5) of lateral forces for a base shear of 80.3 kips. The first story column strengths were determined to prevent a story mechanism using Equation 22. Nominal column strengths at the base had to exceed 1.1(80.3 kips)(12 ft)/4 = 265 k-ft. Beam plastic hinge strengths (taken equal to the ACI nominal moment value using specified material properties) were distributed vertically in proportion to the β_i values given in Table 5. Thus, a virtual work calculation considering the mechanism of Figure 3a provides that external work, W_E, is given by W_E = (80.3 kips)(57.98 ft)θ_p and internal work, W_I, is given by $W_I = 2M_{pc}\theta_p + \Sigma(V_i/V_y)M_{pbr}\theta_p = 2$(265 k-ft)$\theta_p + 4.832(M_{pbr})(2)\theta_p$ where M_{pbr} is a reference plastic strength. Setting $W_E = W_I$ results in M_{pbr} = 428 k-ft.
8. Conventional reinforced concrete frame details provide a positive moment capacity at the face of a joint that is equal to at least one-half the negative moment capacity. To provide sufficient strength to the mechanism, the strengths at opposite ends of the beam ($M_p^+ + M_p^-$) must equal or exceed $2\beta_i M_{pbr}$ at the i^{th} floor level. In the present example, 20 percent of the live load is considered to be present together with 100 percent of the dead load. Load factors used in a routine design would lead to unused gravity moment capacity that would contribute to strength and stiffness during seismic loading and, hence, would increase the lateral strength and reduce the modal periods of the frame.

To avoid incurring these beneficial effects in the example, which both illustrates the design approach and demonstrates its robustness, only dead loads and 20 percent of the live load were considered in combination with the seismic demands to determine M_p^-. Then, M_p^+ was set equal to $0.5(M_p^-)$. Reinforcement steel was proportioned assuming $M_n = M_p^-$.

The resulting cross sections are shown in Figure 13. Grade 60 reinforcement and concrete having f'_c = 5 ksi were used in the design and the mathematical models.

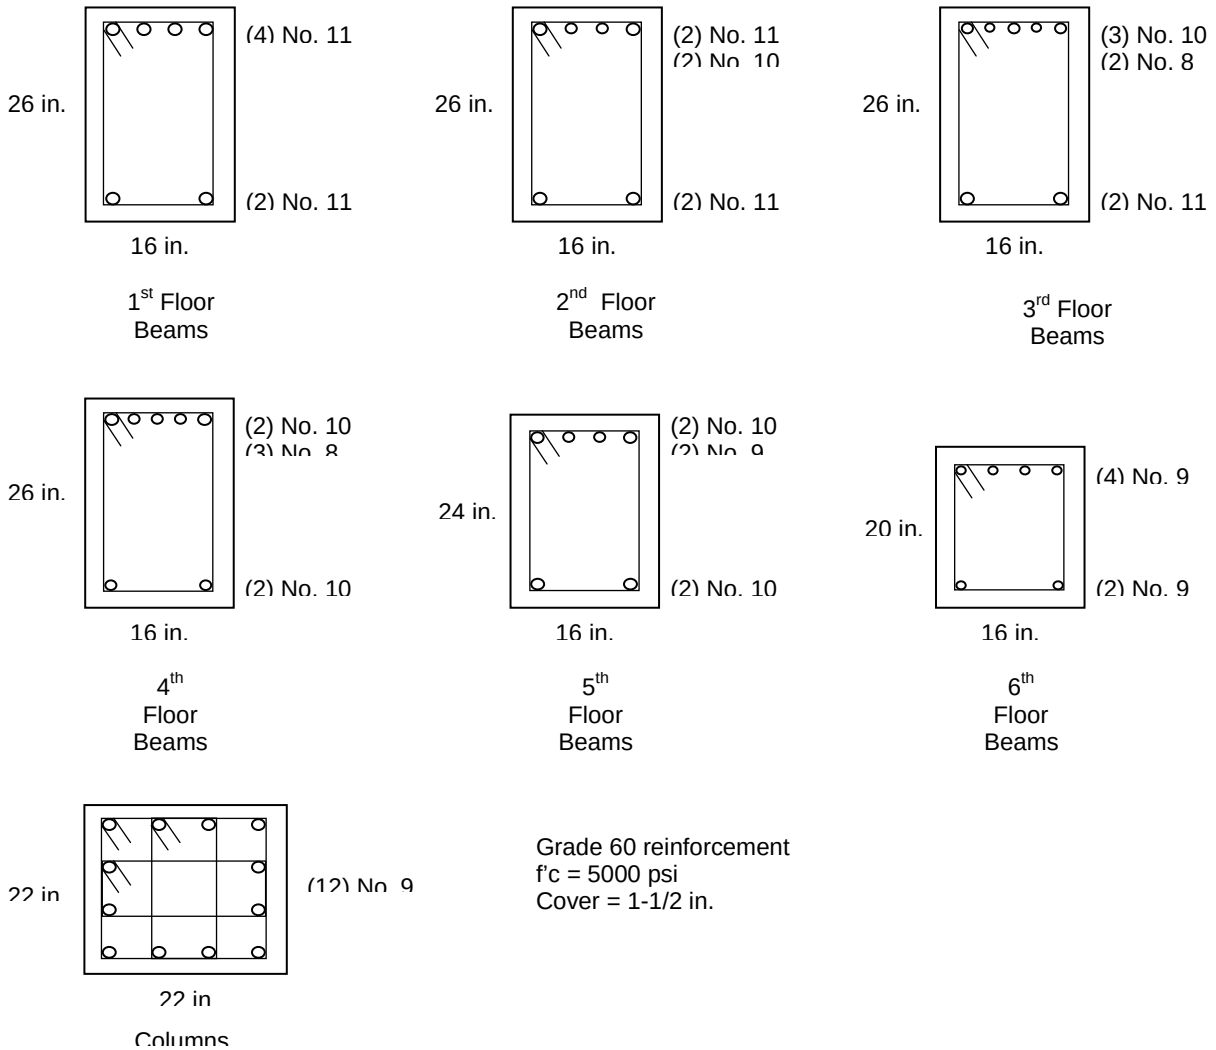

Figure 13 Beam and column section designed in the reinforced concrete frame example.

To validate the assumptions used in the design, a first-mode pushover analysis of a frame was conducted. The frame was modeled in Drain-2DX (Prakash et al., 1993) using fiber elements. Rigid end offsets were used at the joints. Materials were modeled using their nominal strengths; strain hardening of reinforcement was included in the model. Modal properties used to establish the lateral force distribution for the pushover analysis are based on initial (uncracked) properties. The resulting capacity curve is shown in Figure 14. A bilinear curve was fitted to the capacity curve. The yield point (D_y, V_y) is given by (4.85 in., 104 kips), which is in the vicinity of the estimate of (4.75 in, 93.7 kips) that was used as a basis for the design. The higher lateral strength obtained in the pushover analysis is attributed to: (1) reinforcement provided to the beams resulted in beam plastic moment strengths that were slightly greater than the strengths determined in the mechanism analysis; (2) flexural strength provided to resist tributary gravity loads was mobilized in the pushover analysis; and (3) the mechanism analysis was based on centerline dimensions, but the use of rigid end offsets caused the plastic hinges to form at or near the faces of the beam-column joints, thereby increasing the shears associated with flexural hinging.

The first-mode participation factor determined for the mathematical model is 1.37 and the mass participation factor is 0.742, based on uncracked sections. The actual $h_{eff,1}/h$ is 0.751. These values are all close to those assumed for the preliminary design (1.33, 0.85, and 0.69, respectively). The fundamental period of vibration is 2.43 sec, which is significantly less than the 2.76 sec assumed in the design. Thus, an evaluation of the preliminary design is warranted.

The yield strength coefficient is computed as $C_y = V_y/W$ = (104 kips)/(2296 kips) = 0.0453, and $C_y^* = C_y/\alpha_1$ = 0.0453/0.742 = 0.061. Noting that D_y^* = 4.85/1.37 = 3.54 in., one may determine from Figure 12 an expected ductility demand μ = 2.2.

Thus, system ductility demands are acceptable and the expected peak displacement = μD_y = 2.2(4.85 in.) = 10.7 in. is less than the 13.71 in. limit that was established based on allowable story drifts. The design is considered satisfactory.

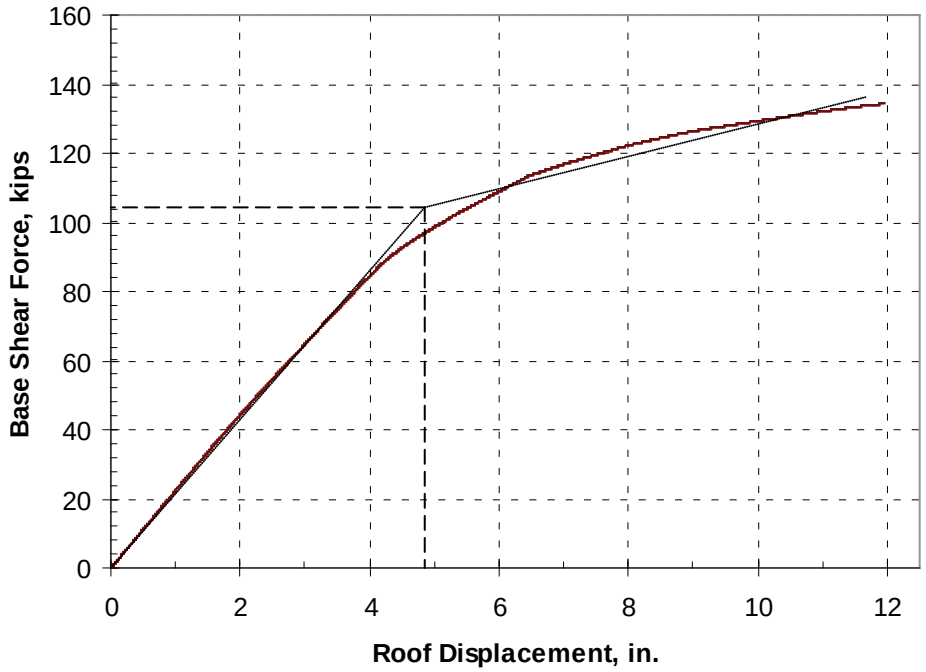

Figure 14 Capacity curve determined in a nonlinear static analysis of the reinforced concrete frame.

CONCLUSION

A simple approach was presented for the design of seismic-force-resisting systems. Estimated yield drifts given in Table 1 and design parameters given in Table 2 were sufficiently accurate that no iteration was required in the example designs. The base shear strength, determined to limit ductility and drift demands, was distributed over the height of the structure according to a new distribution. Required member strengths were determined in conjunction with the development of a desired mechanism using the equations of virtual work. System ductility limits used in the design were derived for currently recognized seismic-force-resisting systems. Roof drift limits are indexed to current allowable story drifts. Thus, the designs obtained with this method are nominally consistent with code performance expectations. Detailing requirements and other limits for such systems as well as other requirements in the 2003 *NEHRP Recommended Provisions* remain applicable.

NOTATION

a A coefficient that represents the effect of site characteristics on peak displacement response.

C_1 A modification factor to account for the influence of inelastic behavior on the response of the system, as determined by Equation 17.

C_2 A modification factor to account for the influence of cyclic degradation of strength and stiffness on the response of the system, as determined by Equation 18.

C_y Base shear coefficient at yield, equal to V_y/W.

C_y^* Yield strength coefficient for equivalent single-degree-of-freedom oscillator (dimensionless).

D_u Roof drift limit, determined as the smaller of $D_{u,\mu}$ and $D_{u,\Delta}$.

$D_{u,\mu}$ Roof drift limit based on design ductility limit in the direction of interest for the design earthquake.

$D_{u,\Delta}$ Roof drift limit based on allowable story drift in the direction of interest for the design earthquake.

$D_y, D`_y$ Effective yield displacement, at the roof.

D_y^* Yield displacement of the equivalent SDOF oscillator.

D_u^* Peak displacement of the equivalent SDOF oscillator.

$F_{i,1}$ Lateral force at Level i of the structure, distributed in proportion to the product of the mode shape amplitude ϕ_{i1} and seismic weight, w_i, at Level i.
$F_{i,\beta}$ Lateral force at Level i of the structure, determined according to Equations 19 and 20.
g Acceleration of gravity.
h Average roof height of structure with respect to the base.
h_i, h_j Height of i^{th} or j^{th} floor above the base.
$h_{eff,1}$ Height of resultant of lateral forces $F_{i,1}$ above the base.
$h_{eff,\beta}$ Height of resultant of lateral forces $F_{i,\beta}$ above the base.
h_{sx} Story height below Level x.
I Importance factor in Section 11.5.1 of the 2003 *NEHRP Recommended Seismic Provisions*.
k_e Effective stiffness associated with secant stiffness to effective yield point.
k_i Initial stiffness, typically associated with elastic properties at small displacement amplitudes.
l_w Length of prismatic wall in plan in direction under consideration.
M_n Nominal flexural strength.
M_p^+ Plastic moment having positive sense.
M_p^- Plastic moment having negative sense.
M_{pbr} Reference plastic moment strength.
M_{pc} Plastic hinge strength of column.
R^* Ratio of strength required for elastic response and yield strength of companion inelastic oscillator.
S_a Design, 5% damped, spectral response acceleration, adjusted for site effects, normalized by g.
S_d Peak displacement of elastic oscillator, equal to $S_a g(T_e/2\pi)^2$.
T_e Effective period, associated with secant stiffness to effective yield point, in seconds.
T_i Initial period, associated with initial stiffness properties, in seconds.
V_i Story shear at the i^{th} story above the base.
V_y Effective yield strength, at the base.
V_y^* Yield strength of the equivalent SDOF oscillator.
w_i Portion of W that is located at or assigned to Level i.
W Effective seismic weight of the building, as defined in Section 12.7.2.
W^* Effective weight of the equivalent SDOF oscillator.
$\mathbf{W}$ Diagonal matrix containing the entries w_i.
W_E External work determined in a virtual work analysis.
W_I Internal work determined in a virtual work analysis.
α Coefficient in Equation 19, taken equal to 0.75.
α_1 Fundamental mode mass coefficient.
$\alpha_{3,stat}$ Estimate of maximum ratio of interstory drift ratio and average roof drift ratio for the first mode.
β_i Ratio of story shear just below Level i and base shear at yield, V_y.
Δ_a Allowable story drift.
$\phi_{i,1}$ Displacement amplitude at Level i of the fundamental mode of vibration of the structure in the direction of interest, normalized to unity at the roof level.
$\boldsymbol{\phi}_1$ Vector containing the values of $\phi_{i,1}$.
Γ_1 Participation factor of fundamental mode of vibration of the structure in the direction of interest.
μ System ductility.
μ_c Effective ductility capacity in the direction of interest for the design earthquake.
μ_d Design ductility limit in the direction of interest for the design earthquake considering the importance factor, I.
μ_t Target allowable effective ductility demand in the seismic force resisting system in the direction of interest considering drift and ductility limits, for the design earthquake.
θ_p Angle used in virtual work analysis, rad.

APPENDIX: YIELD POINT SPECTRA

This appendix provides details on the interpretation, use, and construction of yield point spectra (YPS). YPS (Aschheim and Black, 2000) represent the peak displacement response of an oscillator that has a bilinear load-deformation response. Figure

15 shows such an oscillator and identifies its yield point and peak displacement response schematically. The ductility demand for such an oscillator can be determined for any specific earthquake record using software to compute inelastic response. Alternatively, established ductility (R-μ-T) or displacement coefficient (C_1, C_2) relationships can be applied to smoothed design spectra to estimate the peak displacement for any combination of period and yield strength.

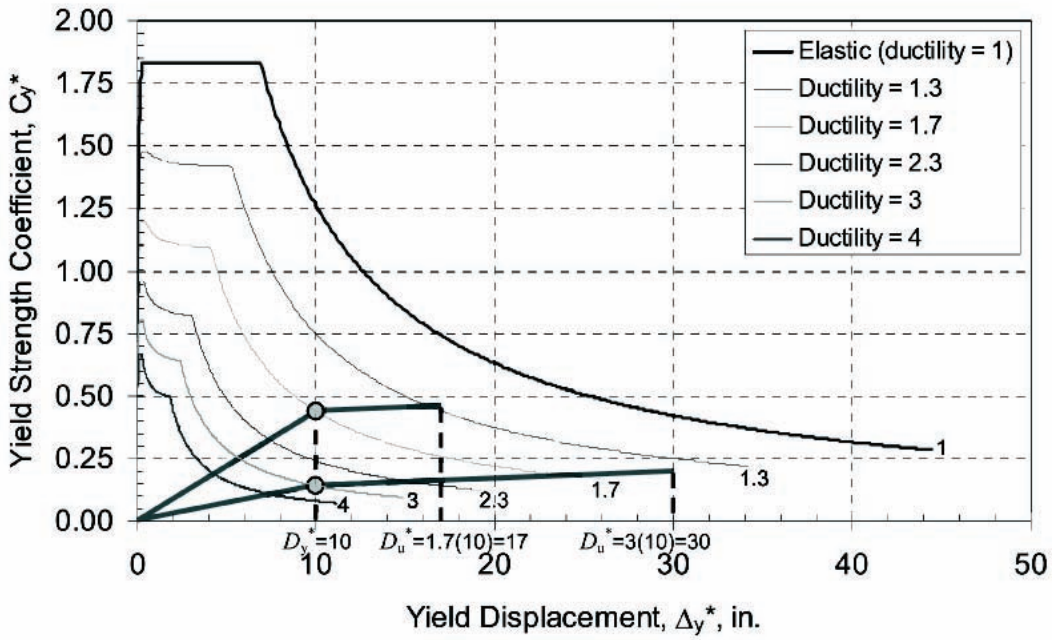

Figure 15 Yield point spectra.

YPS plot displacement ductility demands as a function of the yield point of an SDOF or ESDOF oscillator. In order to be general, the yield strength $V_y^* = C_y^* W$ is normalized by the weight of the oscillator's mass so that yield strength coefficient, C_y^*, is plotted on the ordinate of the YPS. Thus, YPS can be used to determine the expected ductility demand, which depends on where the oscillator's yield point (D_y^*, C_y^*) plots on the spectra. The expected ductility demand allows peak displacement response to be assessed on the YPS. For example, Figure 15 illustrates how changes in strength influence the peak displacement response for a given yield displacement. Thus, in the usual design context, the estimated yield displacement is known and the objective is to determine the strength that limits the drift and ductility demands to acceptable levels. Increasing the strength (C_y^*) causes a reduction in both ductility and drift responses. This is easily generalized to consider multiple performance objectives, with each performance objective resulting in a minimum required strength; the largest of the required strengths provides satisfactory performance for all performance objectives.

Just as in the capacity spectrum method, lines of constant period radiate from the origin. Period is related directly (but not linearly) to the slope C_y^*/D_y^* by Equation 15. Thus, a minimum strength for a given yield displacement (resulting from drift and ductility limits) can also be interpreted as a minimum stiffness or maximum period.

YPS differ from the capacity spectrum method in some fundamental ways. Peak displacements are plotted on the abscissa in the capacity spectrum method, while yield displacements are plotted on the abscissa of YPS. The capacity spectrum method relies on equivalent linearization to account for the influence of nonlinearity in the load-deformation response while ductility or displacement coefficient relationships typically are used with YPS. The terms "yield strength coefficient" and "yield displacement" are used in YPS as alternatives to the terms "spectral acceleration" and "spectral displacement" used in the capacity spectrum method because the latter are clearly defined only for elastic response.

Admissible design regions can be constructed by reversing the process for estimating displacement response. The yield points that correspond to a desired peak displacement can be determined and plotted. For example, points corresponding to a peak displacement of 24 in. are shown in Figure 16. These points are determined as described below.

An elastic oscillator having a yield displacement of 24 in. would also have a peak displacement of 24 in.; thus, the required yield strength coefficient, C_y^*, is located on the $\mu = 1$ curve at this yield displacement. Similarly, an oscillator having a yield displacement of 24/1.3 = 18.5 in. and C_y^* located on the $\mu = 1.3$ curve would have a peak displacement of 24 in. Repeating this process for each ductility curve results in the family of points shown in Figure 16. A line passing through these points represents a boundary of the admissible design region; points below this curve have larger ductility demands and, thus, are

excluded because they would have peak displacements greater than 24 in. For long period systems, results are compatible with the "equal displacement rule" and result in a limit on the period of vibration of the system. For short period systems, this procedure accounts for displacement amplification in establishing the boundary of an admissible design region.

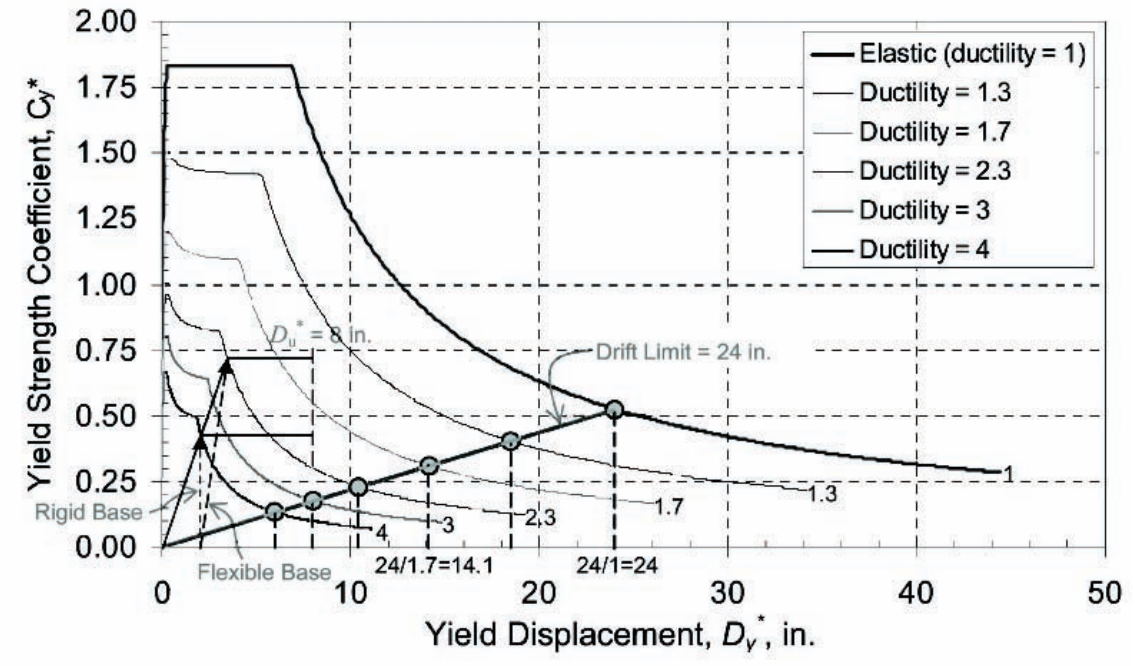

Figure 16 Establishment of the drift limit and illustration of the influence of foundation flexibility on response and required strength.

It is obvious that to ensure ductility demands do not exceed a certain value (e.g., 4) requires excluding yield points below the curve corresponding to this value. The boundaries established by considering drift and ductility limits can be used to establish admissible design regions (ADRs). ADRs can be especially useful in schematic design when comparing alternative seismic-force-resisting systems or for tuning the proportions of a given seismic-force-resisting system in order to modify its yield displacement so that the required lateral strength (or cost) can be minimized while satisfying the performance objective(s).

When appropriate, the influence of elastic foundation flexibility can be addressed using the YPS methodology. Elastic foundation flexibility will cause the yield displacement to increase in proportion to the lateral force. Thus, the system with foundation flexibility can be represented by a line that is inclined (to the right) of the line representing fixed-base conditions (also illustrated in Figure 16). While interstory drift and system ductility limits typically would be unaffected by foundation flexibility, the increase in yield displacement will require that the ductility demand be reduced in order to satisfy a drift limit. As illustrated, this causes the required base shear strength to increase for systems that are controlled by drift. Note that for the shorter period systems controlled by ductility demands, the increase in yield displacement due to foundation flexibility causes a reduction in the required strength.

The construction of YPS is fairly straightforward. Because design spectra and established ductility and displacement coefficient relationships are expressed as functions of period, the usual approach is to determine the strength reduction factor associated with a desired ductility demand for each period of interest. This is usually more straightforward when R-μ-T relationships are used. A simple approach when using displacement coefficients (Equations 16 through 18) in a spreadsheet format is to create functions that return C_1, C_2, and the value of R^* for a given period, target ductility, and site coefficient. The function for $R^*(\mu, T_e, a)$ may use an iterative approach to the determination of R^*, initially assuming $R^* = \mu$. In setting up this function it is useful to note that:

$$\mu = \frac{D_u^*}{D_y^*} = \frac{C_1 C_2 S_d}{D_y} = C_1 C_2 R^* \qquad \text{(A-1)}$$

Then, for any value of μ and T, the yield strength coefficient C_y^* is determined as:

$$C_y^* = \frac{S_a}{R^*} \tag{A-2}$$

and D_y^* is determined as:

$$D_y^* = C_y^* g \left(\frac{T_e}{2\pi} \right)^2 \tag{A-3}$$

The spreadsheet can be organized as shown in Table 6. A smoothed elastic design response spectrum is represented in the first two columns. The spectral displacement, S_d, is given by:

$$S_d = S_a g \left(\frac{T_e}{2\pi} \right)^2 \tag{A-4}$$

because values of S_a have been normalized by the acceleration of gravity.

Table 6 Illustration of Spreadsheet Organization for Determining YPS

Resource Paper 10

SEISMIC DESIGN METHODOLOGY FOR PRECAST CONCRETE FLOOR DIAPHRAGMS

This resource paper describes a design approach for untopped and topped composite precast concrete diaphragms applicable for all seismic design categories (SDC). The methodology was developed as an integral part of a large industry-endorsed and -supported analytical and experimental research project on precast concrete floor diaphragm. The impetus for the research was the seismic vulnerability of precast concrete floor systems as demonstrated by their performance in recent earthquakes, particularly the 1994 Northridge earthquake (EERI, 1994; Iverson and Hawkins, 1994). While several shortcomings in design practices at that time have been identified (Wood et al., 1995; Fleischman et al., 1996), and positive incremental changes made to code provisions for precast concrete diaphragm design (Wood et al., 2000; Hawkins and Ghosh, 2000), it is clear from the recommendations of Appendix A of Chapter 9 of the 2000 NEHRP Recommended Provisions that a better comprehensive design methodology is needed.

The methodology proposed here specifies:

a. The performance for which the precast concrete diaphragm should be designed in terms of forces, displacements, and deformations;

b. The precast concrete diaphragm connection details that must be used to provide this performance; and

c. The required stiffness of the precast concrete diaphragm relative to the stiffness of the lateral-force-resisting system (LFRS).

The objective of the design methodology is to provide a reliable design that does not compromise the safety, reliability, practicality, or economics of precast concrete construction.

The principal researchers for the study described in this paper were: Dr. Robert Fleischman, University of Arizona; Dr. Clay Naito and Dr. Richard Sause, Lehigh University; and Dr. Jose Restrepo, University of California, San Diego. DSDM Industry Task Group Members guiding the research were: Tom D'Arcy, DSDM Task Group Chair, PCI R&D Committee; founder, The Consulting Engineers Group, San Antonio, Texas; Roger Becker, Vice President, Spancrete Industries, Inc., Waukesha, Wisconsin; Dr. Ned Cleland, President, Blue Ridge Design, Inc., Winchester, Virginia; David Dieter, President/General Manager, Mid State Precast, Inc., Cocoran, California; Dr. S. K. Ghosh, DSDM Project Co-Principal Investigator, President, S.K. Ghosh Associates, Inc., Skokie, Illinois; Harry Gleich, Vice President-Engineering, Metromont Prestress, Greenville, North Carolina; Dr. Neil Hawkins, Professor Emeritus, University of Illinois, Urbana-Champaign, Illinois; Paul Johal, PCI Research Director, Precast/Prestressed Concrete Institute, Chicago, Illinois; Dr. Joseph Maffei, Structural engineer, Rutherford & Chekene Engineers, Oakland, California; Susie Nakaki, President, The Nakaki Bashaw Group, Inc., Irvine, California; Dr. Douglas Sutton, Chair, PCI Research & Development Committee, and Professor, Purdue University, West Lafayette, Indiana. The principal researchers were: Dr. Robert Fleischman, University of Arizona; Dr. Clay Naito and Dr. Richard Sause, Lehigh University; Dr. Jose Restrepo, University of California, San Diego.

PRECAST CONCRETE DIAPHRAGM BEHAVIOR

The following aspects of diaphragm behavior must be addressed in an effective seismic design methodology for precast concrete diaphragms (Fleischman et al, 2005a):

1. Diaphragm force levels assumed to occur during an earthquake are likely to significantly exceed those prescribed by current building code provisions;
2. Complex internal force paths can create force combinations/local deformation demands not anticipated by simple "horizontal beam" representations of a floor diaphragm;
3. Significant diaphragm global deformations can amplify demands on gravity-force-resisting system in regions of the structure distant from the primary (vertical-plane) LFRS elements.

These concerns are not unique to precast concrete diaphragms. They are equally applicable to the diaphragms of many large box-type and tilt-up structures. However, the jointed nature of precast concrete diaphragms creates a condition in which these factors can lead to poor structural performance if they are not directly considered in the design. (See Section A2 for a more detailed description of these concerns.)

Because of cracking along the joints between precast units, toppings do not ensure monolithic diaphragm action (Wood et al.,

2000). For untopped or topped precast concrete diaphragms, the critical diaphragm cross-sections occur at the joints between the precast floor units. Thus, the combination of diaphragm forces greater than those specified by codes and internal force combinations not currently recognized by simple beam idealizations of diaphragms can lead to yielding of the discrete reinforcement or connectors crossing the joints. In the event of this yielding, inelastic deformation will concentrate locally at the joints, and the diaphragm stiffness is significantly reduced by cracking and deformation of the elements crossing the joints.

DESIGN RAMIFICATIONS

Precast concrete diaphragm design has traditionally assumed elastic behavior and focused on providing sufficient strength. It has not considered that there may be a need for inelastic deformation capability. The potential for localized concentrations of inelastic deformation demand implies that a prescriptive elastic design for the diaphragm (i.e., one without any ductility requirements for the diaphragm reinforcement) would need to ensure elastic behavior.

The diaphragm forces expected during strong ground shaking can be much larger than current code specified diaphragm design force levels (Lee and Kuchma, 2007; Rodriguez et al., 2001). In some cases, the large diaphragm forces are driven by changes in the structure's dynamic properties after yielding of the primary elements of the LFRS (Fleischman et al., 2002; Eberhard and Sozen, 1993). As a result, even a capacity design approach in which the diaphragm is designed considerably stronger than the primary LFRS (wall or frame) elements and first yielding is successfully produced in those LFRS elements while the diaphragms are still elastic, is no guarantee of sustained elastic diaphragm behavior throughout the seismic event. A prescriptive elastic diaphragm design, therefore, may be difficult to achieve economically for all situations.

Given the complex internal force paths inherent in floor systems, including the effect of openings for stairwells, elevators and parking garage ramps, and the potential for alternate load paths in secondary elements within the floor system, it is unclear whether designs based on simple horizontal beam representations can avoid localized inelastic deformation demands for all situations, even if proper account is taken of the actual diaphragm forces likely in large ground shaking events. A prescriptive elastic diaphragm design, therefore, may be difficult to achieve reliably for all situations.

Deformation capacity needs to be built into the precast floor system (Lee et al., 2007). Accordingly, the approach adopted for the design methodology is to target elastic diaphragm response but anticipate the need for inelastic deformation capacity. In this way, impractical (connectors spaced too closely) or uneconomical (cost of significantly more connectors) designs can be avoided; yet, the penalty for unanticipated load paths or localized concentrated inelastic deformation is no longer a nonductile failure (loss of load carrying capacity) of the floor system but is instead repairable damage to the floor system.

The use of performance targets allows parallel design requirements related to diaphragm flexibility to be considered at the same time as diaphragm strength and deformation capacity. The primary requirement in this regard pertains to limiting the flexible-diaphragm amplified drifts of gravity system columns and walls (out-of-plane displacement of walls) in regions of the structure distant from primary LFRS elements.

PROPOSED DESIGN APPROACH

The design approach for the proposed seismic design methodology is based on performance targets for the diaphragm seismic response. The selected performance targets are enforced through a combination of design factors and detailing requirements. The design methodology provides the designer with the flexibility of selecting from a number of options.

The basic design option (BDO) targets elastic diaphragm behavior for the design basis earthquake (DBE). As such, a certain amount of inelastic diaphragm deformation is anticipated in a maximum considered earthquake (MCE). This target is selected based on the research findings discussed above, showing that attempting to enforce elastic behavior in precast diaphragms for all seismic response situations can be impractical. Instead, the BDO involves the use of more realistic diaphragm design forces, higher for most cases than those currently used in practice, in combination with detailing provisions that build a measure of inelastic deformation capacity into the diaphragm.

In some cases, the basic design objective is neither practical nor necessary. In such cases, two alternatives are offered: an elastic design option (EDO) that may provide the best design option for less demanding cases (e.g., squat diaphragm geometry or a low SDC) and a "relaxed" design option (RDO) in which a limited amount of inelastic diaphragm deformation is accepted in the DBE in order to lower diaphragm design forces. The second option may be necessary for practical designs in demanding cases (e.g., long span untopped diaphragms for use in high SDCs).

Figure 1 shows a schematic of diaphragm response in terms of monotonic pushover curves (diaphragm force vs. diaphragm midspan deformation). The lower curve is the expected performance of current diaphragm designs for high SDCs -- the

diaphragm force in a significant seismic event is expected to exceed current design forces and, in the absence of any detailing requirements, the diaphragm will likely undergo a nonductile failure (shown by the lowest X). The upper curve is the performance intended by the proposed BDO design approach. Shown on this upper curve are key points related to the design approach.

The design approach employs the following features to achieve its objectives:

1. An amplified diaphragm design force,
2. A higher relative strength for the diaphragm shear reinforcement and the connections to the LFRS than the diaphragm chord reinforcement,
3. A classification system for diaphragm reinforcement, and
4. Limits on the diaphragm contribution to interstory drift.

As indicated in Figure 1, the following terminology and notation track these measures during the calibration stage: a diaphragm design force amplification factor, Ψ_D; a diaphragm shear overstrength factor, Ω_v, and an anchorage overstrength factor, Ω_a; diaphragm reinforcement and connection classification categories LDE (low deformability elements), MDE (moderate deformability elements) and HDE (high deformability elements); and a diaphragm drift limit, δ_x.

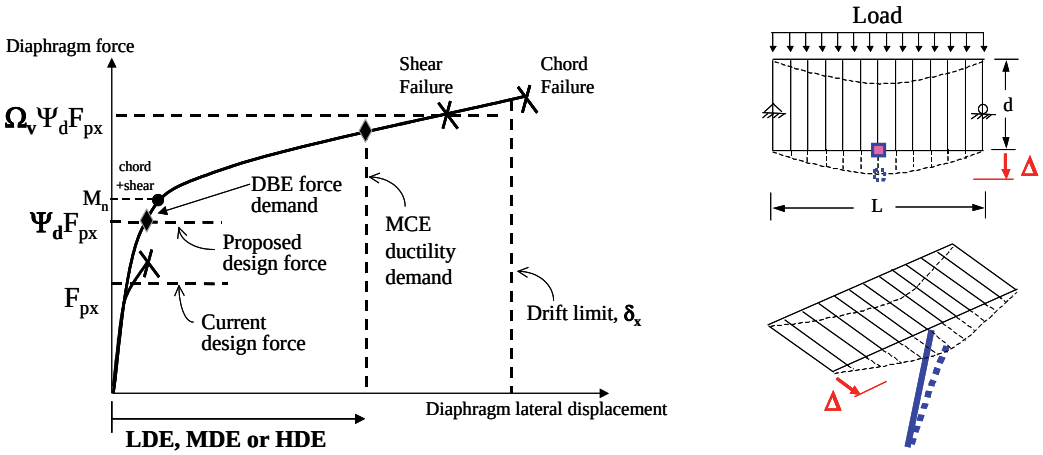

Figure 1 Diaphragm response curve (left) and diaphragm force and deformation (right).

The Ψ_D factor is applied to the current code specified diaphragm design force to increase the diaphragm

strength to the DBE force target. This approach requires some deformation capacity in the diaphragm reinforcement for the MCE event, which may be MDE or HDE depending on the parameters of the design. The Ω_v factor is applied to the diaphragm shear reinforcement to prevent a non-ductile shear failure from occurring while the diaphragm deforms in the MCE demand. This displacement demand needs to be within allowable drift limits (right side of Figure 1).

Figure 2 shows pushover curve schematics for two situations in which the elastic design option (EDO) may be desirable. The left side of Figure 2 shows the low seismic hazard case. The BDO also can be used for this case as shown by the lighter (gray) curve. However, the forces Ψ_eF_{px} required for the EDO (dark black curve) may not be significant in terms of absolute values and, thus, it may be more desirable to relax the stricter requirements of an HDE design.

The right side of Figure 2 shows the squat geometry case. Again, the BDO can be used for this case. The MCE ductility demand is not large (due to diaphragm geometry) and so MDE reinforcement can be used. However, since the mass and length of the squat diaphragm are less than for a longer diaphragm, the internal shear and moment are lower for a given acceleration. Thus, designing the diaphragm strength Ψ_eF_{px} to the upper diamond in Figure 2 (right) (i.e., an EDO) also is feasible. The EDO is a reasonable option for a squat diaphragm geometry or a low SDC diaphragm.

Figure 3 shows the relaxed design option (RDO). This option is desirable when the diaphragm force is sufficiently large to make the spacing of diaphragm connections impractical as is the case for pretopped long span diaphragms for high SDCs. By relaxing the elastic diaphragm requirement for the DBE target, all the design forces for the diaphragm are reduced including the "stacked" factors $\Psi_D\Omega_v$ applied to the shear reinforcement. Naturally, a larger inelastic deformation capacity is required for the MCE and, thus, HDE reinforcement will be required. The different features of the design approach are described below.

Diaphragm Design Force. The diaphragm global performance targets are achieved through specifying appropriate diaphragm design force levels. The proposed design approach will accomplish this objective through the use of amplified diaphragm design forces. The required magnitude of the diaphragm design force amplification Ψ_D is based on the design intent (BDO, EDO, RDO) as well as a number of structural parameters including: diaphragm span, LFRS type, building configuration, and number of stories.

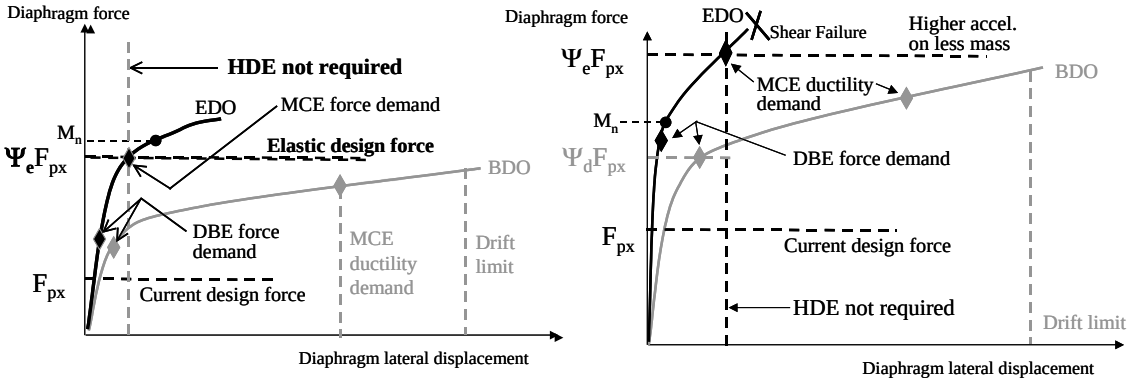

Figure 2 Elastic design option (EDO): low seismic hazard (left) and squat diaphragm geometry (right).

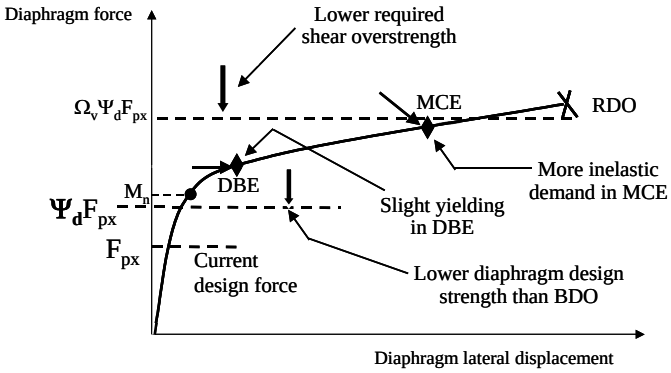

Figure 3 Relaxed design option (RDO).

The manner in which diaphragm force amplification will be introduced into the design methodology is currently under consideration (see Section A2). During the research phase, a generic term, the diaphragm design force amplification factor, Ψ_D, has been used for calibration purposes. The Ψ_D factor is expressed relative to the code prescribed diaphragm design force values in place at the onset of the research project in 2003. A constant diaphragm force pattern, regardless of the floor level in the building, is envisioned for the design methodology. This contrasts with the increasing force values for increasing floor levels in current codes. The Ψ_D factor is calibrated with respect to the maximum diaphragm force relative to current code force values, (typically the force for the uppermost level diaphragm). The research studies completed to date indicate that appropriate Ψ_D values are 1.4 to 2.0 (BDO), 1.0 to 1.5 (RDO) and 1.75 to 2.5 (EDO).

Diaphragm Reinforcement Relative Strength. The design approach uses capacity design concepts to produce a hierarchy of design strengths among the reinforcement groups in the diaphragm. This approach recognizes the need to form a ductile deformation mechanism in an overload situation. The primary diaphragm reinforcement groups are chord reinforcement, shear reinforcement, and collector/anchorage reinforcement. A hierarchy of design strengths is used that is intended to protect the shear and anchorage reinforcement against failure and ensure ductile flexural limit states.

The relative strength increases for the diaphragm shear and anchorage reinforcement are a function of the design intent (BDO, EDO, RDO) as well as structural parameters including diaphragm span, Seismic Design Category, and diaphragm detail classification.

The manner in which the hierarchy of diaphragm reinforcement relative strengths is introduced into the design methodology is still evolving (see Section A3). During the research phase, generic terms, the diaphragm shear overstrength factor, Ω_v, and the anchorage overstrength factor, Ω_a, have been used for calibration purposes. The overstrength factors for the shear reinforcement and anchorages are applied to internal force values based on the already amplified diaphragm design force value (i.e., they are additional to the Ψ_D factor). Initial studies indicate that ranges for Ω_v and Ω_a are likely to be 1.1 to 1.4 and 2.0 to 2.5, respectively.

Diaphragm Detailing. A classification system ensures that the diaphragm details specified have the necessary characteristics to produce the desired performance. A classification system is necessary given the many different types of reinforcing details for precast concrete diaphragms, including proprietary and non-proprietary details.

The diaphragm detail classification system is based on deformation capacity with the following categories: low deformability elements (LDE), moderate deformability elements (MDE), and high deformability elements (HDE). The use of different categories recognizes that expected seismic demands, as controlled by the design factors, will not always require the strictest level of detailing.

The option selected for the diaphragm design will dictate the diaphragm detail categories or vice versa. In general, the EDO needs only LDE elements while the RDO requires HDE elements. The BDO can use MDE or HDE elements depending on the parameters of the design.

The detailing requirements for MDE and HDE elements ensures that a hierarchy of strengths exists among the elements (bars, plates, welds, anchors, etc.) within the reinforcing details so as to promote ductile behavior with the HDE being required to demonstrate a certain level of deformation capacity.

An examination of current detailing practice for representative details (Naito et al., 2005) indicates that such hierarchies are not present in many current details. However, certain existing diaphragm connectors that are LDE can be enhanced to MDE through improved detailing.

The category assigned to a given detail is based on a qualification procedure that includes specifications for detailing requirements and protocols to demonstrate the detail's characteristics through physical testing (see Section A4). The procedure can be used to prequalify existing details or serve as a mechanism for qualifying new detailing concepts.

Diaphragm Stiffness and Strength. The design approach uses an elastic stiffness calculation to ensure that the diaphragm flexibility is within acceptable limits with respect to interstory drift of gravity system columns and walls in regions of the structure distant from the primary LFRS elements and to adjust the diaphragm amplification and overstrength factors for the effect of diaphragm flexibility on the structure's modal properties.

The design approach requires a flexural strength calculation to select the flexural reinforcement. In accordance with research findings and consistent with recent code modifications (ACI, 2008), the flexural strength includes the tension contribution of the diaphragm shear reinforcement to diaphragm flexural strength.

A spreadsheet method has been developed to determine the effective moduli (G_{eff}, E_{eff}) for the calculations of stiffness and diaphragm flexural strength (M_n). The method is based on estimating the neutral axis depth (different formulations are used for strength and stiffness) and spreading the lower joint stiffness over the precast panel (see Section A5). The method has been initially calibrated with respect to analytical results and is currently being calibrated to experimental results.

Diaphragm Load Path. The design approach implicitly accounts for force combinations on individual reinforcing elements within the diaphragm and/or entire diaphragm joints since the design factors are calibrated from analytical models that capture these combined actions. Further, the effects of concentrated inelastic deformations on the local deformation demands for the diaphragm reinforcement are likewise included in the models used for calibration.

However, a design approach that builds a measure of deformation capacity into the diaphragm must ensure that the deformation demands are occurring in the intended regions and not in an alternate unanticipated load path. This is particularly important for precast concrete diaphragms because the precast floor system is an assemblage of several types of precast elements including so-called "secondary" elements (spandrels, inverted tee beams, lite walls) that are not formally included in the diaphragm design but nevertheless may participate in the diaphragm action. The connections for these secondary elements are often industry standard hardware rather than elements designed for a seismic force. These elements do not usually possess sufficient strength or deformation capacity for plastic redistribution. Thus, if a section along the force path cannot accommodate the forces or displacements, a nonductile failure may occur.

Finally, if the diaphragm is irregular, an explicit accounting for the load path may be required. The simple "horizontal" beam procedure currently used in practice can be used if the diaphragm configuration meets certain limiting requirements. If not, the designer will have two choices: apply internal force amplification factors based on the diaphragm configuration or

perform a static FE analysis of the floor system under inertial force to calculate the factors directly. A similar procedure is to be used for the collectors and anchorages. Issues pertaining to the load path are discussed in Section A6.

LIST OF ACRONYMS

AR = aspect ratio
BDO = basic design option
DBE = design basis earthquake
DOF = degree of freedom
DSDM = diaphragm seismic design methodology
EDO = elastic design option
ELF = equivalent lateral force
FE = finite element
HDE = high deformability element
LDE = low deformability element
LFRS = lateral-force-resisting system
MCE = maximum considered earthquake
MDE = moderate deformability element
NLDTA = nonlinear dynamic transient analysis
RDO = relaxed design option
RDOF = reduced degree of freedom
SDC = Seismic Design Category
SP = spandrel

APPENDIX

A1 Key Aspects of Precast Concrete Diaphragm Behavior

A1.1 Diaphragm Force Levels. Research has shown that the maximum diaphragm force event occurring at a given floor during a design basis earthquake (DBE) may be substantially larger than current design force levels (F_{px}) and even larger (two or more times larger) in the maximum considered earthquake (MCE) (DSDM, 2006). Furthermore, the maximum inertial forces may occur in the lower floors of the structure in direct contradiction to current ELF code specified patterns. Such observations have also been deduced from accelerations measured during earthquakes (Hall, 1995) and in shake table tests (Kao, 1998). The relative magnitude of the expected maximum diaphragm force to the current design force has been shown to be dependent on several factors pertaining to building dimensions and configurations, the LFRS type, strength and layout, and the ground motion intensity.

Necessary Feature of Design Methodology. Specification of appropriate diaphragm design force levels and associated diaphragm design force patterns.

Design Methodology Approach. Appropriate diaphragm force levels are assigned through the use of a diaphragm force amplification factor Ψ_D (see Section A2).

A1.2 Diaphragm Internal Force Paths. Current U.S. practice uses a horizontal beam model to determine the internal forces (moment and shear) due to F_{px}. Chord reinforcement is provided to carry the in-plane bending moment; shear reinforcement across panel joints parallel to the seismic force is designed to carry the in-plane shear; and collectors bring these forces to the LFRS. The following observations are made with respect to the current design model:

1. Regions of the diaphragm may be subject to complex force combinations (shear, moment, and thrust coinciding at a section) that are more demanding than the internal forces determined from the simple horizontal beam model. The additional forces can be due to restraint resulting from, or differential movements of, the vertical elements of the LFRS, the direction of application of the seismic excitation, and openings or other irregularities in the floor system.
2. Shear strength design equations based on inclined cracking are not consistent with the observed behavior for topped precast concrete diaphragms (Wood et al., 2000). Further, the 90-degree paths associated with collectors do not provide a fully rational load path to the primary (vertical plane) LFRS elements.
3. In precast concrete diaphragms alternate load paths may occur in the floor system through secondary elements such as spandrels or inverted tee beams. These paths are unanticipated by the horizontal beam model.

4. In ACI 318-08, the assumption that the chord reinforcement alone resisted the assumed design moments is replaced by an approach permitting all the longitudinal reinforcement in the diaphragm to be assumed to contribute to its flexural strength.

The horizontal beam assumption relies implicitly on plastic redistribution because it is assumed that the diaphragm forces are resisted by their intended reinforcement group. However, no formal requirements currently exist for that reinforcement to have the needed deformation capacity. Sufficient deformation capacity must be provided for precast diaphragm reinforcement details so that they can develop and maintain the desired joint strength. This requirement is considered in Section A1.3.

Necessary Features of Design Methodology. An accurate yet simple method is needed for determining diaphragm internal forces including the likely force combinations on individual reinforcement or reinforcement groups and anticipating alternate load paths. Using this method requires that:

1. Precast diaphragm reinforcement details should be designed for force combinations when appropriate.
2. More rational load paths should be used to distribute forces to the primary LFRS elements.
3. The alternate load paths in secondary elements should be accounted for or mitigated, including preclusion of non-ductile failure modes in secondary elements.

Design Methodology Approach. The current "horizontal" beam procedure can be used if the diaphragm configuration meets certain limiting requirements. If not, the designer will have two choices: (1) apply internal force amplification factors based on diaphragm configuration or (2) perform a static FE analysis of the floor system under inertial force to calculate the factors directly. A similar procedure is to be used for collectors and their anchorage to the LFRS.

A1.3 Diaphragm Detailing. Existing precast concrete diaphragm connector details have been developed without full consideration of expected local deformation demands due to joint opening. As described in the previous section, a certain amount of deformation capacity is needed simply to develop the anticipated joint strength. As an example, consider shear reinforcement in high flexure regions. This reinforcement is actually under high tension due to in-plane bending of the diaphragm. The tension deformation demand on the shear reinforcement due to joint opening will be similar to that of the nearby chord reinforcement. Likewise, chord reinforcement in high shear regions must undergo a similar shear deformation demand due to joint sliding as the shear reinforcement. Thus, for an elastic design based on the horizontal beam model, a certain level of reliable deformation capacity is required. However, the design philosophy adopted here will in some cases require the diaphragm to possess a measure of inelastic deformation capacity to provide structural integrity for the diaphragm during strong ground shaking. The intent of this approach is to assume inelastic deformation in certain diaphragm reinforcing elements while protecting other elements through capacity design concepts.

Necessary Features of Design Methodology. Necessary to the design methodology are:

1. Specification of appropriate capacity design factors to protect certain diaphragm reinforcing elements;
2. Specification of the expected inelastic deformation demands for other diaphragm details for a given set of design parameters; and
3. Demonstration of reliable deformation capacity for the diaphragm details in question.

Design Methodology Approach. The relative strength of different diaphragm reinforcement groups is specified by diaphragm overstrength factors applied to the shear reinforcement (Ω_v) and the collectors and their anchorages (Ω_a). The appropriate factor is selected based on a number of design parameters. A classification system (LDE, MDE or HDE) is used to ensure that appropriate precast diaphragm primary reinforcement details are used in conjunction with these design factors to meet the design intent. Precast diaphragm reinforcing elements can be prequalified for a classification or can undergo qualification testing following an established protocol. Appropriate secondary details are required to mitigate unanticipated load paths through secondary elements.

A1.4 Diaphragm Flexibility. Precast concrete construction is commonly and effectively used for building systems with long floor spans. In these structures, distances between the primary LFRS elements can produce a diaphragm that is relatively flexible. The diaphragm flexibility is further increased by the inherent flexibility of a jointed system in comparison to a monolithic system. For these flexible diaphragms, the floor system and connected gravity force-resisting columns in regions removed from the primary LFRS elements can undergo amplified drift demands (Ju and Lin, 1999; Tena-Colunga and Abrams, 1992). These drift demands can be significant for long span precast concrete structures in a MCE (Lee and Kuchma, 2007; Fleischman et al., 2002).

Necessary Feature of Design Methodology. Specification of a diaphragm elastic stiffness calculation procedure that can be used to properly estimate seismic design forces and check drift limits.

Design Methodology Approach. The interstory drift, typically calculated as the difference in LFRS drift for adjacent floor levels, must include a diaphragm deformation component.

A2 Determining Appropriate Diaphragm Force Amplification Factors

A2.1 Previously Proposed Approaches. Table A2-1 shows some of the diaphragm force amplification factors proposed in the past:

1. Nakaki (2000) identified important inconsistencies in the then current code including designing the diaphragm to the primary LFRS "first yield". She proposed using a system overstrength factor Ω_o to amplify the diaphragm design force.
2. Rodriguez, Restrepo and Carr (2001), pointed to the importance of higher mode contributions to diaphragm force and proposed calculating a diaphragm force $F_{dia} = \lambda\Omega_i$ (PGA) W_{dia} where λ is the importance factor, PGA is the peak ground acceleration and Ω_i is a magnification factor based on the vertical location of the floor and the influence of higher modes and for which only the first mode acceleration was reduced by the R factor:
3. Fleischman et al, 1998, investigated precast parking structures and proposed that a constant diaphragm design force pattern be used. Fleischman and Farrow (2003), investigated frame and wall structures with flexible diaphragms, and proposed calculating the diaphragm force using a diaphragm overstrength factor Ω^* where: Ω^* targets the elastic diaphragm response in the DBE and Ω^*_e targets the response for the MCE; there is a diaphragm flexibility factor β that ranges from 0 (rigid) to 0.4 (highly flexible);Ω^* is a function of β and the number of stories for wall structures (see Table A2-2); and Ω^* is 1.0 for frame structures.
4. The 2000 and 2003 *NEHRP Recommended Provisions* Appendix A to Chapter 9 for Untopped Precast Diaphragms proposed a factor that combined the system overstrength factor with the redundancy factor.

Table A2-1 Comparison of Diaphragm Force Amplification Factors

Researcher	Nakaki	Rodriguez/ Restrepo/Carr	Farrow/Fleischman/ Sause	NEHRP Appdx. To Chap. 9
Design Force Approach	Design to LFRS Ultimate	Use R Factor on 1st mode only	Ω is function of diaphragm flexibility	Higher factor for untopped
Design Force	$\Omega_o = 2.8$ [a]	Ω_i	$\Omega^* = 1.0$-3.0	$\rho\Omega_o$

[a] For squat shear walls, use $R = 1$.

Table A2-2 Overstrength Values for Differing Story Numbers and Diaphragm Flexibility

	Ω^*					Ω^*_e				
β / Stories	**0.2**	**0.25**	**0.3**	**0.35**	**0.4**	**0.2**	**0.25**	**0.3**	**0.35**	**0.4**
1	1.0	1.1	1.2	1.4	1.55	1.9	1.85	1.8	1.7	1.6
2	1.2	1.3	1.45	1.7	1.85	2.3	2.25	2.15	2.05	1.95
3	1.4	1.5	1.7	1.95	2.2	2.7	2.6	2.5	2.4	2.3
4	1.6	1.7	1.95	2.2	2.5	3.1	3.0	2.9	2.75	2.6
5	1.8	1.95	2.2	2.5	2.7	3.45	3.35	3.25	3.15	2.9
6	2.0	2.15	2.45	2.8	3.0	3.8	3.65	3.5	3.35	3.2

A2.2 DSDM Project Research Approach. The ratio of the magnitude of the expected maximum diaphragm force to the current code specified force depends on several factors related to building dimensions and configurations, LFRS type and layout, and ground motion intensity (DSDM, 2006). The DSDM project is calibrating the appropriate ratio (Fleischman et al., 2005b) using two research activities:

1. A comprehensive statistical analytical parameter study using nonlinear dynamic transient analysis (NLDTA) of reduced degree-of-freedom (RDOF) models being performed at UCSD.
2. A smaller number of NLDTAs using large degree of freedom three-dimensional finite element (3D-FE) models of prototype structures being performed at the University of Arizona.

The analytical models were built using characteristics obtained from experiments on individual diaphragm reinforcing details performed as part of the overall project (Naito et al. 2005). The analytical models are being verified through comparisons with the results of hybrid testing of joint sub-assemblages at Lehigh University and a half-scale shake table test at UCSD (Fleischman et al, 2005b).

RDOF Study. The left side of Figure A2-1 shows a representation of the RDOF model. The diaphragm is modeled as a beam with its shear and flexural stiffness determined using the method described in Section A5. The parameters varied in this study include: diaphragm span, LFRS type, building configuration, number of stories, Seismic Design Category (SDC), design target, and detailing. Structures are designed for four sites as shown in Table A2-3 and are subjected to suites of 10 ground motions for each site.

Table A2-3 Representative Seismic Sites

Location	Soil	S_S	F_a	S_{MS}	S_{DS}	S_1	F_v	S_{M1}	S_{D1}	SDC
Knoxville	C	0.58	1.17	0.68	0.45	0.147	1.65	0.24	0.16	C
Seattle	C	1.58	1.00	1.58	1.05	0.55	1.30	0.71	0.47	D
Berkeley	C	2.08	1.00	2.08	1.39	0.92	1.30	1.21	0.81	E
Charleston	F	1.39	0.94	1.30	0.87	0.40	2.75	1.10	0.73	E

The right side of Figure A2-1 shows sample results from a suite of 10 earthquake motions for a single set of design parameters (Berkeley DBE, three-story, perimeter shear wall layout, aspect ratio of 2). Median floor acceleration is plotted along the length of the floor for each story. The current code design value is shown as a straight broken line. For this design case, a Ψ_D factor of approximately 1.4 is required to target elastic response for the median response in the DBE for all the diaphragms in the structure.

3D-FE Analysis. On the left, Figure A2-3 shows an example of a 3D-FE model for a three-bay two-story parking structure. Spring elements with cyclic characteristics represent the shear and chord reinforcement, described further in Appendix 3, and the plastic hinging in the walls. The effect of secondary elements such as spandrels and their connections are included.

On the right, Figure A2-3 shows sample results of chord reinforcement axial, (opening), deformation demand for designs using different Ψ_D (OD) factors. A Ψ_D =1.0 leads to a maximum (inelastic) chord deformation demand of 0.9 inch in the DBE. This value drops to 0.35 inch for Ψ_D = 1.5, and the response is fully elastic for Ψ_D = 2.0. The MCE demands for the latter two cases are 0.5 and 0.12 inch, respectively.

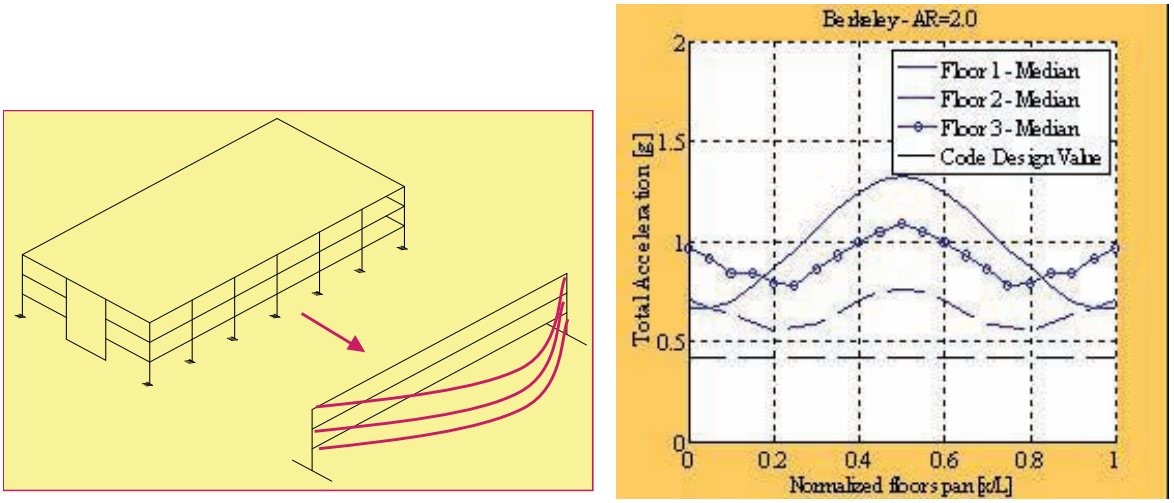

Figure A2-1 Schematic of RDOF model (left) and sample results for the floor (right).

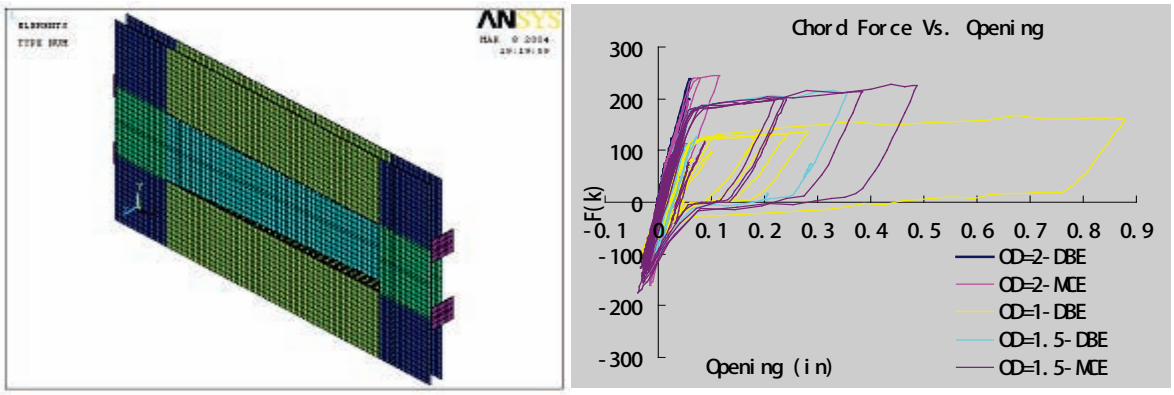

Figure A2-3 Schematic of 3D-FE model (left) and sample results for chord force v_s. opening.ght).

Such results allow calibration of Ψ_D with respect to diaphragm detail classification (LDE, MDE and HDE). Testing has shown that HDE chord details can reliably achieve cyclic tension deformation amplitudes of 0.6 inch and that MDE details reliably achieve 0.25 inch deformation (see Section A4). For this design, the use of $\Psi_D = 1.5$ and HDE details is a viable RDO solution. For a BDO solution, $\Psi_D = 2.0$ would be required although MDE reinforcement could be used.

Possible Expression for Diaphragm Force Amplification. The proposed form for the amplification factor is:

$$F_{px} = \frac{w_{dia}\Psi_{vert}}{\mu_{dia}} F_x$$

where F_x = the story force; ω_{dia} = the dynamic amplification of diaphragm (depends on story); ψ_{vert} = the overstrength of vertical LFRS; and μ_{dia} = the ductility capacity of the diaphragm as a whole – depends on connections used (for elastic diaphragm design (e.g., short spans, low SDC), $\mu_{dia} = 1.0$).

A3 Determining Appropriate Diaphragm Reinforcement Relative Strength. The methodology uses a capacity design approach to protect specific diaphragm reinforcement groups (Standards New Zealand, 1997). The required relative strength of the panel to panel shear reinforcement, and the diaphragm to LFRS anchorage reinforcement, to the chord reinforcement has been found to depend on several factors including diaphragm dimensions and configurations, and diaphragm detailing (Fleischman and Wan, 2007). The DSDM project is calibrating the shear and anchorage relative strength factors using two research activities:

1. A comprehensive parameter study of precast floor diaphragms using nonlinear static "pushover" analyses of simplified representations of individual diaphragms (Fleischman and Wan, 2007).
2. A smaller number of 3D-FE nonlinear dynamic transient analyses (NLDTA) of prototype structures to calibrate or verify the findings from the first research activity.

2D-FE Study. The graphic on the left side of Figure A3-1 shows a schematic of the 2D diaphragm model used for nonlinear pushover analyses. The parameters that were varied for this model were diaphragm span and aspect ratio (AR), Seismic Design Category (SDC), and diaphragm detailing classification.

On the right, Figure A3-1 shows the diaphragm pushover curves for a single set of diaphragm design parameters ($AR = 3$, L =180', Charleston) with increasing diaphragm shear reinforcement relative strength Ω_v. The greater the Ω_v value, the greater the deformation capacity achieved by the diaphragm. A Ω_v of 2.15 is needed to develop the full diaphragm flexural strength. However, using less shear reinforcement (Ω_v of 1.76 and 1.37), while not preventing shear failure, delays the failure sufficiently to allow some increased inelastic deformation in the diaphragm. Note that, as indicated in the inserts in Figure A3-1, a chord failure occurs at midspan while a shear failure occurs at the first panel-to-panel joint (assuming that $\Omega_a > \Omega_v$). The performance is also characterized by the overall ductility of the diaphragm, μ.

Design charts have been constructed using the results of the studies. On the left, Figure A3-2 shows, for a given diaphragm geometry, the Ω_v values required to achieve specific design targets (diaphragm yield strength, M_y: diaphragm ultimate strength, M_u; diaphragm ductility ratio, μ; and interstory drift, ϕ). Likewise, by examining the internal state of the diaphragm, the right side of Figure A3-2, the required deformation capacity of the diaphragm chord reinforcement, $\delta_{t,max}$, needed to achieve a given design target was determined.

The appropriate design target for a given design is being determined from the second research step: NLDTAs of 3D-FE models of the prototype structures.

3D-FE Analysis. The 3D FE analyses determine the expected local demands on diaphragm reinforcement crossing diaphragm joints by realistically modeling the connector behavior in finite element models of prototype precast structures. These structures are designed for differing SDCs per current code with requirements adjusted using the diaphragm design factors described in this document. The structures are subject to a suite of 10 ground motions scaled to the expected seismic hazard (DBE and MCE) for the design in question.

The finite element models employ discrete coupled springs that represent the shear-tension response of the diaphragm reinforcement crossing the joint. Contact elements are placed in parallel to model the compression zone and friction contributions. The characteristics for the spring elements are obtained from experiments on panels with differing individual diaphragm reinforcement details.

On the left, Figure A3-3 shows a photograph of one of the Lehigh Phase 1 tests used to determine FE connector model characteristics (Naito et al., 2005). On the right, Figure A3-3 shows a sample test result for a shear connector under cyclic loads and the response of the calibrated spring element adjusted to match the test result.

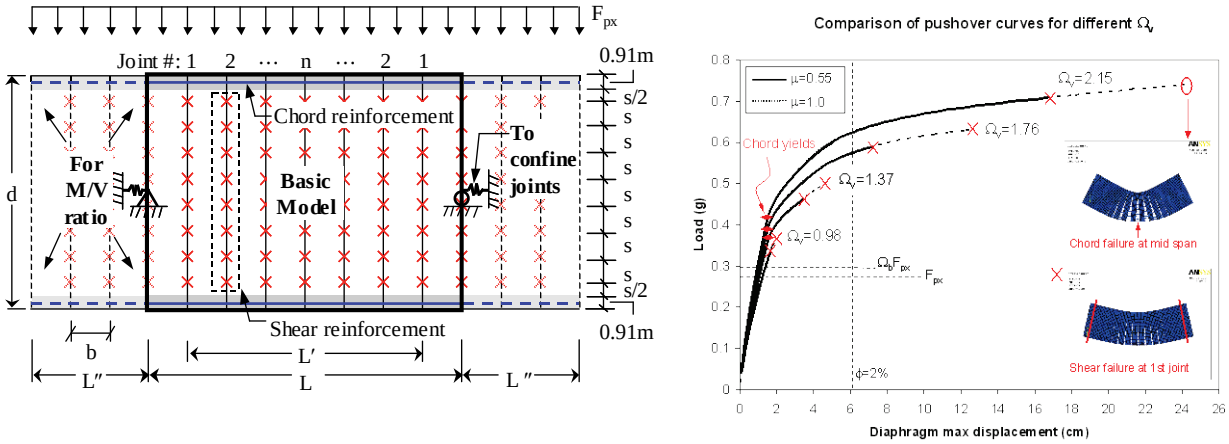

Figure A3-1 Schematic of 2D FE model (left) and sample results for diaphragm shear overstrength factor Ω_V.

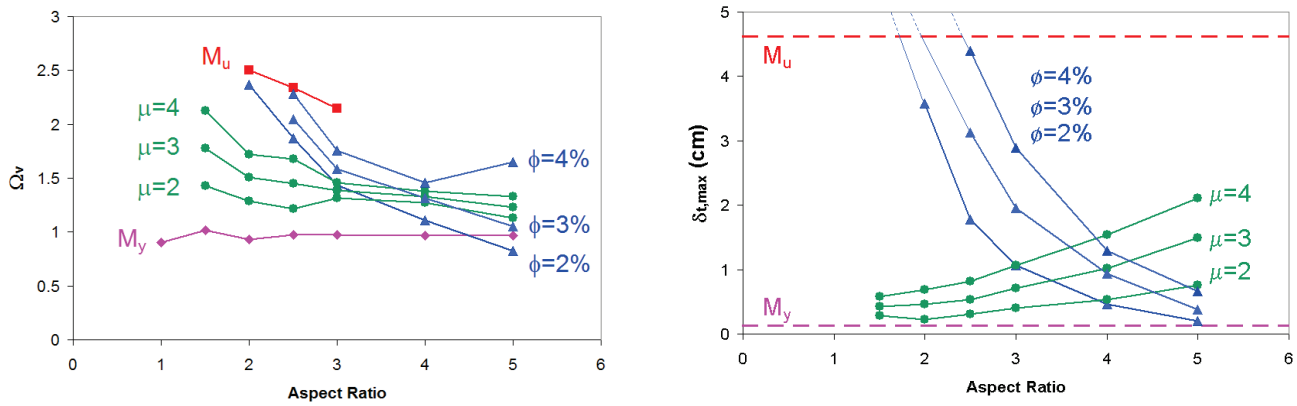

Figure A3-2 Design charts: Ω_V vs. aspect ratio (left) and deformation capacity *c* vs. aspect ratio (right).

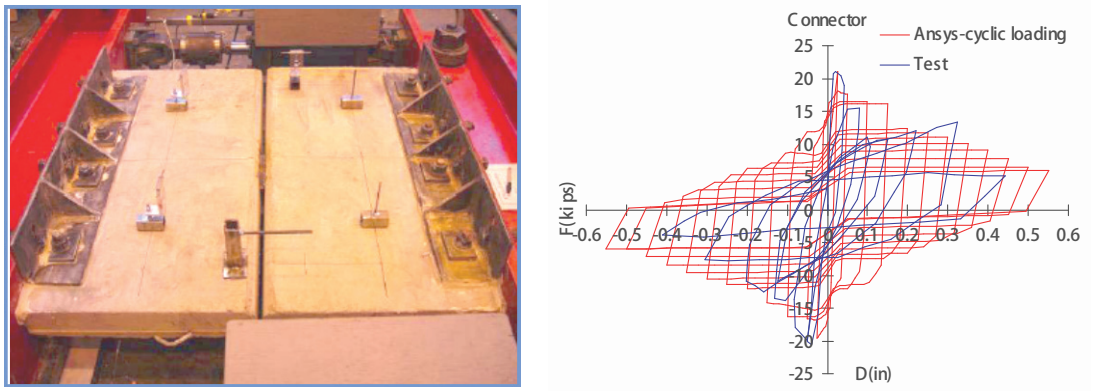

Figure A3-3 Lehigh Phase 1 test specimen and sample results for cyclic shear response (test & FE model) (right).

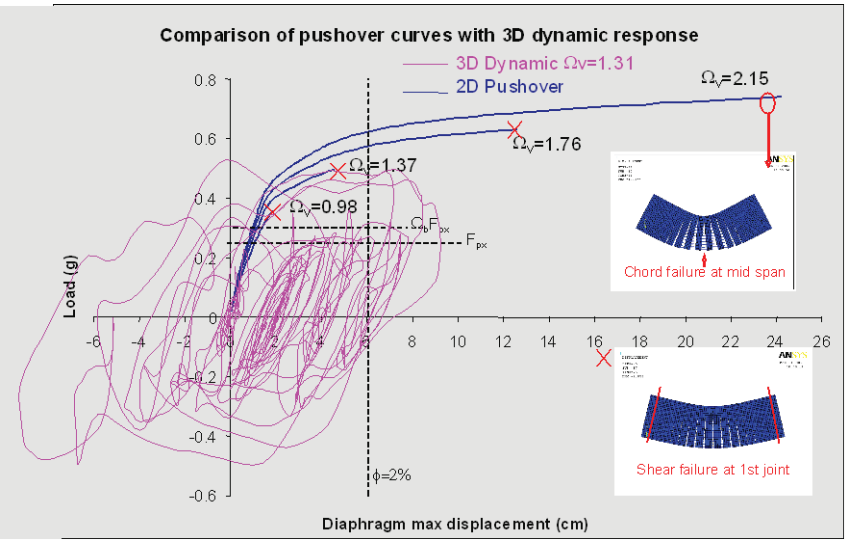

Figure A3-4 Superposition of 3D-FE global EQ demand results on 2D pushover.

Figure A3-4 shows the pushover curve global results (diaphragm force vs. diaphragm deformation) for an *AR* = 3, *L* = 180', and the Charleston site for the critical floor from the 3D-FE model (three-story structure, Ψ_D=1.5) under the Charleston MCE. As can be seen, this technique allows a target displacement to be determined for the diaphragm for a given set of design parameters. For instance, use of Ω_v = 2.15 (shown previously to develop the full flexure strength of the diaphragm) is unnecessary. Instead, an Ω_v somewhat greater than 1.4 is sufficient to accommodate the MCE diaphragm demands for this structure.

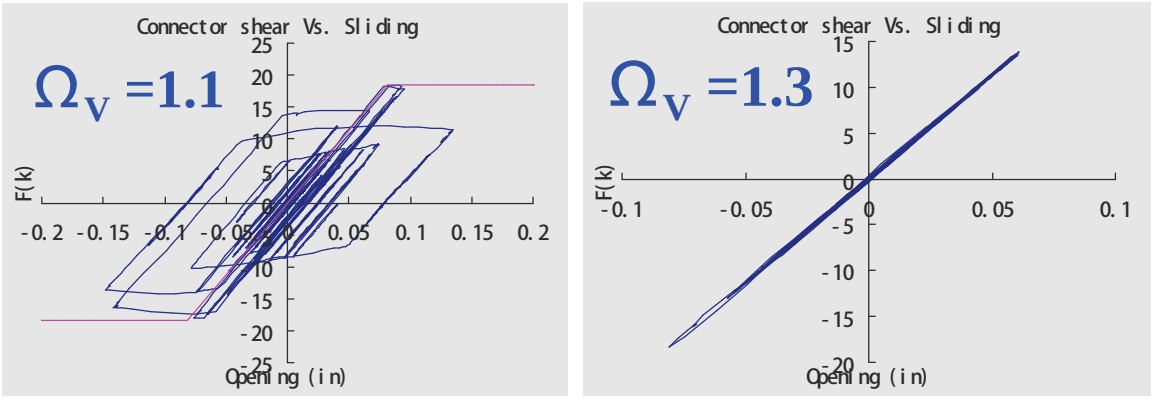

Figure A3-5 Sample results for critical shear connector, Ψ_D = 1.5 Berkeley MCE: (a) Ω_v = 1.1, (b) Ω_v = 1.3. deformation demand.

Figure A3-5 shows how the 3D-FE earthquake simulations are used to calibrate Ω_v. Shown are the response demands for the critical shear connector at the critical shear joint in the diaphragm (lower insert in Figure A3-4) for a given MCE earthquake. A shear overstrength factor Ω_v of 1.1 was used on the left side of Figure A3-5. This value was insufficient to prevent the connector from undergoing shear degradation for this single deterministic evaluation of one structure, one design and one ground motion. Raising the Ω_v value to 1.3 on the right side of Figure A3-5 was sufficient to keep this critical detail elastic throughout the MCE event.

A4 Diaphragm Detail Classification and Qualification Procedures. Proper performance of connection details is critical for the effective design and safety of precast concrete building systems. As part of the design methodology a qualification procedure is proposed that provides a systematic approach for assessing the strength and deformation capacity of embedded connections as used in conventional double tee panel systems (Ren and Naito, 2007). In addition, a recommendation is provided for categorizing connectors based on measured performance. The recommendation is limited to testing of the in-

plane and out-of-plane response of connections. A catalog of connections that have undergone this qualification and classification procedure is being compiled.

The ACI 318 code used for prestressed and non-prestressed concrete construction in the United States provides limited guidance on the design of precast connections. As noted in its Chapter 16, the various components in a connection have different properties, and those properties affect the overall behavior of the connection. Therefore, when a connection is designed using materials with different structural properties, their relative stiffness, strength, and ductility must be considered in evaluating performance.

A ductile flexural mechanism cannot form unless the connection components are designed to ensure that performance. A typical diaphragm connection consists of anchorage bars, welded plate, slug, and slug weld components. The desired connection performance is achieved by the development of a predictable yield mechanism in the anchorage bars and the protection of all other components against premature failure. For example, the weld strength must be not less than the anchorage bar strength.

Scope. The qualification document provides both a testing procedure and a classification framework that establish specific acceptance criteria for in-plane and out-of-plane performance of precast concrete diaphragm connections. For consistency with the emerging design methodology, acceptance criteria are based on prequalification of the deformation capacity. The terminology of low deformability element (LDE), medium deformability element (MDE) and high deformability element (HDE) is used to categorize the response of connections. A procedure for determining the capacity of connectors based on experimental results is described.

Testing Agency. Testing is to be performed by a recognized independent testing agency. That testing and reporting must be supervised by a professional engineer familiar with the proposed design procedure and experienced in testing and seismic structural design.

Test Modules. A minimum of two modules should be tested for each characteristic connection configuration in the prototype diaphragm. Connections are to be tested full scale unless both connections and modules have a scale large enough to represent fully the complexities and behavior of the real materials and of the load transfer mechanisms in the prototype diaphragm. For modules that are to be subjected to loadings that include in-plane loadings there must be at least two connections per module.

Reference Deformation. For each connection type, a monotonic test to failure must first be conducted to obtain a reference deformation used in subsequent cyclic tests. This reference deformation characterizes the effective yield deformation of the connection. That deformation is the deformation corresponding to the maximum load on a secant stiffness line drawn through the load and deformation for 75 percent of the maximum load.

In-plane Displacement Based Protocols. The modules are to be loaded under in-plane pure shear, pure tension, shear combined with tension, and out-of-plane shear. Tests are to be conducted under displacement control at quasi-static rates (< 0.05 in./sec) and force control. The specified testing sequence for cyclic loading is shown in Figure A4-3 where, at a ductility ratio of 1.0, the applied displacement is equal to the reference deformation.

Data Acquisition. Data must be recorded from the test such that a quantitative, as opposed to qualitative, interpretation can be made of the performance of the test module. A continuous record must be made of the force versus deformation. For in-plane tests, the axial and shear forces and the deformations transverse and parallel to the joint are to be recorded. For out-of-plane tests the vertical force and deformation are to be recorded. For static testing, data are to be recorded at a rate of 1.0 cycle/second.

Test Observations. Photographs must be taken that show the condition of the test module at the completion of testing as well as significant points throughout the testing history. Ideally, photos should be taken at the end of each group of cycles. Photos taken at points of interest, such as first cracking, yield, ultimate load and post-test, are adequate for most evaluations.

Test Report. The test report must be sufficiently complete and self-contained for a qualified expert to be satisfied that the tests have been designed and conducted in accordance with the required criteria and that the results satisfy the intent of the qualification document.

The test report must contain sufficient evidence for an independent evaluation of the performance of each test module. As a minimum, all of the following information is needed:

1. A description of the theory used to predict test module strength and deformation.
2. Details of test module design and construction, including engineering drawings.
3. Specified materials properties used for design and actual material properties obtained by testing.
4. Description of test setup, including panel details and photographs.

5. Description of instrumentation, location, and purpose.
6. Description and graphical presentation of applied loading protocol.
7. Description of observed performance, including photographic documentation, of test module condition at key loading cycles.
8. Graphical presentation of force versus deformation response.
9. Test data, report data, name of testing agency, report author(s), supervising professional engineer, and test sponsor.

Acceptance Criteria. Based on the requirements in FEMA 356 and ASCE/SEI 41-06 (ASCE/SEI41), each component is classified as a primary or secondary element or component prior to the development of component acceptance criteria and the intended response of each connection is classified as deformation-controlled (ductile) or force-controlled (nonductile). It is assumed that the connection represents a primary component of the structural system and that all actions applied to the connection can be classified as deformation-controlled or force-controlled.

As depicted in Figure A4-1 taken from ASCE/SEI 41, Type 1 and Type 2 responses are representative of ductile behavior. There is an elastic range (point 0 to point 1) followed by a plastic range (point 1 to point 3). Type 3 response is representative of a brittle or nonductile behavior. There is an elastic range (point 0 to point 1) followed by a loss of strength.

If connections display the Type 1 or Type 2 response and have $\Delta_e > 2\Delta_g$, they are classified as deformation-controlled; otherwise, they are classified as force-controlled. If connections display the Type 3 response, they are classified as force-controlled.

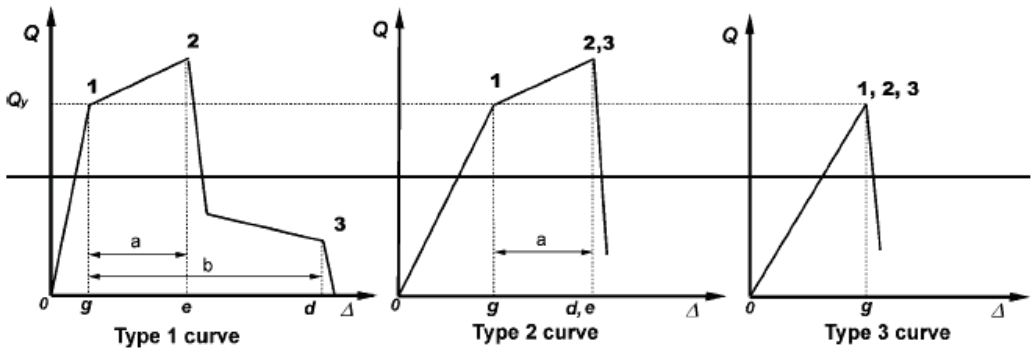

Figure A4-1 Connection classification per ASCE/SEI 41 procedures.

Deformability Category. Based on the experimental data collected to date and finite element analyses of diaphragms with differing sizes and differing configurations subject to differing earthquake records, the typical required tension opening, d_t, and shear displacement, d_v, values for deformability categorization are as shown in Table A4-1. The typical required ductility demands, μ, and joint rotation demands, ϕ, obtained from finite element analysis for diaphragms of differing sizes subject to differing earthquake records are shown in Figure A4-2. That figure illustrates how the information gained through the activities described in Section A3 are combined with the classification system described in this section. The results of Figure A4-2 are based on the data shown in Figure A3-2, cross-referenced to the requirements of the deformability categories.

Table A4-1 Typical Values for Deformability Categorization

Deformability Category	Tension deformation d_t [in.]	Shear deformation d_v [in.]
Low deformability	$0.00 < d \le 0.15$	$0.00 < d \le 0.30$
Medium deformability	$0.15 < d \le 0.50$	$0.30 < d \le 0.70$
High deformability	$D > 0.50$	$D > 0.70$

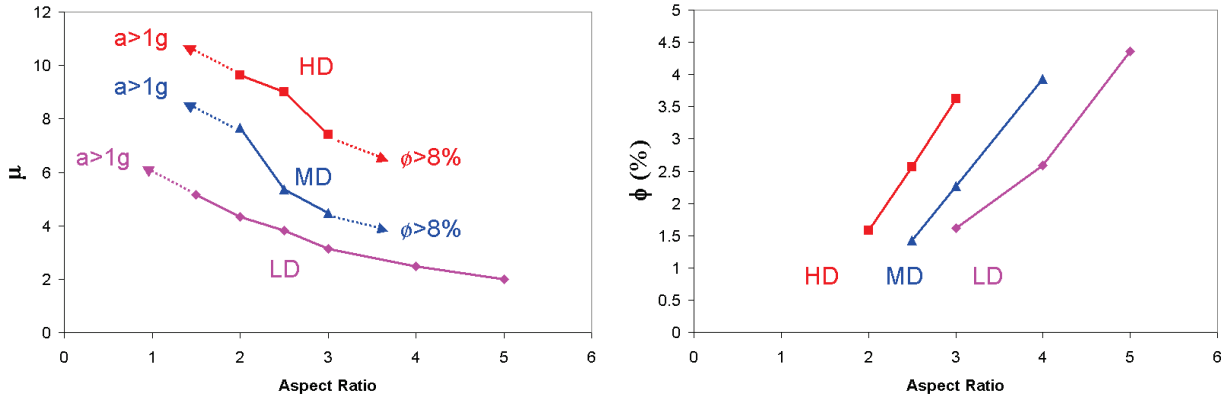

Figure 4-2 Component response classification.

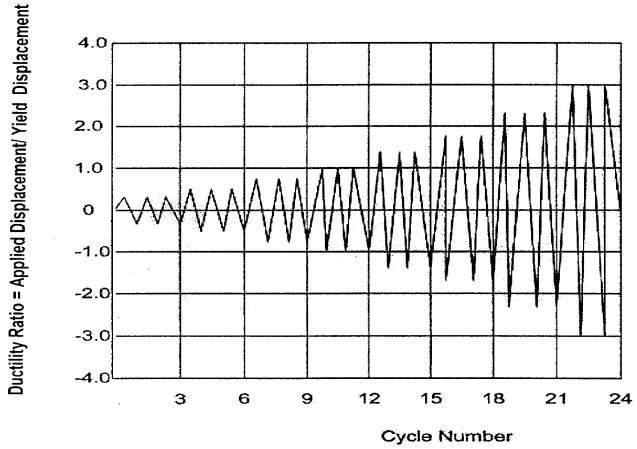

Figure A4-3 Example of specified test sequence.

A5 Diaphragm Strength and Stiffness Calculations. Several methods have been proposed for calculating the stiffness of a precast concrete diaphragm (Zheng and Oliva, 2005; Farrow and Fleischman, 2003; Nakaki,2000). The methodology uses the spreadsheet-compatible method, developed by Wan and Fleischman (2009), that has similarities to the prior approaches.

The spreadsheet method is used to calculate the elastic stiffness of the precast diaphragm in terms of equivalent elastic modulus and shear modulus and the flexural yield strength of the precast diaphragm including any contributions from the shear reinforcement to that strength. The calculation is based on a rational method and is used in the proposed design methodology to either manually determine the diaphragm deflection or conveniently model the floors in design software. It also is used to determine the nominal strength of the diaphragm for comparison to the design moment M_u caused by $\Psi_D F_{px}$. The method is calibrated by comparisons to finite element analyses of diaphragms with differing geometries and reinforcing details. The method assumes that plane sections remain plane at joints between precast units and that theconcrete in the precast unit is linear elastic and uncracked and the slab thickness is constant (i.e., contributions of washes and curbs in parking garage floors are ignored). Reinforcement in the diaphragm compression zone is ignored in determining compression stiffness (i.e., deformation is based on precast concrete unit only). The same number and type of shear connectors are used at all joints in the diaphragm and are evenly distributed along the length of the joint. Shear reinforcement is assumed to respond elastically at diaphragm yield, in accordance with the proposed design methodology (Fleischman et al., 2005a).

The method also assumes initial positions for the neutral axis and center of compression and calculates an effective flexural stiffness of the joint based on those positions and the elastic stiffness of the discrete diaphragm reinforcing elements. This value is combined with the elastic stiffness of the panel to create an overall flexural rigidity and, finally, E_{eff}. Shear stiffness of the joint and the panels are calculated and combined in a similar manner to find an effective diaphragm shear modulus G_{eff}. A similar approach is used to find the diaphragm moment strength except that discrete strengths are used instead of discrete stiffnesses and a different formulation is used to determine the position of the neutral axis at yield than in the elastic state.

The left part of Figure A4-1 compares the stiffness calculated by this method with that determined from FEM analyses (Wan and Fleischman, 2009). The right side of Figure A4-1 shows the same comparison for strength. The method shows reasonable agreement with FEM results. In addition, the methods are being calibrated using experimental results from the hybrid panel tests and will be further validated in the in the half-scale shake table.

A6 Diaphragm Load Path. Several methods exist for determining diaphragm internal load paths that are alternates to the horizontal beam approach. For example, strut and tie methods are used outside the United States (Fédération Internationale du Béton, 2003). The design methodology maintains the horizontal beam approach but recognizes alternate methods may be useful and provides for use of those methods.

The design methodology imposes structural integrity requirements. Required are:

1. Adequate anchorage of diaphragms to the primary LFRS elements, including the carrying of superimposed gravity loads and accommodating imposed rotations from walls (Menegotto, 2000);
2. Maintenance of seating for the precast units (Mejia-McMaster and Park,1994); and
3. Provision of minimum ductility requirements for joint reinforcing details.

An important component of the structural integrity measures is also the treatment of secondary members such as spandrels (see Figure A6-1 where the spandrel is SP). The effect of the spandrel (e.g., as shown in Figure A6-2) has been quantified through analytical studies (Wan and Fleischman, 2008).

A7 Draft Precast Diaphragm Seismic Design Procedure. This section provides a draft design procedure showing the use of the concepts from the design methodology. The generic design terminology used previously in this document is used in this draft procedure. This outline is intended only to show one possible procedure, and this procedure will not necessarily be the final procedure recommended.

It is assumed that the following parameters of the design have been established:

1. Design base shear coefficients based on SDC and hazard maps,
2. Structural floor plan, and
3. Vertical element lateral force system (LFRS) layout.

Step 1. Calculate roof force F_i (as per 2006 IBC)

Step 2. Determine the maximum floor span, aspect ratio

- Determine the length between vertical elements of the LFRS, L_{cl}.
- Calculate effective span, $L_{eff} = \alpha L_{cl}$ where the "effective span" factor α (see Figure A7-1 for examples) takes value of
  - i. $\alpha = 1.0$ perimeter
  - ii. $\alpha = 0.7$ interior
  - iii. $\alpha = 2.0$ overhang
- Determine the diaphragm effective aspect ratio, $AR = L_{eff}/d$
- Determine the diaphragm configuration -- squat, intermediate, or long
  - Use Table A7-1
  - Use the critical AR from all floors, all spans

Step 3. Select diaphragm design option and diaphragm reinforcement

Case 1 -- No predetermined diaphragm reinforcement

A. Select diaphragm design option (EDO, BDO, RDO).
- Base on effective floor span and SDC,
- See Table A7-2.
  - Determine restrictions on design options (shaded areas are restricted in Table A7-2).

B. Determine classifications for primary diaphragm reinforcement
- For each primary diaphragm reinforcement group
  - Chord reinforcement
  - Shear reinforcement
  - Collectors/anchorages
    - Determine allowable categories
      - See Table A7-3
    - Select category (LDE, MDE, HDE)

C. Select primary diaphragm reinforcement
- Select prequalified connectors
  - Match the selected classification for each primary reinforcement group

Case 2 -- Predetermined diaphragm reinforcement

A. Determine classifications for primary diaphragm reinforcement
- For prequalified connectors - look up
- For nonprequalified connectors
  - Qualify connectors following qualification protocol of Section A4

B. Determine allowable design option
- Use Table A7-3
- Check design option with Table A7-2

Step 4. Determine diaphragm force amplification factor, Ψ_d

- Ψ_d factor based on
  - i. Design option
  - ii. L_{eff} and AR
  - iii. LFRS type
  - iv. Number of stories

v. Building configuration
- Take factor from Table A7-4
- Or determine using a series of design coefficients:
  i. Determine design force modification factors
    - $C_n = f(n)$ where n = number of stories
    - C_{LRFS} = 1.0 for frame and 1.5 for wall
    - C_{config} = 1.0

Step 5. Estimate diaphragm properties
- Calculate K_{dia}
  i. E_{eff}
  ii. G_{eff}
- Calculate M_y
  i. Based on chord and shear reinforcement
  ii. Use spreadsheet method of Section A5
  iii. Modify values for secondary elements

Step 6. Estimate diaphragm target deformation
- Estimate based on
  i. SDC
  ii. Leff and/or AR
  iii. LFRS type
  iv. Ψ_d factor
  v. Diaphragm properties

Step 7. Calculate shear overstrength factor, Ω_v
- Estimate based on
  i. L_{eff} and/or AR
  ii. Design intent
  iii. Diaphragm properties
  iv. Target deformation
  v. Shear reinforcement classification
- Use set of tables or charts to determine Ωv

Step 8. Check diaphragm-induced drifts
- Calculate story drift in normal fashion
- Determine drift amplifier
  i. Based on
    - K_{dia}
    - *AR, Leff*
    - *Number of stories*
    - *LFRS type*
- For drift, use worst case of Leff or AR.
- For diaphragm force calculations use average among all spans

Draft Design Tables

C. Define diaphragm stiffness requirement

Diaphragm Stiffness Required for		**Serviceability Deflection**	**Diaphragm Force Levels**	**Lateral System Force Distribution**	**Gravity System Seismic Drifts**
Design procedure can use		Diaphragm clear span between lateral system elements	(Absolute) Diaphragm Stiffness Value	Stiffness relative to the lateral system or diaphragm flexibility index	Diaphragm Deflection Calculation
Diaphragm stiffness based on		Diaphragm span	Boundary conditions	Construction type (topped/untopped)	Reinforcement size, type, spacing
Diaphragm Stiffness Components	**Contributor**	Chord steel, pour strips, bond beams	Welded wire fabric	Flange-to-flange connectors	Shear keys
	Components	Flexure, dowel	Shear-friction, flexure	Shear, flexure (non-tension compliant)	Shear

[a] Regular and special detailing differ in requirements for spacing, cover, transverse reinforcement etc to obtain two levels of ductility for collector and chords.
[b] See Table A7-4B, Web Reinforcement Tensile Characteristics.
[c] $\delta_u > \delta_t$ where δ_t is the target tension displacement and δ_u is the failure displacement demand as defined in the qualification testing protocol (see Table A7-5). These values are being determined by UCSD and UA research on global/local ductility demands.
[d] See stiffness requirements (Table A7-4C).

Table A7-5 Qualification Testing

(Testing Protocol - Connector tension capacity to be determined through cycling component testing)

	Shear Loading	Tension Loading	Shear/Tension Loading	Capacity
Monotonic	1 test [a]	1 test [a]	-	δ_u [d]
Cyclic	1 test [b]	1 test [b]	2 test [c]	δ_u [d]

[a] To determine monotonic envelope

[b] Displacement control loading, cycled twice at ductility ratios of 0.75, 1.0, 1.5, 2.0, 3.0, etc.

[c] Proportional components of equal tension/compression and reversing shear.

[d] δ_u is defined as either the displacement of first fracture of weld or component; displacement of anchor pullout; or displacement corresponding to strength degradation at which response drops below 80 percent of the nominal strength.

Table A7-6 Prequalified Details

Construction Type	Welded wire fabric[a]			Slab bar reinforcement[b]			Flange Connector			Shear Key		
	A	B	C	A	B	C	A	B	C	A	B	C
Topped Composite	-	6x6	10x10	-	reg.	special	-	DT-PQB[c]	DT-PQC[c]	-	HC-PQB[c]	HC-PQC[c]
Topped Noncomposite	-	6x6	10x10	-	reg.	special						
Untopped							-	DT-PQB	DT-PQC	-	HC-PQB	HC-PQC

[a] Mesh matrix geometry, wire size deformed and plain that meets the B and C detail requirements in Table A7-6 as determined by the Lehigh research tests.

[b] Embedded slab reinforcement to follow detailing requirements as described in Table A7-4.

[c] These represent details that can be prequalified by meeting the criteria determined in the research. The data can originate from previous tests, tests in the Lehigh pilot program or other parallel testing programs (Pincheira et al., 2005). For instance, DT-PQB may contain standard hairpin flange-to-flange connections; DT-PQC may contain proprietary connectors such as the JVI connector (Oliva, 2000, Shaikh and Feile, 2002). The HC-PQC could for instance include serrated hollow-core units studied by Menegotto, 2000.

Resource Paper 11

SHEAR WALL LOAD-DEFLECTION PARAMETERS AND PERFORMANCE EXPECTATIONS

Light-frame shear wall buildings of wood and cold formed steel (CFS) exhibit both similarities and differences in design, construction, and anticipated seismic performance. This resource paper is intended to identify anticipated load-deflection parameters and define performance expectations towards which both wood and CFS standard committees can steer future standard updates and future detailing recommendations. It was developed by a joint task group of TS6, Steel Design, and TS7, Wood Design, for consideration by the design community.

Discussed are wood and cold formed steel (CFS) light-frame buildings with seismic-force-resisting systems designed in accordance with the 2006 International Building Code and ASCE/SEI 7-05 (ASCE/SEI 7). The main objective of the ASCE/SEI 7 seismic design provisions is to protect the health, safety, and welfare of the general public by minimizing the earthquake-related risk to life. Structural and nonstructural damage can be expected as a result of the "design ground motions" since ASCE/SEI 7 allows inelastic response in the structural system. For ground motions in excess of the design levels, the intent of these design provisions is for the structure to have a low likelihood of collapse.

RECOMMENDATIONS

1.1 Systems with *R* = 6.5 and 7.0. This section addresses wood and CFS light-frame shear wall systems with wood structural panel sheathing. Bearing wall systems are assigned a seismic response modification coefficient, *R*, of 6.5 and building frame systems, an *R* of 7.0. Details of design and construction are to be in accordance with the *Special Design Provisions for Wind and Seismic* (SDPWS) (AF&PA, 2005) for wood construction, and AISI S213-07, *Standard for Cold-Formed Steel Framing – Lateral Design* (AISI, 2007), for CFS construction.

1.1.1 Analysis Model. ASCE/SEI 7-05 equivalent lateral force or simplified seismic design procedures for determination of seismic demand are intended to be used with an analysis model that includes designated portions of the seismic-force-resisting systems sheathed with wood structural panels.

1.1.2 Vertical Shear Wall Element Parameters. Table 1-1 documents observed load deflection behavior and related parameters in site-built wood structural panel shear walls. Behavior that varies from these parameters is outside the scope of this paper. See Figure 1-1 for an illustration of these parameters.

Table 1-1 Vertical Shear Wall Element Parameters[a]

Vertical Shear Wall Element Parameter	Value
1. Ratio of peak capacity (V_U) to ASD design capacity (V_{ASD})	2.5 to 5.0[b]
2. Minimum ratio of drift at 0.80V_U post peak capacity ($\Delta_{0.8VU}$) to drift at ASD design capacity (Δ_{ASD})	11
3. Minimum drift at 0.80 V_U post peak capacity ($\Delta_{0.8VU}$)	0.028h[c]
4. Drift at peak element strength (V_U)	0.01h to 0.04h
5. Minimum equivalent viscous damping in a single loading cycle reaching peak strength (V_U)	15 percent of critical

[a] h = story clear height.
[b] Where the ratio exceeds 5, vertical and lateral element detailing must consider the effect of additional overstrength.
[c] This value is the minimum drift at 0.80V_U post peak capacity for elements with a drift at peak element strength less than 0.028h. This minimum drift at residual strength should always be greater than the drift at peak strength (see Figure 1-1).

The parameters given in Table 1-1 are derived from wood structural panel sheathed shear walls with wood framing tested using the CUREE protocol (CUREE, 2001a). In particular, Parameters 1 through 3 are taken from a database of 48 wood-frame shear walls assembled by the AC322 Seismic Equivalency Task Group (2007). Data from the following test reports are included: Martin, Skaggs and Keith (2005), Martin (2004), Martin and Skaggs (2003), Martin (2002), Rosowsky, Elkins and Carroll (2004), and Pardoen et al. (2003). Variation in the parameters is known to occur within the broad range of wood structural panel shear walls based on differences in framing type, framing design, detailing, fasteners, and with testing

protocols that vary from the CUREE protocol such as the sequential phased displacement protocol (SPD) (SEAOSC, 1997). See Section C1.1.2 for further discussion.

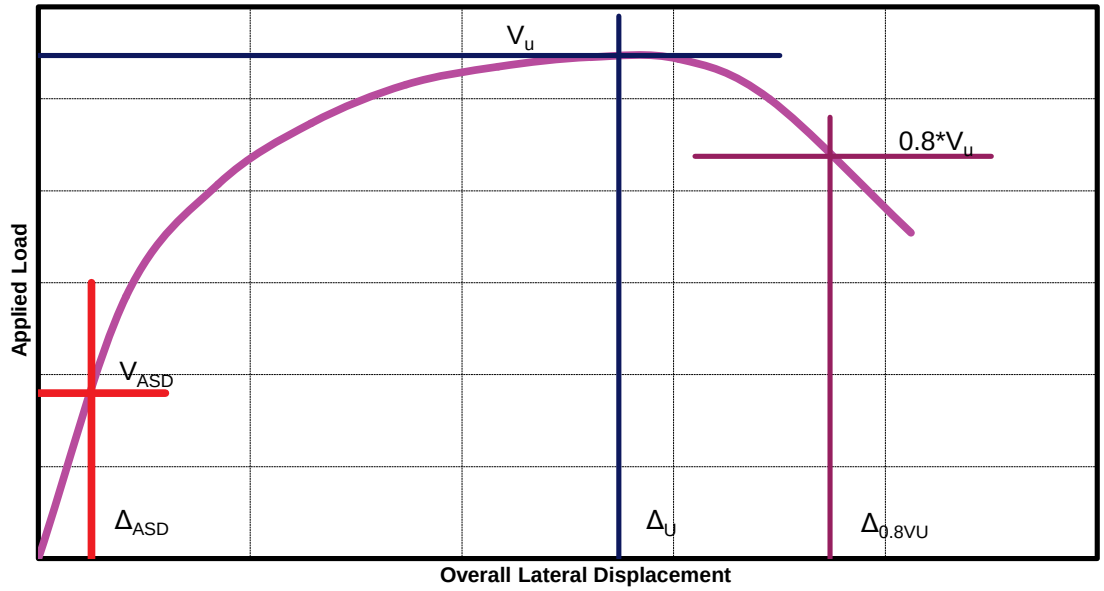

Figure 1-1 Vertical shear wall element parameters.

1.1.3 Vertical Shear Wall Element Performance Expectations. The following recommendations for vertical shear wall elements are intended to allow development of a yield mechanism in the sheathing to framing connection to enable performance as specified in Section 1.1.2:

1. Shear wall shear capacity is intended to act as the weak link in the shear wall assembly.
2. Vertical boundary member tension strength should not act as a weak link in the shear wall assembly. Boundary member design for tension should address reduced net sections and accumulated tension from multiple stories.
3. Vertical boundary member compression strength should not act as a weak link in the shear wall assembly. Boundary member design for compression should include consideration of member buckling, and transfer of compression loads in and out of compression members.
4. Boundary member tension connections between elements (i.e., floor-to-floor) and to the foundation should not act as a weak link in the shear wall assembly.
5. Shear transfer connections between elements and to the foundation should not act as a weak link in the shear wall assembly.
6. Collector members, splices in collectors, and connection of collectors to vertical shear wall elements should not act as a weak link in the shear wall assembly.
7. Boundary member and connection deformation should be accounted for in shear wall design and detailing, including connections floor-to-floor and to the foundation.

1.1.4 Estimated Peak Unit Shear Capacity, v_u. For CFS elements, the shear wall peak unit shear capacity, v_U, is intended to be determined from monotonic or cyclic (CUREE, 2004) testing. If the SPD protocol is used to determine the nominal unit shear strength for wood structural panel shear walls with CFS framing, the unit shear strength should be increased by 20 percent (Boudreault, 2005). In addition, if the stabilized backbone curve is used, the unit shear strength should be increased another 10 percent. If the CUREE protocol is used, no adjustment is required. As an alternative, the shear wall peak unit shear capacity, v_u, may be estimated as the AISI tabulated nominal seismic unit shear strength times 1.3.

For wood elements, the shear wall peak unit shear capacity, v_U, is intended to be determined from monotonic or cyclic (CUREE, 2004) testing but also may be taken from nominal unit shear values set forth in Table 4.3A, Column B, of AF&PA *Special Design Provisions for Wind and Seismic* (SDPWS).

1.2 Systems with $R = 2.0$ and 2.5. In ASCE/SEI 7, wood and CFS light-frame shear walls are assigned seismic response modification coefficients, R, equal to 2.0 or 2.5 if they are sheathed with other than wood structural panels or steel sheets. Sheathing materials may include gypsum wallboard, interior plaster, exterior three-coat Portland cement plaster (stucco),

fiberboard, particleboard, and diagonal lumber sheathing when permitted by the applicable AF&PA or AISI standard. This section applies only if the R = 2.0 or 2.5 system is used in the building direction under consideration in each story from the level under consideration to the roof; mixed seismic-force-resisting systems are beyond the scope of this paper.

1.2.1 Analysis Model. ASCE/SEI 7 equivalent lateral force or simplified seismic design procedures for determination of seismic demand are intended to be used with an analysis that includes designated portions of the seismic-force-resisting system. All vertical elements considered in the analysis model are intended to meet the aspect ratio, design, and detailing requirements of the applicable AF&PA or AISI standard.

1.2.2 Vertical Shear Wall Element Parameters. Table 1-2 documents observed load deflection behavior and related parameters in site-built light-frame shear walls sheathed with other than wood structural panels (and other than sheet steel). Parameters are given in Table 1-2 for both the CUREE protocol and the SPD protocol. Behavior that varies from these parameters is outside the scope of this paper.

Table 1-2 Vertical Shear Wall Element Parameters[a]

Vertical Shear Wall Element Parameter	Value
1. Minimum drift (Δ_U) at peak element strength (V_U)	0.0025 h
2. Minimum ratio of peak capacity (V_U) to ASD design capacity (V_{ASD})	2.0

[a] h = story clear height.

1.2.3 Vertical Shear Wall Element Performance Expectations. Adequate seismic performance of buildings designed using shear walls sheathed with other than wood structural panel shear walls (or steel sheets, also an R = 6.5 system) is almost entirely dependent on shear wall element strength rather than on ductility. Building drift demands are anticipated to be significantly less than those for R = 6.5 or 7 buildings. To accommodate this behavior, it is recommended that the nominal strength of the following be adequate to match or exceed the peak capacity, V_U, of the shear wall sheathing:

1. Boundary member tension connections between elements and to the foundation.
2. Shear transfer between elements and to the foundation.
3. Collector member splices and connections to vertical elements.
4. Members and connections supporting discontinued shear walls or frames (revises ASCE/SEI 7 Section 12.3.3.3)

1.3 Details of Construction

Seismic performance of light-frame shear walls requires attention to details of construction and quality assurance. Provisions for construction and quality assurance are incorporated in the AFPA, AISI, and ASCE/SEI 7 standards and the model building codes.

COMMENTARY

This resource paper was developed by a joint task group of TS6 and TS7 members in recognition of both the similarities and the differences between wood and cold formed steel (CFS) light-framed shear wall systems with wood structural panel sheathing. Because of differences in material behavior and cyclic load response, a simple transcription of design requirements for wood to steel and steel to wood is not practical. The approach taken is to identify performance expectations for light-frame shear wall seismic-force-resisting systems; material specific differences in design method can then be accommodated in future development of approaches to achieving the desired performance. This paper includes performance expectations for those systems currently included in ASCE/SEI 7 – that is, systems with R = 6.5 and 7 as well as systems with R = 2 and 2.5. Questions regarding appropriateness of the assigned R factors are beyond the scope of this paper. Steel sheet shear walls also are beyond the scope of this paper.

C1.1 Systems with R = 6.5 and 7.0

Section 1.1 addresses wood structural panel sheathed shear wall systems. It is intended that, except as specifically addressed in this paper, these systems be designed in accordance with ASCE/SEI 7, AF&PA *Special Design Provisions for Wind and Seismic* for wood construction, and AISI S213-07, *North American Standard for Cold-Formed Steel Framing – Lateral Design*, for CFS construction. Because the R factors assigned to these systems are relatively high, significant inelastic behavior is anticipated in design level seismic events, including potential for loading in the range of post-peak-capacity deflections.

The typical wood light-frame building responds to a seismic event by racking the wall elements while the floor and roof diaphragms remain close to elastic. Consequently, the walls largely determine the seismic response characteristics of light-frame construction. In R = 6.5 and 7.0 wood structural panel shear wall systems, sheathing is most commonly installed in 4 foot by 8 to 10 foot sheets and fastened to wall framing with nails (for wood frame) and screws (for CFS). The primary source of seismic drift and energy dissipation of wood shear walls is the bending and yielding of the shear wall sheathing to framing fasteners around the perimeter of each sheathing panel accompanied by slip between the sheathing and framing. In CFS frame shear walls, drift and energy dissipation are generally related to the tilting (rotation) of the sheathing fasteners as well as the bearing deformations in the wood structural panel or steel adjacent to the connections; again, the deformations at the sheathing fasteners are accompanied by slip between the sheathing and framing.

This paper addresses only the combinations of sheathing and fastening currently included in the AF&PA and AISI standards. This is because the cycled load behaviors of these combinations are known to provide for required inelastic behavior. Other combinations of sheathing and fastening and other methods of attachment should be tested in reverse-cyclic loading.

C1.1.1 Analysis Model. Virtually all wood or CFS shear wall buildings are designed for seismic loads using the ASCE/SEI 7 equivalent lateral force method or simplified method. Analysis for these systems includes vertical wall elements that are designated to be part of the seismic-force-resisting system. For R = 6.5 and 7 systems, all designated shear walls will be sheathed with wood structural panel sheathing. Recent studies have confirmed that, for these buildings, the strength and stiffness contribution of finish materials and partition walls plays a significant role in the seismic performance of these buildings. Despite this understanding, analysis models used to evaluate and distribute seismic demand are intended to include only designated wood structural panel shear walls. This does not preclude consideration of the effect of walls sheathed with other than wood structural panels when evaluating a building for presence of structural irregularities.

C1.1.2 Vertical Shear Wall Element Parameters The parameters addressed in this section are intended to allow discussion of hysteretic behavior for site-built wood structural panel shear walls from which performance expectations and detailing recommendations can follow. The parameters in Table 1-1 were accepted by the authors of this paper for wood structural panel shear walls with wood framing; they were accepted as interim values for wood structural panel shear walls with CFS framing. A database of testing with CFS members was not accepted by the AC322 Seismic Equivalency Task Group in time for consideration in this paper.

The parameters are not intended to be used to assign R factors to vertical shear wall systems nor are they intended to address prefabricated shear wall elements. Vertical elements whose parameters do not conform to those described in Table 1-1 are outside the scope of this paper.

Parameters 1 through 3 in Table 1-1 mirror parameters recommended by the AC322 task group (AC322, 2007). The values are derived from a group of 48 wood light-frame shear walls sheathed with wood structural panel sheathing nailed to wood framing and tested using the CUREE protocol. The tabulated numbers for parameters two and three are the average values minus one standard deviation. Further commentary on the Table 1-1 parameters follows:

1. Parameter 1 -- Provision of overstrength beyond ASD design capacity is understood to be fundamental to earthquake performance of buildings braced with wood structural panel shear walls.
2. Parameter 2 -- Deformation capacity at peak strength well beyond deformation capacity at design level is understood to be fundamental to earthquake performance of buildings braced with wood structural panel shear walls. In this parameter, 80 percent post-peak capacity is specified.
3. Parameter 3 -- Testing and analysis suggests that wood structural panel sheathed shear walls are capable of supporting post-peak loading. At a post-peak capacity of 80 percent of peak, the shear wall element drift of not less than 0.028h is expected.
4. Parameter 4 -- The range of vertical element drift recognizes both the allowable story drift permitted by ASCE/SEI 7 and some variation of vertical shear wall elements above and below this drift.
5. Parameter 5 -- The criterion looks at one cycle in which the shear wall element reaches peak strength. If the CUREE protocol is used, this would be anticipated to be in the range of the 6^{th} to 8^{th} loading cycle. The areas within the curve for both positive and negative excursions are intended to be summed and an equivalent viscous damping ratio calculated. See Filiatrault et al. (2003) for details of equivalent viscous damping calculation.

See Line, Waltz, and Skaggs (2008) for further discussion of the AC322 parameters. The parameters currently included do not consider degrading reloading stiffness. This parameter might be considered for inclusion at a future time.

C1.1.3 Vertical Shear Wall Element Performance Expectations. Performance expectations described in this section support the sheathing-to-framing fastening as the primary source of inelastic behavior and energy dissipation in the vertical shear wall elements. Failure of the boundary members or connections addressed in Section 1.1.3, Items b, c, d, e, and f could

cause a more critical and possibly sudden and brittle failure of the vertical shear wall element. In general, further study is needed to determine whether or not the desired behavior requires detailing provisions beyond those currently required by ASCE/SEI 7, SDPWS, and AISI S213.

Item 2, vertical boundary member tension design -- Tension boundary members should be sized such that they are not the weak link in the shear wall assembly. For wood boundary members, it is recognized that most members will be stronger than the calculated nominal capacity due to the 5 percent basis of reference wood member strength properties in underlying design and product standards. It is also recognized that tension post capacity in use will be sensitive to placement of knots and other characteristics because the strength controlling characteristic of the wood member is not always located in the area of maximum tension force.

This section also includes a reminder that net tension at reduced net sections and accumulated tension from multiple stories need to be considered. In addition, tension member design should include consideration of flexure due to the eccentricity of the tie-down load.

Item 3, vertical boundary member compression design -- Compression boundary members should be sized such that they are not the weak link in the shear wall assembly. See also comments on tension design above.

Item 4, boundary member tension connections between elements and to the foundation -- Tension connections for boundary members are required as part of a complete load path through the building. This includes both tension connections from boundary members above to boundary members below and anchorage to the foundation. Tension connections use tie-down brackets, steel straps, or continuous rod or cable systems. Again, the tension connection should not be the weak link in the shear wall element.

Item 5, shear transfer connections -- The lateral forces at the foundation are resisted by a distributed connection along the shear walls oriented parallel to and in the plane of the load. These connections are most commonly anchor bolts at foundation sill plates and nailing or sheet metal angles at framed floors. This connection is typically designed to be independent of the connections used to resist the overturning forces (i.e., resists only horizontal shear and not tension due to overturning). This connection should be designed such that it is not the weak link in the shear wall system.

Item 6, collectors -- There has been a lack of observed failures in light-frame collector elements. To ensure that the failure is not in the collector, however, the connection of the collector to the shear wall or the splice of the collector should be designed such that they are not the weak link in the shear wall system.

Item 7, boundary member and connection deformation -- Excessive deformation of boundary members and their connections can lead to the premature failure of sheathing to framing fastening due to large imposed deformations. See the discussion in Commentary Sections 12.2.3.11 and 12.2.3.12 of the 2003 *NEHRP Recommended Provisions* (BSSC, 2003). Deformation in top plates, collectors, and shear transfer connections is not currently specifically discussed. Consideration might be given the these sources of deformation in the future.

C1.1.4 Estimated Peak Unit Shear Capacity, v_U. It is intended that estimated values of the peak unit shear capacity, v_U, be used in evaluating the performance expectations of Section 1.1.3. Because the referenced testing of wood-frame shear walls uses the CUREE protocol, it is not anticipated that conversion of peak unit shear capacity from other protocols will be needed. Under no circumstances is it intended that tests conducted using the SPD protocol be converted to compare to the five parameters of Table 1-1 since accurate adjustments of all five parameters are not available.

C1.2 Systems with R = 2.0 and 2.5

In ASCE/SEI 7, wood and CFS light-frame walls are assigned seismic response modification coefficients, R, equal to 2.0 or 2.5 if they are sheathed with other than wood structural panels or steel sheets. Specifically, R, C_d, and Ω_0, are 2.0, 2.5, and 2.0 for bearing wall systems and 2.5, 2.5, and 2.5 for building frame systems. This commonly includes sheathing with gypsum wallboard, interior plaster, exterior three-coat Portland cement plaster (stucco), particle board, fiberboard and diagonal lumber sheathing. This may also include wood structural panel sheathing used alone or in combination with other sheathing materials.

Adequate seismic performance of buildings designed using shear walls sheathed with other than wood structural panels (or sheet steel) is almost entirely dependent on shear wall element strength rather than ductility. As ductility is replaced with strength, reliability of the bracing system becomes highly dependent on adequate capacity, adequate detailing, and adequate understanding of seismic demand. For the materials currently included in the AISI and AF&PA standards, there is a level of comfort with design for R = 2 or 2.5 systems. This comes both from a history of design of these systems using R = 4.5 under the Uniform Building Code (ICBO, various) and recent analytical studies suggesting generally adequate performance with R = 2 design (ATC, 2007).

C1.2.1 Analysis Model. Since a low R value is being utilized, the level of inelastic response is assumed to be lower than if an $R \geq 6.0$ were to be used. Therefore, the combination of the relatively brittle finish materials with the more ductile wood structural panel walls is allowed, provided the R of 2 or 2.5 is used for all vertical elements. This level of design is often used when the building design has a relatively large number of interior walls that will be used as resistance since interior walls are usually sheathed with brittle materials such as gypsum wallboard.

C1.2.2 Vertical Shear Wall Element Parameters. The vertical shear wall elements included in this group have widely varying load-deformation characteristics. In general, however, it is anticipated that they have much less ductility and deformation capacity and more rapid post-peak drop in capacity than wood structural panel sheathing.

For Table 1-2, Parameter 1, the minimum drift criterion of 0.0025h recognizes that a building braced with these shear wall types will have measurable drift during design level earthquake loading.

For Table 1-2, Parameter 2, it is anticipated that shear walls using sheathing materials currently assigned R = 2 or 2.5 have ratios of ASD to peak capacity of 2 or higher.

CUREE (CUREE, 2001a) and SPD (SEAOSC, 1997) protocols are combined in Table 1-2 because available test data are not sufficient to identify separate parameters for each.

C1.2.3 Vertical Shear Wall Element Performance Expectations. For this group of shear wall sheathing materials, the failure would ideally be the sheathing fastening to framing (or the sheathing material) rather than the boundary members or their connections. This preferred failure would allow development of the sheathing fastening capacity and avoid what might be a more critical failure mode such as sliding or overturning of the wall framing. As a step towards achieving this, the intent of Section 1.4.3 is to have the sheathing peak shear capacity and the capacity of the boundary members and their connections balanced or close to balanced.

For sheathing materials having an ASD to peak strength ratio of approximately 2 from ASD capacity to peak capacity, standard ASD or LRFD detailing practice is thought to provide boundary member connection factors of safety adequate to support failure in the sheathing. Factors of safety of 2.1 to 5 might be anticipated for individual fasteners. Factors of safety of 2.5 to 3 are commonly anticipated for prefabricated connectors. It is anticipated, however, that some connections such as steel straps that are controlled by steel net section might have lower factors of safety.

For sheathing materials having an ASD to peak strength ratio greater than 2, it is recognized that failure could occur in connections of boundary members. At this time, recommendations to design connections to support the higher ratios are viewed as too stringent.

Boundary members (shear wall chords and collector members) are specifically excluded from the detailing list because these members are not viewed as possible weak links given the current range of tabulated unit shears for the sheathing materials. If sheathing members with higher unit shears are to be used, boundary member design should be reconsidered.

Resource Paper 12

EVALUATION OF GEOLOGIC HAZARDS AND DETERMINATION OF SEISMIC LATERAL EARTH PRESSURES

Summarized in this resource paper are the procedures commonly used for evaluating potential site geologic hazards and seismic lateral earth pressures due to earthquakes. The geologic hazards include slope instability, liquefaction, ground displacement, and surface fault rupture. Geologic hazards evaluations should be carried out by qualified geotechnical professionals and documented in a report. Reporting requirements are given in Part 1 of the 2009 NEHRP Recommended Seismic Provisions Exception to ASCE/SEI 7-05 (ASCE/SEI 7) Section 11.8. Seismic lateral earth pressure discussions consider both yielding and nonyielding walls.

GEOLOGIC HAZARDS

Screening Evaluation. Evaluation of an earthquake-induced geologic hazard may initially consist of a screening evaluation. Although a screening evaluation typically does not require use of detailed analytical procedures, it should be based on detailed site information including topography, geology, groundwater conditions, subsurface soil and rock stratigraphy and engineering properties, and level of ground shaking. The potential for changes in site conditions over time or as part of site development should be considered. If the findings of a screening evaluation clearly demonstrate the absence of a geologic hazard, then more detailed evaluations, using procedures such as those described in the following sections, need not be conducted. If a screening evaluation does not demonstrate the absence of a hazard, the more comprehensive quantitative evaluations described below should be conducted to assess the potential for slope instability, liquefaction, ground displacement, and surface fault rupture.

The following reference publications provide guidelines on screening evaluations:

1. Slope instability -- Blake et al. (2002), Stewart et al. (2003), U.S. Army Corps of Engineers (2005), and California Geological Survey (2008).
2. Liquefaction -- Martin and Lew (1999) and California Geological Survey (2008). As noted later in this section under "Recent Updates to the SPT Procedure," the "Chinese Criteria" for identifying clayey soils susceptible to liquefaction should be abandoned in favor of more recent research.
3. Total and differential settlement -- Martin and Lew (1999) and California Geological Survey (2008). Total and differential settlement can be important design considerations at sites underlain by poorly compacted fills or loose young alluvium.
4. Surface fault rupture -- California Geological Survey (2002) and U.S. Army Corps of Engineers (2005).

Slope Instability Hazard. When subjected to earthquake-induced ground shaking, sloping ground can pose a hazard to structures located on or in proximity to a slope. The potential severity of the hazard depends on the steepness of the slope, soil and groundwater conditions within the slope, the strength and duration of ground shaking, and the potential consequences of slope movement. In some situations, acceptable slope movement can be on the order of feet whereas in other situations – particularly where buildings are involved – movements of more than a few inches may be unacceptable. A critical first step in the assessment of the slope instability hazard is, therefore, to establish the performance criteria for the slope. Normally this requires detailed discussions between the geotechnical engineer and the structural designer and with the project owner.

Pseudostatic Method of Analysis. The stability of slopes composed of dense (nonliquefiable) or nonsaturated sandy soils or nonsensitive clayey soils can be determined using either pseudostatic- or deformation-based procedures. For initial evaluations, the pseudostatic analysis may be used although the deformational analysis described in the next section is now preferred.

In the pseudostatic analysis, inertial forces generated by earthquake shaking are represented by an equivalent static horizontal force acting on the slope. The seismic coefficient for this analysis is generally taken as proportional to the site peak ground acceleration, a_{max} (see details in Stewart et al., 2003). The vertical component of ground acceleration is normally assumed to be zero during this representation. The factor of safety for a given seismic coefficient can be estimated by using traditional slope stability calculation methods. A factor of safety of less than 1.0 indicates that the slope will yield and slope deformation can be expected, and a deformational analysis should be made using the techniques discussed below.

A common practice when using the pseudostatic method is to define the seismic coefficient used in the stability analysis as a fraction of the peak ground acceleration. The reduction is introduced to account for the transitory nature of the ground motions. Implicit within this approach is that deformation of the slope is acceptable. To limit permanent displacements to less than 2 inches (5 cm), the recommended approach is to use the peak ground acceleration multiplied by f_{eq}, as discussed in Blake et al. (2002) and Stewart et al. (2003), in the pseudostatic analysis and then, if the resulting factor of safety is less than 1.0, to conduct a deformational analysis.

When conducting a pseudostatic stability analysis, two key assessments must be made by the designer during the set-up of the stability model:

1. An accurate characterization of the site must be developed. This characterization needs to consider the final slope geometry, the soil types and layering within the slope, and groundwater conditions likely to exist during the seismic event. The existence of thin soil layers that could serve as slip planes is particularly important in the characterization process.
2. The appropriate soil strength to use for the seismic analyses must be selected. This determination will depend on various factors including whether the soil is fine- or coarse-grained, the effective stress conditions, the degree of saturation of the material, and the stress history for the soil. For saturated materials, in most situations the undrained strength of the soil is appropriate because of the short duration of seismic loading. Blake et al. (2002) provides important guidance on the use of drained or undrained soil properties, the appropriate type of testing, the use of peak versus residual strengths, and whether reductions in strength are appropriate to account for the effects of loading rate and repeated cycles of load.

For sites where soils could liquefy or where sensitive soils are known to occur, special studies will be required. If liquefaction is predicted under the seismic event, the strength of the soil in a liquefied state should be used in the pseudostatic stability analyses. Additional discussions of the strength of liquefied soils are presented below in the liquefaction hazard section of this resource paper. If sensitive clayey soils exist, special laboratory tests may be required to establish the amount of degradation in soil strength that will occur with cyclic loading.

Deformational Methods of Analysis. Deformational analyses resulting in estimates of slope displacement are now accepted practice. The most common analysis, termed a Newmark analysis (Newmark, 1965), uses the concept of a frictional block sliding on a sloping plane or arc. In this analysis, seismic inertial forces are calculated using a history of horizontal acceleration as the input motion. Slope movement occurs when the driving forces (gravitational plus inertial) exceed the resisting forces. This approach estimates the cumulative displacement of the sliding mass by double-integrating increments of relative acceleration that occur during periods of time when the driving forces exceed the resisting forces. Expressed differently, displacement or yield occurs when the earthquake ground accelerations exceed the acceleration required to initiate slope movement or yield acceleration.

The yield acceleration depends primarily on the strength of the soil and the gradient and height and other geometric attributes of the slope. The same comments on the characterization of the slope and soil strength given above for the pseudostatic analysis apply for the deformational analysis; however, consideration can be given to the modification of strength with cycles of earthquake loading. See Figure 1 for forces and equations used in analysis and Figure 2 for a schematic illustration for a calculation of the displacement of a soil block toward a bluff.

Two methods are commonly used to estimate slope displacements by the Newmark method. The more rigorous approach involves use of earthquake records that will be representative of expected ground shaking at the site during a seismic event. These records need to be scaled to be consistent with the response spectra adjusted for site response effects. If more than one characteristic source mechanism contributes to the earthquake hazard, it may be necessary to select sets of records that are characteristic of each source mechanism. In this case, multiple potential sources are considered because of the dependency of slope displacement on earthquake magnitude or duration -- i.e., a large distant earthquake may result in lower peak ground acceleration but longer duration of shaking, which potentially could result in more cumulative deformation than a nearby earthquake of higher peak ground acceleration but short duration. Computer programs (e.g., Jibson and Jibson, 2003) are typically used to determine the cumulative displacement from the earthquake records.

An acceptable alternative method for the determination of displacements on many projects involves the use of charts or simplified equations that show or estimate displacements for different acceleration ratios, where the acceleration ratio is defined as the ratio of yield acceleration to the maximum horizontal equivalent acceleration (MHEA) in the slide mass. These charts and equations have been developed by calculating the cumulative displacement following the Newmark method for large sets of earthquake records. The charts include those by Franklin and Chang (1977), Makdisi and Seed (1978), Wong and Whitman (1982), Hynes and Franklin (1984), Martin and Qiu (1994), Bray and Rathje (1998), Bray et al. (1998), and Jibson (2007). Simple equations include those by Bray and Travasarou (2007), Jibson (2007), Saygili and Rathje (2008), and Rathje and Saygili. (2008). Figure 3 shows the simplified chart from Bray et al. (1998) that was recommended for use by Blake et al. (2002). The $D_{5\text{-}95}$ term in this figure is the significant duration of shaking – with its relationship differing

depending on whether or not the site is within 10 km of the earthquake source. Choosing which charts to use should be made on the basis of the type of slope and the degree of conservatism necessary for the project. It is important to recognize that when using one of the charts, or the Newmark method in general, a number of simplifying assumptions are made regarding the relationship between the MHEA and the peak acceleration at the site as well as other factors. These assumptions may limit the degree of accuracy to which the deformations can be estimated.

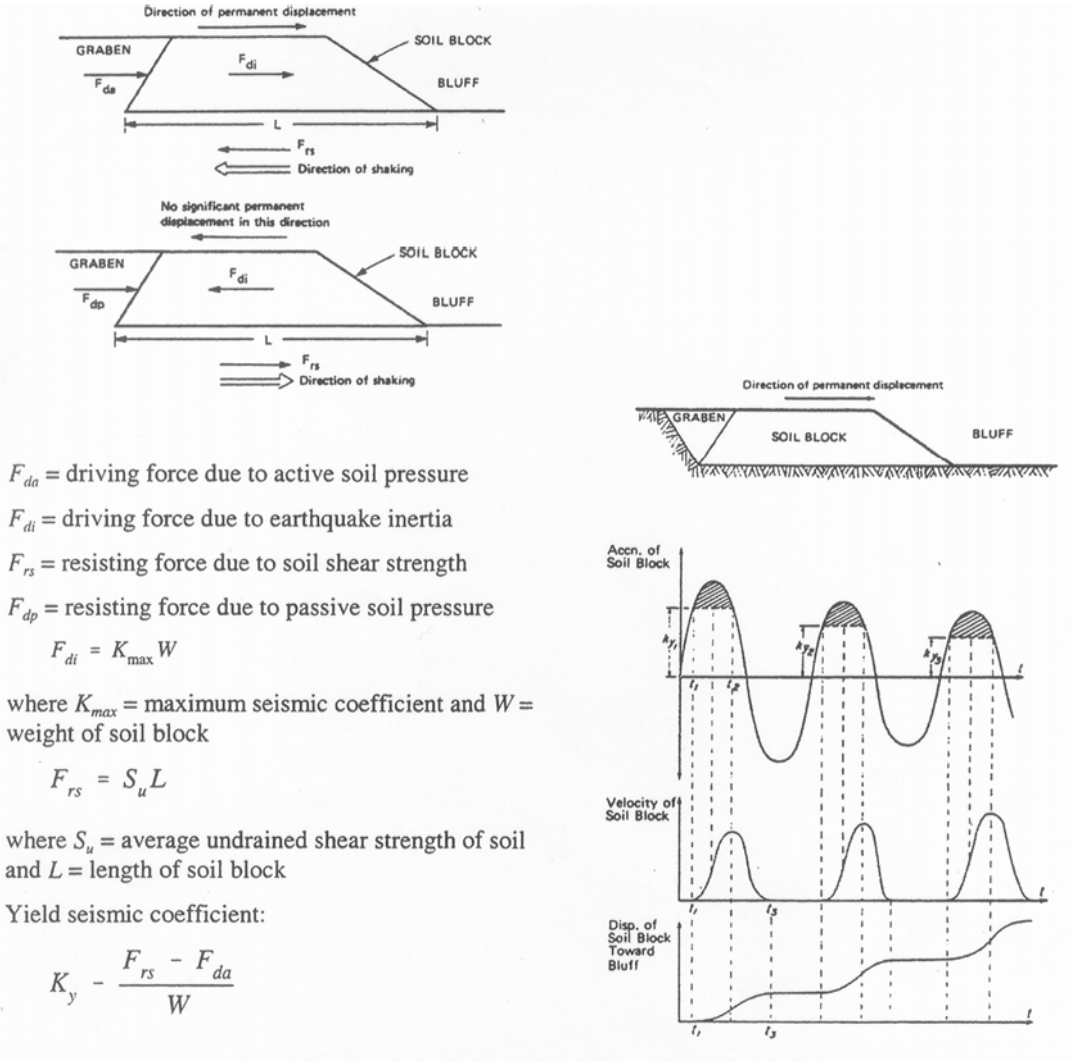

Figure 1 Forces and equations used in analysis of translatory landslides for calculating permanent lateral displacements from earthquake ground motions (National Research Council, 1985; from Idriss, 1985).

Figure 2 Schematic illustration for calculating displacements of soil block toward the bluff (National Research Council, 1985; from Idriss, 1985, adapted from Goodman and Seed, 1966).

Slope deformations also can be estimated using more rigorous two-dimensional computer modeling methods. FLAC (Itasca, 1997) and PLAXIS (Plaxis, 2008) are programs commonly used by practitioners for evaluating the response of slopes to seismic loads. These computer programs allow various soil geometries, soil layering, and groundwater conditions to be modeled. Earthquake records representative of the seismic event are used to conduct the time-history analysis. Results provide an understanding of the development of deformations with time, the location of critical surfaces of deformation, and the effects of pore water pressure buildup on slope movement. As with any rigorous model, the accuracy of the deformation estimate is critically dependent on the properties and geometry of the model and earthquake record selection.

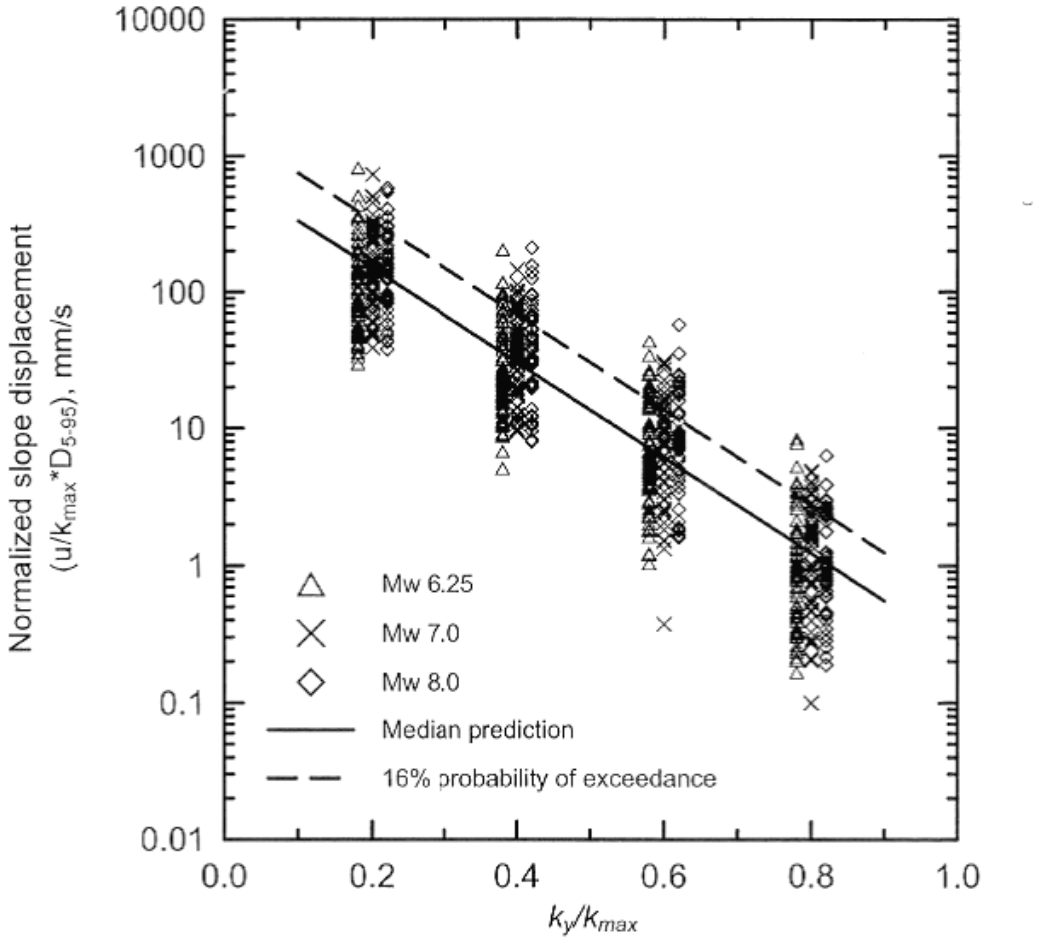

Figure 3 Normalized sliding displacement (Bray et al., 1998) as recommended by Blake et al. (2002).

Mitigation of Slope Instability Hazard. Three general mitigative measures might be considered for locations where slope instability is determined to represent a hazard: (a) design the structure to resist the hazard, (b) stabilize the site to reduce the hazard, or (c) choose an alternative site. Ground displacements generated by slope instability are similar in destructive character to fault displacements generating similar senses of movement: compression, shear, extension or vertical. Thus, the general comments on structural design to prevent damage described in the fault displacement section of this paper apply equally to slope displacement.

Techniques to stabilize a site include increasing the resistance of the soil to displacement by subsurface drainage, buttresses, retaining walls, ground anchors, reaction piles or shafts; ground improvement using densification or soil mixing methods; and chemical treatment. Additional details for these mitigation methods can be found in various reports including Blake et al. (2002).

Liquefaction Hazard. Liquefaction is the second and, perhaps, the most widely known geologic hazard that must be considered at a building site. This hazard occurs when earthquake-induced ground shaking results in loss of strength within water-saturated, loose granular soils. The consequence of this strength loss relative to a building can be reduction in bearing capacity, total and differential settlement, and horizontal ground displacement from lateral spreading or flow failures within the ground. In this section, the hazard of differential settlement, whether due to liquefaction of water-saturated soils or compaction of non-saturated soils, is addressed.

Design to prevent damage due to liquefaction consists of: (a) evaluation of the liquefaction hazard, (b) evaluation of potential ground displacement, and (c) when necessary, mitigation of the hazard by designing to resist either ground displacement or strength loss, by reducing the potential for liquefaction, or by choosing an alternative site with less hazard. Before providing guidance in these areas, the following subsections summarize the methods used to evaluate the liquefaction hazard and recent updates to the most commonly used method of assessing a liquefaction hazard – the empirical standard penetration test procedure.

Methods of Liquefaction Hazard Evaluation. The liquefaction hazard at a site is commonly expressed in terms of a factor of safety. This factor is defined as the ratio between the available liquefaction resistance, expressed in terms of the cyclic stresses required to cause liquefaction, and the cyclic stresses generated by the earthquake. Both of these stress parameters are commonly normalized with respect to the effective overburden stress at the depth in question to define a cyclic resistance ratio (CRR) and a cyclic stress ratio induced by the earthquake (CSR).

Three different methods have been proposed and are used to various extents for evaluating liquefaction potential:

1. Empirical methods are the most widely used methods in practice. These procedures rely on correlations between observed cases of liquefaction/non-liquefaction and measurements made in the field with conventional exploration methods. Seed and Idriss (1971) first published the widely used "simplified procedure" utilizing the standard penetration test (SPT). Since then, field test methods in addition to the SPT have been utilized in similar simplified procedures. These methods include cone penetrometer tests (CPTs), Becker hammer tests (BHTs), and shear wave velocity tests (SVTs). These empirical procedures are summarized in the proceedings from a workshop (referred to as the Liquefaction Workshop) held in 1996 (NCEER, 1997; Youd et al., 2001). Martin and Lew (1999) provides additional details on the use of these procedures relative to engineering practice; Idriss and Boulanger (2008) summarize recent developments in use of empirical methods for assessing liquefaction potential in a recently published EERI Monograph *Soil Liquefaction during Earthquakes*. The Idriss and Boulanger (2008) EERI Monograph updates an earlier EERI Monograph by Seed and Idriss (1982).
2. Analytical methods are used less frequently to evaluate liquefaction potential; however, they may be required for special projects or where soil conditions are not amenable to the empirical method. Analytical methods also are likely to continue to gain prominence with time as numerical methods and soil models improve and are increasingly validated. The analytical method originally (circa 1970s) involved determination of the induced shearing stresses with a program such as SHAKE and comparison of these stresses to results of cyclic triaxial or cyclic simple shear tests. Today, the analytical method usually refers to a computer program that incorporates a soil model that calculates the buildup in pore water pressure. These more rigorous numerical methods include one-dimensional nonlinear effective stress codes such as DESRA, DMOD, SUMDES, and TESS and two-dimensional nonlinear effective stress codes such as FLAC, TARA, and DYNAFLOW. This new generation of analytical methods features soil models that are fitted to or derived from laboratory data or from liquefaction curves developed from SPTs or other field information. These methods are limited by the ability to represent the soil model from either the laboratory or field measurements and by the complexity of the wave propagation mechanisms, including the ability to select appropriate earthquake records to use in the analyses.
3. Physical modeling originally involved the use of centrifuges or relatively small-scale shaking tables to simulate seismic loading under well-defined boundary conditions. Physical model testing also now includes large laminar boxes mounted on very large shake tables (e.g., Kagawa et al., 2004) and full-scale field blast loading tests (e.g., Ashford et al., 2004 and Ashford et al., 2006). This type of modeling is one of the main focus areas of the 2004-2014 Network for Earthquake Engineering Simulation (NEES) supported by the National Science Foundation. Soil used in the small-scale and laminar box models is reconstituted to represent different density and geometrical conditions. Because of difficulties in precisely modeling in situ conditions at liquefiable sites, small-scale and laminar box models have seldom been used in design studies for specific sites. However, physical models are valuable for analyzing and understanding generalized soil behavior and for evaluating the validity of constitutive models under well-defined boundary conditions. Blast loading tests have been conducted to capture the in situ characteristics of the soil for research and design purposes (e.g., at Treasure Island, California; for the Cooper River Bridge in South Carolina, and in Japan). However, the cost and safety issues of blasting methods limit their use to only special design or research projects.

Most liquefaction hazards assessments for buildings involve use of the SPT empirical method -- partly because of the wide acceptance of this method and also because it can be easily integrated into the geotechnical investigations normally performed during building design. The SPT method is based on recommendations developed at the Liquefaction Workshop as described in NCEER (1997) and Youd et al. (2001) or on one of the updates to this methodology as discussed below.

Although the SPT empirical method is the most commonly used of the empirical approaches, it is important to recognize that for certain site conditions alternate empirical methods, such as the CPT, BHT, and SVT methods, are acceptable and even preferred. This is particularly the case with the CPT method. Advantages of the CPT method compared to the SPT method are the ability of this method to detect thin liquefiable layers that could serve as sliding surfaces and the greater standardization of the method; however, the CPT approach has the disadvantage that soil samples are not obtained. When possible, a combination of procedures is recommended to take advantage of the best features of each.

Recent Updates to the SPT and CPT Procedures. The methods presented in the Liquefaction Workshop and summarized in the following section represent a consensus-based approach for determining the onset or triggering of liquefaction; however,

the consensus workshop occurred over 10 years ago. A number of significant modifications to the methods presented in the Liquefaction Workshop have been recommended over the past 10 years. These modifications include:

1. Changes to the stress reduction coefficient (r_d),
2. Modifications to the magnitude scaling factor (MSF) which also is referred to as the duration weighting factor (DWF),
3. Revisions to the overburden correction term for CRR (K_σ) and the fines correction term (FC),
4. Refinements to the overburden correction for penetration resistance (C_N), and
5. Changes to the relationship between cyclic stress ratio causing liquefaction and the normalized penetration resistance (i.e., the fundamental liquefaction strength curve such as shown in Figure 4).

These modifications are discussed in detail in papers by Cetin et al. (2004), Idriss and Boulanger (2004, 2006, 2008), and Moss et al. (2006); each set of recommended revisions resulted after detailed study and supplementation of the databases of case histories upon which the original relationships were developed.

Another important observation during the past 10 years involves the fines criteria used to judge whether or not a soil is liquefiable. Originally, the "Chinese Criteria" was accepted as the method to determine whether or not a cohesionless soil was liquefiable. However, recent work summarized in Boulanger and Idriss (2006), Bray and Sancio (2006), and Idriss and Boulanger (2008) indicates that the Chinese Criteria will be unconservative in some situations, and alternate methods of assessing whether a soil with cohesive fines will be susceptible to liquefaction or cyclic strength reduction need to be considered. The methods recommended by Boulanger and Idriss (2006) and Bray and Sancio (2006) also establish whether the simplified empirical field methods described previously should be used to estimate liquefaction potential or whether other methods, such as laboratory testing, would be more suitable for evaluating the effects of cyclic loading on soil strength.

Methods are also now available for treating the probability of liquefaction, given a certain ground motion and SPT blowcount. Cetin et al. (2004) and Moss et al. (2006) present a comprehensive treatment of liquefaction probability. These researchers suggest that following the deterministic approach for estimating liquefaction potential discussed above results in approximately 15 percent probability of liquefaction. The approach presented by Cetin et al. (2004) allows limiting SPT blowcounts to be determined for alternate probabilities and the probability associated with a given set of blowcounts and ground motions (in terms of CSR) to be defined. Kramer and Mayfield (2007) show how the probability of ground shaking can be combined with the probability of liquefaction in a performance-based approach to evaluating liquefaction potential. This probabilistic framework forms an important basis for the performance-based design methods currently being developed.

Despite these many important modifications to the general approach for assessing liquefaction hazards over the past 10 years, the profession has not developed a consensus on which of the modifications should be used as a baseline for evaluating liquefaction hazard – similar to the recommendations in NCEER (1997) and Youd et al. (2001) based on the Liquefaction Workshop. Procedures suggested by Idriss and Boulanger (2004, 2006, 2008) and those developed by Cetin et al. (2004) and Moss et al. (2006) present important changes to the liquefaction hazard analysis. However, until a consensus is reached or an adequate period of vetting occurs, it is difficult to recommend which of these procedures should be used.

It is important that the newer methods be used consistently. In other words, the Idriss and Boulanger method should be used with the various improvements recommended by Idriss and Boulanger including the revised liquefaction strength plot. Likewise, if the Cetin et al. method is going to be used, it should be used in its entirety. It also is important to use these new methods with some caution, particularly at the limits of the procedure (e.g., at higher blowcounts, deeper depths, and higher CSR values). If the more recent methods are used, the prudent approach will be to check the liquefaction hazard with an alternate method, such as the SPT procedure discussed below. Differences between the hazard estimates resulting from different methods could reflect a real uncertainty in the prediction, and this uncertainty would need to be considered when judging the hazard at a site.

Empirical SPT Method for Evaluating Liquefaction Hazard. Procedures for evaluating the liquefaction hazard using the Liquefaction Workshop methodology are summarized below. As discussed above, the recent changes in the methodology proposed by Idriss and Boulanger (2004, 2006, 2008), Cetin et al. (2004), and Moss et al. (2006) offer alternatives to this approach.

1. The first step in the liquefaction hazard evaluation using the empirical SPT approach is to define the normalized cyclic shear stress ratio (CSR) from the peak horizontal ground acceleration expected at the site. This evaluation is made using the following equation:

$$CSR = 0.65\left(a_{\max}/g\right)\left(\sigma_0/\sigma_0'\right)r_d \qquad (1)$$

where (a_{max}/g) is the peak horizontal acceleration at ground surface expressed as a decimal fraction of gravity, σ_0 is the vertical total stress in the soil at the depth in question, σ_0' is the vertical effective stress at the same depth, and r_d is the deformation-related stress reduction factor. The peak ground acceleration, a_{max}, commonly used in liquefaction analysis is that which would occur at the site in the absence of liquefaction. Thus, the a_{max} used in Eq. 1 is the estimated rock acceleration corrected for soil site response but with neglect of excess pore-water pressures that might develop.

The stress reduction factor, r_d, used in Eq. 1 was originally determined using a plot developed by Seed and Idriss (1971) showing the reduction factor versus depth. The consensus from the Liquefaction Workshop was to represent r_d by the following equations:

For $z \le 9.15$ m, $r_d = 1.0 - 0.00765z$ (2a)

For 9.15 $m < z \le 23$ m, $r_d = 1.174 - 0.267z$ (2b)

2. The second step in the liquefaction hazard evaluation using the empirical approach involves determination of the normalized cyclic resistance ratio (CRR). The most commonly used empirical relationship compares CRR with corrected SPT resistance, $(N_1)_{60}$, from sites where liquefaction did or did not develop during past earthquakes. Figure 4 shows this relationship for magnitude 7.5 earthquakes with an adjustment at low values of CRR recommended by the Liquefaction Workshop. Similar relationships have been developed for determining CRR from CPT soundings, from BHT blowcounts, and from shear wave velocity data as discussed by Youd et al. (2001) and as presented in detail in NCEER (1997).

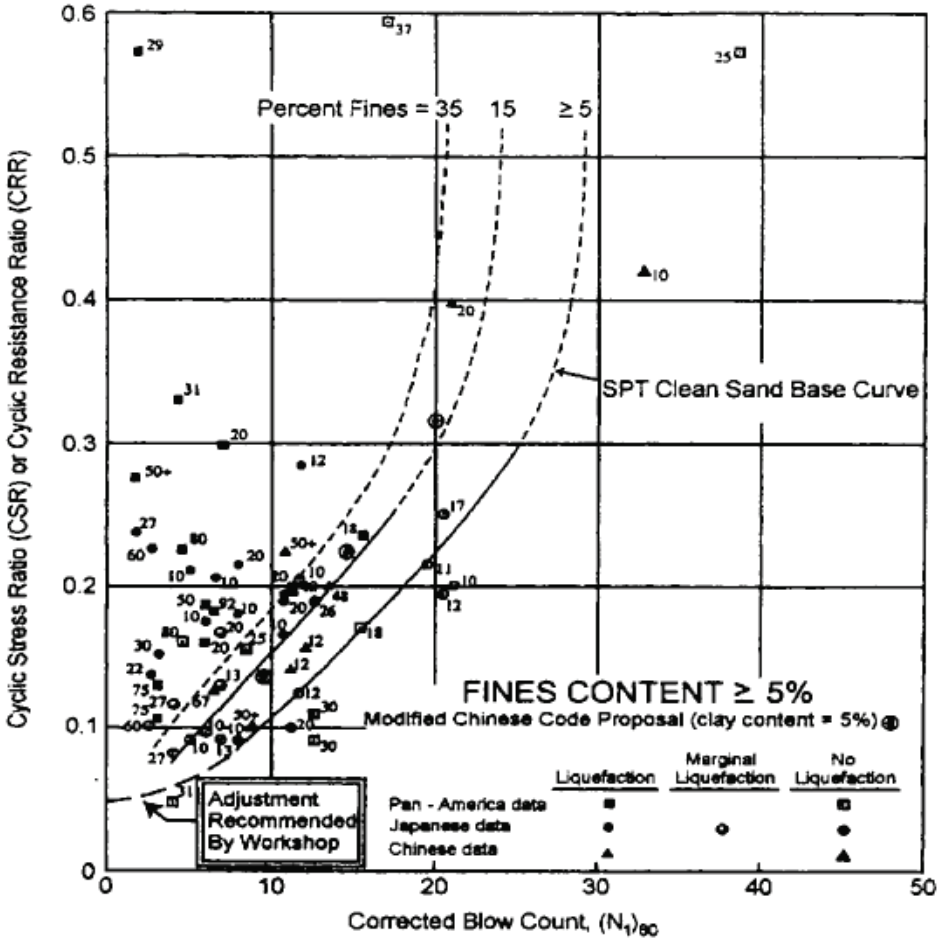

Figure 4 SPT clean sand base curve for magnitude 7.5 earthquakes with data from liquefaction case histories (modified from Seed et al., 1985, to reflect NCEER, 1997, and Youd et al., 2001).

It should be noted that nearly all the field data used to develop the simplified procedure are for depths less than 50 feet; therefore, there is greater uncertainty in the use of empirical approaches at greater depths. Common practice is to use the

SPT or CPT method to depths of 75 feet. In some locations, deep deposits of low blowcount or low CPT end resistance values occur (e.g., in the Puget Sound area and along the Columbia River). It is still prudent to consider these low blowcount materials as susceptible to liquefaction even if they are located at depths greater than 75 feet. For these sites, it is important to correct the CRR with an overburden correction factor (K_σ). Alternatively, it may be appropriate to use strain-based procedures (Dobry et al., 1982) or one-dimensional effective stress modeling methods.

In Figure 4, CRRs calculated for various sites are plotted against $(N_1)_{60}$, where $(N_1)_{60}$ is the SPT blowcount normalized for an overburden stress of 100 kPa and for an energy ratio of 60 percent. Solid symbols represent sites where liquefaction occurred and open symbols represent sites where surface evidence of liquefaction was not found. Curves were drawn through the data to separate regions where liquefaction did and did not develop. As shown, curves are given for soils with fines contents (FC) ranging from less than 5 to 35 percent.

The $(N_1)_{60}$ in Figure 4 is adjusted for various factors before its use as recommended by the Liquefaction Workshop and discussed by Youd et al. (2001). These include an adjustment for fines, such that only the clean sand curve in Figure 4 is used, as well as adjustments for a number of other testing related parameters, including whether or not liners are used in the SPT sampler and the energy calibration factor. These adjustments are all in conventional use by the profession and can readily be found in references by Martin and Lew (1999) and by Youd et al. (2001).

It is very important that the engineer consider these correction factors when conducting the liquefaction analyses. Failure to consider these corrections can result in inaccurate liquefaction estimates -- leading to either excessive cost to mitigate the liquefaction concern or excessive risk of poor performance during a seismic event – potentially resulting in unacceptable damage.

Special mention needs to be made of the energy calibration term, C_E. This correction has a very significant effect on the $(N_1)_{60}$ used to compute CRR. The value of this correction factor can vary greatly depending on the SPT hammer system used in the field and on site conditions. The automatic hammer now used to conduct SPTs avoids much of the uncertainty in energy; however, even it should be periodically calibrated. These calibration measurements are relatively inexpensive and represent a small increase in overall field exploration costs. Many drilling contractors in areas that are seismically active provide calibrated equipment as part of their routine service.

Before computing the factor of safety from liquefaction, the CRR result obtained from Figure 4, using the corrected SPT blow count identified in the equation for $(N_1)_{60}$, must be corrected for earthquake magnitude M if the magnitude differs from 7.5. The magnitude correction factor is shown in Figure 5. This plot was developed during the Liquefaction Workshop on the basis of input from experts attending the workshop. The range shown in Figure 5 is used because of uncertainties. Research conducted since the Liquefaction Workshop has shown that magnitude scaling factors near the lower limit of the recommended range are appropriate for M < 7.5 (Liu et al., 2001; Cetin et al., 2004; Boulanger and Idriss, 2006).

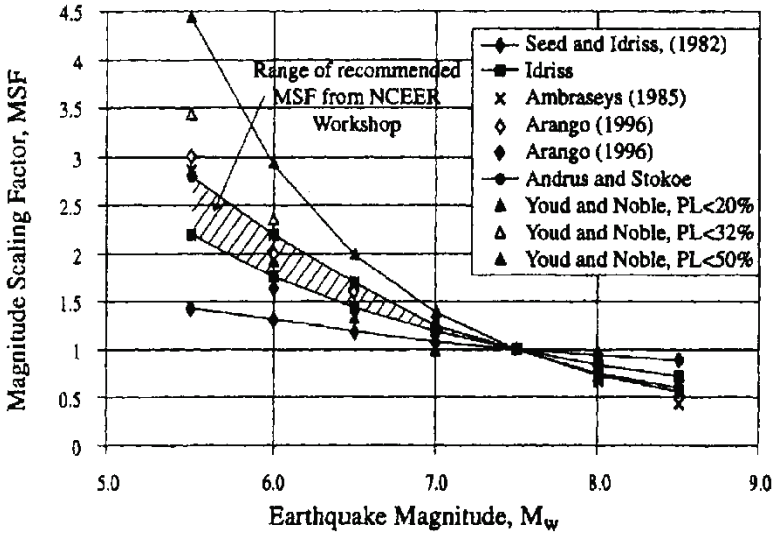

Figure 5 Magnitude scaling factors derived by various investigators (NCEER, 1997; Youd et al., 2001).

The magnitude, M, needed to determine a magnitude scaling factor from Figure 5 should be consistent with the hazard level used in the ground motion determination. When the general procedure for ground motion estimation is used (ASCE/SEI 7 Sections 11.4.1 to 11.4-6) and the MCE (per ASCE/SEI 7) is determined probabilistically, the magnitude

used in these evaluations can be obtained as the dominant magnitude(s) determined from deaggregation information available by latitude and longitude from a U.S. Geological Survey (USGS) website: http://earthquake.usgs.gov/research/hazmaps/. When the general procedure is used and the MCE is bounded deterministically near known active fault sources, the magnitude of the MCE should be the characteristic maximum magnitude assigned to the fault in the construction of the MCE ground motion maps. Where the site-specific procedure for ground motion estimation is used (ASCE/SEI 7 Sections 11.4.7 and Chapter 21), the magnitude of the MCE should be similarly determined from the site-specific analysis. In all cases, it should be remembered that the likelihood of liquefaction at the site (as defined later by the factor of safety F_L in Eq. 3) is determined jointly by a_{max} and M and not by a_{max} alone. Because of the longer duration of strong ground-shaking, large distant earthquakes may in some cases generate liquefaction at a site while smaller nearby earthquakes may not generate liquefaction even though a_{max} of the nearer events is larger than that from the more distant events.

A more recent procedure developed by Kramer and Mayfield (2007) estimates the return period for liquefaction directly without the use of the magnitude scaling factors. This approach considers both the peak acceleration hazard curve and the distribution of earthquakes contributing to the ground motion hazard.

3. The final step in the liquefaction hazard evaluation using the empirical approach involves the computation of the factor of safety (F_L) against liquefaction using the equation:

$$F_L = CRR/CSR \qquad (3)$$

If F_L is greater than 1.0, then liquefaction should not develop. If at any depth in the sediment profile, F_L is equal to or less than 1.0, then there is a liquefaction hazard. Although the curves shown in Figure 4 envelop the plotted data, it is possible that liquefaction may have occurred beyond the enveloped data and was not detected at the ground surface. For this reason, a factor of safety of 1.1 to 1.3 is usually appropriate for building sites -- with the actual factor selected on the basis of the importance of the structure and the potential for ground displacement at the site.

Additional guidance on the selection of the appropriate factor of safety is provided by Martin and Lew (1999). They suggest that the following factors be considered when selecting the factor of safety:

1. The type of structure and its vulnerability to damage.
2. Levels of risk accepted by the owner or governmental regulations with questions related to design for life safety, limited structural damage, or essentially no damage.
3. Damage potential associated with the particular liquefaction hazard. Flow failures or major lateral spreads pose more damage potential than differential settlement. Hence factors of safety could be adjusted accordingly.
4. Damage potential associated with the earthquake magnitude. A magnitude 7.5 event is potentially more damaging than a 6.5 event.
5. Damage potential associated with SPT values; low blowcounts have a greater cyclic strain potential than higher blowcounts.
6. Uncertainty in SPT- or CPT-derived liquefaction strengths used for evaluations. Note that a change in silt content from 5 to 15 percent could change a factor of safety from, say, 1.0 to 1.25.
7. For high levels of ground motion, factors of safety may be indeterminate. For example, if $(N_1)_{60cs} = 20$, $M = 7.5$ and fines content = 35 percent, liquefaction strengths cannot be accurately defined due to the vertical asymptote on the empirical strength curve.

Martin and Lew (1999) indicate that the final choice of an appropriate factor of safety must reflect the particular conditions associated with the specific site and the vulnerability of site-related structures. Table 1 summarizes factors of safety suggested by Martin and Lew.

As a final comment on the assessment of liquefaction hazards, it is important to note that soils composed of sands, silts, and gravels are most susceptible to liquefaction while clay soils generally are not susceptible to this phenomenon. The curves in Figure 4 are valid for soils composed primarily of sand. The curves should be used with caution for soils with substantial amounts of gravel. Verified corrections for gravel content have not been developed; a geotechnical engineer, experienced in liquefaction hazard evaluation, should be consulted when gravelly soils are encountered.

Evaluation of Potential for Loss of Ground Support, Increased Loads, and Ground Displacements. Liquefaction by itself may or may not be of engineering significance. Only when liquefaction is accompanied by loss of ground support, increased soil loads, and/or ground deformation does this phenomenon become important to structural design. Surface manifestations, loss of bearing capacity, increased lateral earth pressures, ground settlement, flow failure, and lateral spread are ground failure mechanisms that have caused structural damage during past earthquakes. These types of ground failure are described

in National Research Council (1985), Martin and Lew (1999), and U.S. Army Corps of Engineers (2005) and are discussed below. The type of failure and amount of ground displacement are a function of several parameters including the looseness of the liquefied soil layer, the thickness and extent of the liquefied layer, the thickness and permeability of unliquefied material overlying the liquefied layer, the ground slope, and the nearness of a free face.

Table 1 Factors of Safety for Liquefaction Hazard Assessment (from Martin and Lew, 1999)

Consequences of Liquefaction	$(N_1)_{60cs}$	Factor of Safety
Settlement	< 15	1.1
	≥ 30	1.0
Surface manifestations	≤ 15	1.2
	> 30	1.0
Lateral spread	≤ 15	1.3
	> 30	1.0

Evaluation of Potential for Loss of Ground Support, Increased Loads, and Ground Displacements. Liquefaction by itself may or may not be of engineering significance. Only when liquefaction is accompanied by loss of ground support, increased soil loads, and/or ground deformation does this phenomenon become important to structural design. Surface manifestations, loss of bearing capacity, increased lateral earth pressures, ground settlement, flow failure, and lateral spread are ground failure mechanisms that have caused structural damage during past earthquakes. These types of ground failure are described in National Research Council (1985), Martin and Lew (1999), and U.S. Army Corps of Engineers (2005) and are discussed below. The type of failure and amount of ground displacement are a function of several parameters including the looseness of the liquefied soil layer, the thickness and extent of the liquefied layer, the thickness and permeability of unliquefied material overlying the liquefied layer, the ground slope, and the nearness of a free face.

Surface manifestations refer to sand boils and ground fissures on level ground sites. For structures supported on shallow foundations, the effects of surface manifestations on the structure could be tilting or cracking. Criteria are given by Ishihara (1985) and Youd and Garris (1995) for evaluating the influence of thickness of layers on surface manifestation of liquefaction effects for level sites. These criteria may be used for noncritical or nonessential structures on level sites not subject to lateral spreads (see later in this section). Differential settlements associated with these surface manifestations may also require consideration.

Loss of bearing capacity can occur if the foundation is located within or above the liquefiable layer. The consequence of bearing failure could be settlement or tilting of the structure. Usually, loss of bearing capacity is not likely for light structures with shallow footings founded on stable, nonliquefiable materials overlying deeply buried liquefiable layers, particularly if the liquefiable layers are relatively thin. Simple guidance for how deep or how thin the layers must be has not yet been developed. Martin and Lew (1999) provide some preliminary guidance based on the Ishihara (1985) method. Final evaluation of the potential for loss of bearing should be made by a geotechnical engineer experienced in liquefaction hazard assessment.

Another possible consequence of liquefaction is increased lateral pressures against basement and retaining walls. The liquefied material will have an at-rest earth pressure coefficient (K_0) between 1.0 and the K_0 value for the non-liquefied soil, depending on the strength of the liquefied soil. A common approach is to conservatively assume that the liquefied soil is a dense fluid having a unit weight of the liquefied soil. The wall then is designed assuming that hydrostatic pressure for the dense fluid acts against the wall. If unsaturated soil is present above the liquefied soil, it is treated as a surcharge that increases the fluid pressure within the underlying liquefied soil by an amount equal to the thickness times the total unit weight of the surcharge soil. This procedure applies equivalent horizontal earth pressures that are greater than typical at-rest earth pressures but less than passive earth pressures.

To prevent buoyant rise of a structure as a consequence of liquefaction, the total weight of the structure should be greater than the volume of the basement or other cavity times the unit weight of liquefied soil. Structures with insufficient weight to counterbalance buoyant effects could differentially rise during an earthquake.

For saturated or dry granular soils in a loose condition, the amount of ground settlement can approach 3 to 4 percent of the thickness of the loose soil layer in some cases. This amount of settlement could cause tilting or cracking of a building, and therefore, it is usually important to evaluate the potential for ground settlement during earthquakes.

Tokimatsu and Seed (1987) published an empirical procedure for estimating ground settlement. It is beyond the scope of this discussion to outline that procedure which, although explicit, has several rather complex steps. The Tokimatsu and Seed

procedure can be applied whether liquefaction does or does not occur. For dry cohesionless soils, the settlement estimate from Tokimatsu and Seed should be multiplied by a factor of 2 to account for multi-directional shaking effects as discussed by Martin and Lew (1999). Duku et al. (2008) present updated relationships for the calculation of settlement of unsaturated clean sands. An alternate approach for settlement of liquefiable soils is that proposed by Ishihara and Yoshimine (1992).

Earthquake-induced ground settlement usually will not occur uniformly at a site. Differences in soil layering and soil consistency will lead to differential settlement. The amount of differential settlement can be estimated if sufficient geotechnical information is available for a site. If such information is not available, a common approach is often to assume that differential settlement will range from 0.5 to 0.75 times the total settlement obtained from one of the above predictive methods.

Flow failures or flow slides are the most catastrophic form of ground failure that may be triggered when liquefaction occurs. They may displace large masses of soils tens of feet. Flow slides occur when the average static shearing stresses on potential failure surfaces are less than the average shear strengths of liquefied soil on these surfaces. Standard limit equilibrium static slope stability analyses may be used to assess flow failure potential with the residual strength of liquefied soil used as the strength parameter in the analyses.

The determination of residual strengths is very inexact, and consensus as to the most appropriate approach has not been reached to date. Relationships for residual strength of liquefied soil that are often used in practice are those of Seed and Harder (1990), Olson and Stark (2002), and Idriss and Boulanger (2007). These strengths have been empirically determined from forensic analyses of flow failures.

Lateral spreads are ground-failure phenomena that can occur on gently sloping ground underlain by liquefied soil. They may result in lateral movements in the range of a few inches to several feet. Earthquake ground-shaking affects the stability of gently sloping ground containing liquefiable materials by seismic inertial forces combined with static gravity forces within the slope and by shaking-induced strength reductions in the liquefiable materials. Temporary instability due to seismic inertial forces is manifested by lateral "downslope" movement. For the duration of ground shaking associated with moderate- to large-magnitude earthquakes, there could be many such occurrences of temporary instability during earthquake shaking producing an accumulation of "downslope" movement.

Various analytical and empirical techniques have been developed to estimate lateral spread ground displacement; however, no single technique has been widely accepted for engineering design. Three approaches are used depending on the requirements of the project: Empirical procedures, simplified analytical methods, and more rigorous computer modeling use correlations between past ground displacement and site conditions under which those displacements occurred. Youd et al. (2002) presents an empirical method that provides an estimate of lateral spread displacements as a function of earthquake magnitude, distance, topographic conditions, and soil deposit characteristics. As shown in Figure 6, the displacements estimated by the Youd et al. (2002) method are generally within a factor of two of the observed displacements.

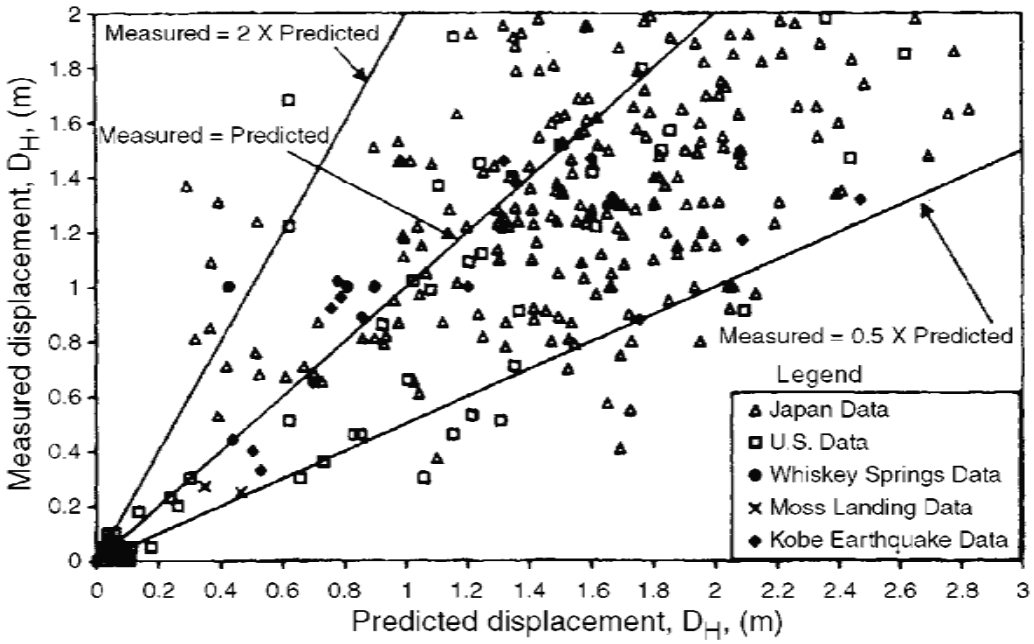

Figure 6 Measured versus predicted displacements for displacements up to 2 meters (Youd et al., 2002).

Bardet et al. (2002) presents an empirical method having a formulation similar to that of Youd et al. (2002) but using fewer parameters to describe the soil deposit. The Bardet et al. (2002) model was developed to assess lateral spread displacements at a regional scale rather than for site-specific applications. Various other empirical methods are also available, including an alternate SPT method by Rausch and Martin (2000) and both SPT- and CPT-based methods by Zhang et al. (2004). These methods can result in large differences in predicted displacement; therefore, it is usually best to use several methods when estimating displacement. Because of the uncertainty in results, these methods normally are used for preliminary screening or comparative evaluations.

Simplified analytical techniques generally apply some form of Newmark's analysis of a rigid body sliding on an infinite or circular failure surface with ultimate shear resistance estimated from the strength of the liquefied soil. Additional discussion of the simplified Newmark method is provided in the discussion of slope instability hazard. A key question for this approach is the method of defining the strength of the liquefied soil. The same residual strength as used for flow failure assessments often has been used for the spreading analyses. However, many researchers will argue that lateral spreads do not involve the same boundary conditions as occur for lateral flows and, specifically, that the ratcheting mechanism of loading with dilation at larger strains is not properly considered. No consensus currently exists on the most suitable method for obtaining the liquefied strength for lateral spreading analyses; however, the use of the residual strength from flow failures is thought to be conservative for most lateral spreading analyses. Work by Olson and Johnson (2008) appear to support the acceptability of use of the residual strength. In view of the current uncertainties, a cautious approach must be taken when estimating deformations for cases involving liquefaction.

More rigorous computer modeling typically involves use of nonlinear finite element or finite difference methods to predict deformations (e.g., using the FLAC and PLAXIS software). As noted previously, the accuracy of this approach is critically dependent on the properties and geometry of the model as well as the earthquake record selection. Of particular importance for the liquefaction problem is the completeness of the pore pressure model and its ability to handle various soil conditions. For example, the soil model within the nonlinear computer analysis programs often is calibrated for only specific conditions. If the site is not characterized by these conditions, errors in estimating the displacement by a factor of two or more can easily occur.

Mitigation of Liquefaction Hazard. Three general measures might be considered for mitigation of liquefaction hazards: (a) design the structure to resist the hazard, (b) stabilize the site to reduce the hazard, or (c) choose an alternative site.

Structural measures that are used to reduce the hazard include deep foundations, mat foundations, or footings interconnected with ties:

1. Deep foundations have performed well at level sites where liquefaction effects were limited to ground settlement and ground oscillation with no more than a few inches of lateral displacement. Deep foundations, such as piles, must consider the potential for reduced soil support through the liquefied layer and may be subjected to lateral displacements across the layer. Loss in lateral support may require ground improvement around the deep foundations or strengthening of the pile. Downdrag forces resulting from post-seismic soil settlement must also be considered. Downdrag forces can result in pile settlement after the earthquake as liquefied soils settle relative to the pile. These downdrag forces result in added structure load and potentially pile settlement, depending on the strength of the soil below the deepest depth of liquefaction. Mitigation procedures for downdrag can include use of bitumen coatings or sleeves that isolate the pile from downdrag forces.
2. Well reinforced mat foundations also have performed well at localities where ground displacements were less than 1 foot, although releveling of the structure was required in some instances (Youd, 1989). Strong ties between footings also should provide increased resistance to damage where differential ground displacements are less than 1 foot.

Evaluations of structural performance following two Japanese earthquakes, 1993 Hokkaido Nansei-Oki and 1995 (Kobe) Hyogo-Ken Nanbu, indicate that small structures on shallow foundations performed well in liquefaction areas where ground displacements were small. Sand boil eruptions and open ground fissures in these areas indicate minor effects of liquefaction including ground oscillation and up to 1 foot of lateral spread displacement. Many small structures (mostly houses, shops, schools, etc.) were structurally undamaged although a few tilted slightly. Foundations for these structures consist of reinforced concrete perimeter wall footings with reinforced concrete interior wall footings tied into the perimeter walls at intersections. These foundations acted as diaphragms causing the soil to yield beneath the foundation which prevented fracture of foundations and propagation of differential displacements into the superstructure.

At sites where expected ground displacements are unacceptably large or where excessive strength loss beneath a foundation needs to be mitigated, ground modification to lessen the liquefaction or ground failure hazard may be required. Techniques for ground stabilization to prevent liquefaction of potentially unstable soils include removal and replacement of soil; compaction of soil in place using vibrations, heavy tamping, compaction piles, or compaction grouting; buttressing; chemical

stabilization with grout; and installation of drains. Further discussion of mitigation methods is given by the National Research Council (1985) and Martin and Lew (1999).

In some situations the structure cannot be strengthened and ground improvement is not practical or possible. For these locations selection of an alternative site may be required.

Surface Fault Rupture Hazard. Fault ruptures during past earthquakes have led to large surface displacements that are potentially destructive to engineered construction. Displacements, which range from a fraction of an inch to tens of feet, may occur along traces of active faults. The sense of displacement ranges from horizontal strike-slip to vertical dip-slip to many combinations of these components. The following paragraphs summarize procedures to consider when assessing the hazard of surface fault rupture. Sources of detailed information for evaluating the hazard of surface fault rupture include Slemmons and dePolo (1986), the Utah Section of the Association of Engineering Geologists (1987), Swan et al. (1991), Hart and Bryant (1997), Hanson et al. (1999), and California Geological Survey (2002). Other beneficial references are given in the bibliographies of these publications.

*Assessment of Surface Faulting Hazard***.** The evaluation of surface fault rupture hazard at a given site is based extensively on the concepts of recency and recurrence of faulting along existing faults. The magnitude, sense, and frequency of fault rupture vary for different faults or even along different segments of the same fault. Even so, future faulting generally is expected to recur along pre-existing active faults. The development of a new fault or reactivation of a long inactive fault is relatively uncommon and generally need not be a concern. For most engineering applications related to foundation design, a sufficient definition of an active fault is given in CDMG Special Publication 42 (Hart and Bryant, 1997): "An active fault has had displacement in Holocene time (about the last 11,000 years)."

As a practical matter, fault investigations should be conducted by qualified geologists and directed at the problem of locating faults and evaluating recency of activity, fault length, the amount and character of past displacements, and the expected amount and potential of future displacement. Identification and characterization studies should incorporate evaluation of regional fault patterns as well as detailed study of fault features at and in the near vicinity (within a few hundred yards to a mile) of the site. Detailed studies can include trenching to accurately locate, document, and date fault features.

The following approach should be considered in fault hazard assessment, and some of the investigative methods outlined should be carried out beyond the site being investigated:

1. A review should be made of the published and unpublished geologic literature about the region along with records concerning geologic units, faults, ground-water barriers, etc.
2. A stereoscopic study of aerial photographs and other remotely sensed images should be made to detect fault-related topography/geomorphic features, vegetation and soil contrasts, and other lineaments of possible fault origin. The study of predevelopment aerial photographs often is essential to the detection of fault features. Recently, the use of LiDAR (LIght Detection And Ranging) has been found to provide excellent identification of fault traces in areas where tree growth and vegetation normally would obscure evidence of faulting from the air.
3. A field reconnaissance study generally is required and should include observation and mapping of features such as bedrock and soil units and structures, geomorphic surfaces, fault-related geomorphic features, springs, and deformation of man-made structures due to fault creep. Field study should be detailed within the site with less detailed reconnaissance of an area within a mile or so of the site. Evidence from prehistoric liquefaction (paleoliquefaction) also can provide important information regarding the magnitude and timing of fault displacement in the site area or region.
4. Subsurface investigations may be necessary to evaluate location and activity of fault traces when uncertainty exists about the location or activity of a fault. These investigations may include trenches, test pits, and/or boreholes to permit detailed and direct observation of geologic units and faults.
5. The geometry of faults may be further defined by geophysical investigations including seismic refraction, seismic reflection, gravity, magnetic intensity, resistivity, ground penetrating radar, etc. These indirect methods require knowledge of specific geologic conditions for reliable interpretation.
6. Geophysical methods alone never prove the absence of a fault, and they typically do not identify the recency of activity.
7. More sophisticated and more costly studies may provide valuable data when special geological conditions exist or when requirements for critical structures demand a more intensive investigation. These methods might involve repeated geodetic surveys, strain measurements, or monitoring of microseismicity and radiometric analysis (C^{14}, K-Ar), stratigraphic correlation (fossils, mineralology) soil profile development, paleomagnetism (magnetostratigraphy), or other dating techniques (thermoluminescense, cosmogenic isotopes) to evaluate the age of faulted or unfaulted units or surfaces.

The following information should be developed to provide documented support for conclusions relative to location and magnitude of faulting hazards:

1. Maps should be prepared showing the existence (or absence) and location of active faults on or near the site. The distribution of faulting (fault zone width) and fault-related surface deformation should be shown.
2. The type, amount, and sense of displacement of past surface faulting episodes should be documented, if possible.
3. From this documentation, estimates of location, magnitude, and likelihood or relative potential for future fault displacement can be made, preferably from measurements of past surface faulting events at the site, using the premise that the general pattern of past activity will repeat in the future. Estimates also may be made from published empirical correlations between fault displacement and fault length or earthquake magnitude (e.g., Wells and Coppersmith, 1994). Where fault segment length and sense of displacement are defined, these correlations may provide an estimate of future fault displacement (either the maximum or the average to be expected). Probabilistic studies may be considered to evaluate the probability of fault displacement (e.g., Youngs et al., 2003).
4. The degree of confidence and limitations of the data should be addressed.

Both deterministic and probabilistic methods are available for estimating the amount or probability of future fault displacement (e.g., Youngs et al., 2003). Because techniques for making these estimates are not standardized, peer review of reports is useful to verify the adequacy of the methods used and the estimated amount or frequency of movement, to aid the evaluation by the permitting agency, and to facilitate discussion between specialists that could lead to the development of standards.

The following guidelines are given for the safe siting of engineered construction in areas crossed by active faults:

1. Where ordinances have been developed that specify safe setback distances from traces of active faults or active fault zones, those distances must be complied with and accepted as the minimum for safe siting of buildings. ASCE/SEI 7 Section 11.8 precludes structures in Seismic Design Category E or F from being sited where there is a known potential for an active fault to cause rupture of the ground surface at the structure. States also may adopt more definitive requirements. For example, the general setback requirement in California is 50 feet from the traces of an active fault. That setback distance is mandated for structures near faults unless a site-specific special geologic investigation shows that a lesser distance could be safely applied (*California Code of Regulations*, Title 14, Division 2, Section 3603(a)).
2. In general, safe setback distances may be determined from geologic studies and analyses as noted above. Setback requirements for a site should be developed by the site engineers and geologists in consultation with professionals from the building and planning departments of the jurisdiction involved.

Where sufficient geologic data have been developed to accurately locate the zone containing active fault traces and the zone is not complex, a smaller setback distance may be specified. For complex fault zones, greater setback distances may be required. Dip-slip faults, with either normal or reverse motion, typically produce multiple fractures within rather wide and irregular fault zones. These zones generally are confined to the hanging-wall side of the fault leaving the footwall side little disturbed. Setback requirements for such faults may be rather narrow on the footwall side, depending on the quality of the data available, and larger on the hanging wall side of the zone. Some fault zones may contain broad deformational features such as pressure ridges and sags rather than clearly defined fault scarps or shear zones. Nonessential structures may be sited in these zones provided structural mitigative measures are applied as noted below. Studies by qualified geologists and engineers are required for such zones to assure that either (a) the structure is not sited across the trace of an active fault or (b) building foundations can withstand probable ground deformations in such zones.

Mitigation of Surface Faulting Hazards. There is no mitigative technology that can be used to prevent fault rupture from occurring. Thus, where a surface faulting hazard exists, the site must be avoided or the structure must be designed to withstand ground deformation or surface fault rupture.

In general practice, it is economically impractical to design a structure to withstand more than a few inches of fault displacement. Some buildings with strong foundations, however, have successfully withstood or diverted a few inches or even feet of surface fault rupture without damage to the structure (Youd, 1989; Kelson et al., 2001). Well reinforced mat foundations and strongly inter-tied footings have been most effective. Deep foundations such as driven piles or drilled shafts are not preferred. In general, less damage has been inflicted by compressional or shear displacement than by vertical or extensional displacements.

SEISMIC LATERAL EARTH PRESSURES

Determination of Lateral Pressures on Basement and Retaining Walls Due to Earthquake Motions. Paragraph 1 of Section 11.8.3 as modified by the 2009 *Provisions* Part 1 exception requires that seismic lateral pressures on basement walls

and retaining walls be determined for Seismic Design Category D, E, and F structures but does not specify the methods for calculating these pressures. Discussion and guidance regarding different approaches for determining seismic lateral pressures are given below.

Observations after past earthquakes have found that retaining walls for waterfront structures often have performed poorly in major earthquake due to excess pore water pressure and liquefaction conditions developing in relatively loose, saturated granular soils. However, damage reports for basement walls and retaining structures away from waterfronts are generally limited with only a few cases of stability failures or large permanent movements (Whitman, 1991). Due to the apparent conservatism or overstrength in static design of most walls, the complexity of nonlinear dynamic soil-structure interaction and the poor understanding of the behavior of retaining structures with cohesive or dense granular soils, Whitman (1991) recommends that "engineers must rely primarily on a sound understanding of fundamental principles and of general patterns of behavior."

Seismic earth pressures on retaining walls are discussed below for two categories of walls: "yielding" walls that can move sufficiently to develop minimum active earth pressures and "nonyielding" walls that do not satisfy this movement condition. Note that in this context, yielding refers to permanent displacement of the wall as a result of the seismic event and does not mean that stresses within the structural system were exceeded. The amount of movement to develop minimum active pressure is very small. A displacement at the top of the wall of 0.002 times the wall height is typically sufficient to develop the minimum active pressure state. Generally, free-standing gravity or cantilever walls are considered to be yielding walls (except massive gravity walls founded on rock) whereas building basement walls restrained at the top and bottom often are considered to be nonyielding.

Yielding Walls. *Limit Equilibrium Force Approach.* At the 1970 Specialty Conference on Lateral Stresses in the Ground and Design of Earth Retaining Structures, Seed and Whitman (1970) made a significant contribution by reintroducing and reformulating the Mononobe-Okabe (M-O) seismic coefficient analysis (Mononobe and Matsuo, 1929; Okabe, 1926), the earliest method for assessing the dynamic lateral pressures on a retaining wall. The M-O method is a limit-equilibrium approach based on a Coulomb failure wedge with the assumption that the wall displaces or rotates outward sufficiently to produce the minimum active earth pressure state.

The M-O formulation is expressed as:

$$P_{AE} = (1/2)\gamma H^2 (1 - k_v) K_{AE} \qquad (4)$$

where P_{AE} is the total (static + dynamic) lateral thrust, γ is unit weight of backfill soil, H is the height of backfill behind the wall, k_V is vertical ground acceleration divided by gravitational acceleration, and K_{AE} is the static plus dynamic lateral earth pressure coefficient which is dependent on (in its most general form) angle of friction of backfill, angle of wall friction, slope of backfill surface, and slope of back face of wall as well as horizontal and vertical ground acceleration. The formulation for K_{AE} is given in textbooks on soil dynamics (Prakash, 1981; Das, 1983; Kramer, 1996) and discussed in detail by Ebeling and Morrison (1992).

The value of a_{max} used in the K_{AE} determination is the instantaneous peak acceleration, not an average of the ground motion over the duration of strong shaking. In the past, it was common practice for geotechnical engineers to reduce the instantaneous peak by a factor from 0.5 to 0.7 to represent an average seismic coefficient for determining the seismic earth pressure on a wall. The reduction factor was introduced in a manner similar to the method used in a simplified liquefaction analyses to convert a random acceleration record to an equivalent average series of cyclic loads. This approach can result in confusion on the magnitude of the seismic active earth pressure and, therefore, is not recommended. Any further reduction to represent average rather than instantaneous peak loads is a structural decision and must be an informed decision made by the structural designer. As discussed in this paper in the section on the displacement-based approach, a reduction in a_{max} is, however, permitted if the wall can undergo permanent displacements. There is no consensus on the appropriate a_{max} value to use in the earth pressure determination. Recent centrifuge modeling work by Al Atik and Sitar (2007) suggests that estimating seismic lateral earth pressures utilizing the full peak ground acceleration overestimates the seismic earth pressure forces for some structures.

The M-O equation makes several other very important assumptions, including that the soil behind the retaining wall is a uniform, cohesionless soil and that the groundwater elevation is below the base of the retaining wall. The implications of these assumptions are discussed later in this section.

Seed and Whitman (1970), as a convenience in design analysis, proposed to evaluate the total lateral thrust, P_{AE}, in terms of its static component (P_A) and dynamic incremental component (ΔP_{AE}):

$$P_{AE} = P_A + \Delta P_{AE} \qquad (5a)$$

or

$$K_{AE} = K_A + \Delta K_{AE} \quad (5b)$$

or

$$\Delta P_{AE} = (1/2)\gamma H^2 \Delta K_{AE} \quad (5c)$$

Seed and Whitman (1970), based on a parametric sensitivity analysis, further proposed that for practical purposes:

$$\Delta K_{AE} = (3/4)K_h \quad (6)$$

$$\Delta P_{AE} = (1/2)\gamma H^2 (3/4)k_h = (3/8)k_h \gamma H^2 \quad (7)$$

where k_h is horizontal ground acceleration divided by gravitational acceleration. Unless permanent displacement of the wall is acceptable, k_h should be taken equal to the site peak ground acceleration, a_{max}. For the distribution of the dynamic thrust, ΔP_{AE}, Seed and Whitman (1970) recommended that the resultant dynamic thrust act at $0.6H$ above the base of the wall (i.e., inverted trapezoidal pressure distribution). Note that this approach assumes dry, cohesionless backfill material. If soil conditions behind the wall have a cohesive soil component (i.e., a c-ϕ soil), this simplified approach is no longer appropriate.

Equation 7 generally is referred to as the simplified M-O formulation and is not applicable for sloping ground above the wall. For walls that are in excess of 15 feet in height, special studies also can be conducted to evaluate the coherency of ground motions behind the wall from which an average seismic coefficient can be developed. Anderson et al. (2008) provide simplified guidance on the selection of factors that adjust for coherency. These special studies require consideration of the frequency characteristics of ground motion, as well as the stiffness of the soil and the wall height, and usually require use of a finite element or difference computer model.

Since its introduction, there has been a consensus in geotechnical engineering practice that the simplified M-O formulation reasonably represents the dynamic (seismic) lateral earth pressure increment for yielding retaining walls. However, there are limitations associated with the M-O approach, and these limitations can have a significant effect on the magnitude of estimated seismic active earth pressure.

Although the M-O approach is simple to use, certain designs become very difficult to solve with the standard M-O equations. These designs involve high ground accelerations, combinations of moderate-to-high ground accelerations and steep backslopes, and mixed backfill conditions (i.e., either c-ϕ soils occur or only a thin zone of granular backfill is placed between the wall and the native soil behind the fill zone, particularly where the native soils is cohesive or rock). For these cases, the M-O approach does not provide realistic answers.

An acceptable alternative approach for these cases is to use a generalized limit equilibrium (slope stability) computer program. With this alternate approach, appropriate soil properties and geometry can be modeled, and the seismic coefficient can be defined on the basis of the peak ground acceleration or a reduced seismic coefficient if displacement is acceptable. For most seismic loading cases, the total stress (undrained) c-ϕ parameters will be appropriate for design because of the rate of seismic loading. With this generalized limit equilibrium method, the external force required for stability is computed. This force represents the dynamic earth pressure on the wall. The total force can be distributed as a uniform seismic pressure or the seismic increment can be determined and applied as an inverted triangle. Note that when subtracting the static force from the total seismic earth pressure, it is necessary to determine the static earth pressure under the conditions used during the pseudostatic seismic analysis. This could mean determining the static earth pressure for the same c-ϕ combination as used for the seismic analysis.

Displacement-based Approach. The alternate approach for the design of yielding walls is to evaluate the movement of the wall during seismic loading. Various methods are available for conducting displacement-based analyses ranging from extensions of the M-O formulations to two- and three-dimensional computer modeling. One of the key requirements for the displacement-based approach is the determination of the level of acceptable displacements. This determination will depend both on the wall type and on the nature of facilities next to the wall. These nearby facilities can range from buildings to buried utilities.

Careful attention needs to be given to the characterization of soil conditions behind the wall when using a displacement-based approach. Both the geometry of fill and native deposits, as well as the strength of the soil under cyclic loading, must be considered. Initially, the peak strength of the soil can be used for the analysis; however, if significant deformations are predicted, it may be necessary to repeat the analysis using the residual strength of the soil. See discussions of site characterization in the seismic slope stability section for additional guidance on the selection of soil strengths.

Richards and Elms (1979) introduced a method for seismic design analysis of yielding walls considering translational sliding as a failure mode and based on tolerable permanent displacements for the wall. Elms and Martin (1979) showed that k_h =

$a_{max}/2$ is adequate for design if the wall is allowed to slide up to $10a_{max}$ where a_{max} is the seismic ground motion and displacement is in inches. For seismically active areas, the displacement associated with 10 a_{max} can be 4 to 6 inches.

In practice, $k_h = a_{max}/2$ often is used without regard for the displacement that is associated with this assumption. Clearly, several inches of movement can be tolerable for some types of yielding walls, but not all. For example, a semi-gravity cantilever wall could be designed to slide several inches; however, the anchors for a tieback wall would likely restrict this level of movement from occurring for a well designed anchored wall. Use of $k_h = a_{max}/2$ requires that the designer check to confirm that deformations will develop without damaging the wall or other nearby facilities. Various factors can limit displacements, such as physical obstructions or underestimating the amount of soil strength that will be mobilized. If movement cannot be tolerated or if the wall may not move enough to mobilize the yield condition, then either the full a_{max} should be used for determination of seismic earth pressure or more rigorous procedures such as described below should be used.

There are a number of other empirical formulations for estimating permanent displacements under a translation mode of failure; these have been reviewed by Whitman and Liao (1985). Nadim (1980) and Nadim and Whitman (1984) incorporated the failure mode of wall tilting as well as sliding by employing coupled equations of motion that were further formulated by Siddharthan et al. (1992) as a design method to predict the seismic performance of retaining walls taking into account both sliding and tilting. Alternatively, Prakash et al. (1995) described design procedures and presented design charts for estimating both sliding and rocking displacements of rigid retaining walls. These design charts are the results of analyses for which the backfill and foundation soils were modeled as nonlinear viscoelastic materials. A simplified method that considers rocking of a wall on a rigid foundation about the toe was described by Steedman and Zeng (1996) and allows the determination of the threshold acceleration beyond which the wall will rotate. A simplified procedure for evaluating the critical threshold accelerations for sliding and tilting was described by Richards et al. (1996).

Validation of methods for evaluating tilting of yielding walls has been limited to a few case studies and back-calculation of laboratory test results. Evaluation of wall tilting requires considerable engineering judgment. Because the tilting mode of failure can lead to instability of a yielding retaining wall, it is suggested that this mode of failure be avoided in the design of new walls by proportioning the walls to prevent rotation in order to displace only in the sliding mode.

An alternative displacement-based approach is the use of two-dimensional computer codes such as FLAC and PLAXIS. These methods allow a more detailed evaluation of soil-structure interaction for different wall geometries and external loads, different soil and structural properties, and different earthquake loading conditions. Results from these analyses can be particularly helpful in understanding the deformations that occur within and near the retaining wall including the soil in front of and behind the wall. As noted above, these methods require considerable expertise in terms of soil and structural modeling and selection of earthquake records and should be used with particular care. Although results may appear very reasonable, small changes in model setup or input parameters selection can significantly affect the quality of results, potentially leading to unconservative design decisions.

Nonyielding Walls. By definition, nonyielding walls do not deform when subjected to seismic earth pressures. This type of response requires a very stiff wall in combination with a rigid base condition. Most nonyielding walls will be located on rock or very stiff soil. Even in this condition, wall flexibility can be sufficient to develop active seismic earth pressures significantly reducing the loading on basement walls. Where a basement wall is located on rock or very stiff soil and where structural analyses determine that the wall flexibility is such that deformations will not develop seismic active earth pressures (i.e., deformations < $0.002H$ where H is the wall height), the wall should be designed as a nonyielding wall. The following discussion provides guidance on two methods for dealing with cases where rigid wall conditions occur. Also included is a discussion of soil-structure interaction methods for evaluating earth pressures on basement walls where uncertainties on the flexibility of the wall occur.

Simplified Wood Approach. Wood (1973) analyzed the response of a rigid nonyielding wall retaining a homogeneous linear elastic soil and connected to a rigid base. For such conditions, Wood established that the dynamic amplification was insignificant for relatively low-frequency ground motions (i.e., motions at less than half of the natural frequency of the unconstrained backfill), which would include many earthquake problems. For uniform, constant k_h applied throughout the elastic backfill, Wood (1973) developed the dynamic thrust, ΔP_E, acting on smooth rigid nonyielding walls as:

$$\Delta P_E = F k_h \gamma H^2 \tag{8}$$

The value of F is approximately equal to unity (Whitman, 1991) leading to the following approximate formulation for a rigid nonyielding wall on a rigid base:

$$\Delta P_E = k_h \gamma H^2 \tag{9}$$

As for yielding walls, the point of application of the dynamic thrust is taken typically at a height of 0.6*H* above the base of the wall.

It should be noted that the model used by Wood (1973) does not incorporate any effect on the pressures of the inertial response of a superstructure connected to the top of the wall. This effect may modify the interaction between the soil and the wall and thus modify the pressures from those calculated assuming a rigid wall on a rigid base.

Although the study performed by Wood included dynamic analysis of a rigid wall with fixed base condition, the solution commonly used and presented in Equations 8 and 9 is based on static "1g" loading of the soil and wall and does not include the effects of the wave propagation in the soil. The subject of soil-wall interaction is addressed in the following sections.

Ostadan Rigid Wall Approach. Ostadan (2005) observed that for partially embedded structures subjected to ground shaking, the characteristics of the dynamic earth pressure amplitudes versus frequency of the ground motion were those of a single-degree-of-freedom (SDOF) system and proposed a simplified method to estimate the magnitude and distribution of dynamic thrust. Results provided by Ostadan (2005) utilizing this simplified method, which also were confirmed by dynamic finite element analyses, indicate that, depending on the dynamic properties of the backfill as well as the frequency characteristics of the input ground motion, a range of dynamic earth pressure solutions would be obtained for which the M-O solution and the Wood (1973) solution represent a "lower" and an "upper" bound, respectively.

The solution by Ostadan considers the kinematic soil-structure interaction effects and is based on the dynamic soil properties and the ground motion characteristics. This solution assumes a rigid wall on rigid foundation and does not include the effect of the superstructure and its inertia on seismic soil pressure.

The five-step method to compute the seismic soil pressure following Ostadan's method is:

1. Perform free-field soil column analysis and obtain the ground response motion at the depth corresponding to the base of the wall in the free-field. The response motion in terms of acceleration response spectrum at 30 percent damping should be obtained. The free-field soil column analysis may be performed using the computer program SHAKE with input motion specified either at the ground surface or at the depth of the foundation basemat. The choice for location of control motion should be consistent with the development of the ground motion.

2. Use Equation 10 to compute the total soil mass (m) using the Poisson's ratio (ν) and mass density of the soil.

$$m = 0.50(\rho)H^2\,(\Psi\nu) \tag{10}$$

   where ρ is the mass density of the soil (total weight density divided by acceleration of gravity), H is the height of the wall, and $\Psi\nu$ is a factor to account for the Poisson's ratio as defined by the following equation.

$$\Psi\nu = 2 / [(1-\nu)(2-\nu)]^{0.5} \tag{11}$$

3. Obtain the total lateral seismic force from the product of the total mass obtained in Step 2 and the acceleration spectral value of the free-field response at the soil column frequency obtained at the depth of the bottom of the wall (Step 1). The soil column frequency (f_s) is an output provided by SHAKE:

$$f_s = v_s/(4H) \tag{12}$$

   where v_s is the average strain-compatible shear wave velocity of the soil column over the height of the wall.

4. Obtain the maximum lateral seismic soil pressure at the ground surface level by dividing the lateral force obtained in Step 3 by the area under the normalized seismic soil pressure, 0.744*H*.

5. Obtain the pressure profile by multiplying the peak pressure from Step 4 by the pressure distribution relationship given by:

$$p(y) = -0.0015+5.05y-15.84y^2+28.25y^3-24.59y^4+8.14y^5 \tag{13}$$

   where y is the normalized height ratio (Y/H) measured from the bottom of the wall (ranging from 0 at the bottom of the wall to 1 at the top of the wall) and Y is the distance of the point under consideration from the bottom of the wall.

The area under the seismic soil pressure curve can be obtained from integration of the pressure distribution over the height of the wall. The total area is 0.744*H* x p_{max} for a wall with the height of *H* and maximum pressure of p_{max} at the top.

With this method, the site-specific dynamic soil properties, soil nonlinear effects, and the characteristics of the ground motion are considered in the computation of the seismic soil pressure. A complete verification of the five-step method against finite element solutions and comparison with the Wood solution and the M-O method is presented by Ostadan (2005).

Soil-structure-interaction Approach and Modeling for Partially Embedded Structures. Lam and Martin (1986), Soydemir and Celebi (1992), Veletsos and Younan (1994a and 1994b), and Ostadan (2005), among others, argue that the earth pressures acting on the walls of partially embedded structures (e.g., basement walls) during earthquakes are primarily governed by soil-structure interaction (SSI) and, thus, these partially embedded structures should not be treated as a nonyielding wall. Soil-structure interaction includes both a kinematic component -- i.e., the interaction of a massless rigid wall with the adjacent soil as modeled by Wood (1973) but including the wave propagation in the soil -- and an inertial component -- i.e., the interaction of the wall, connected to a responding superstructure, with the adjacent soil. Detailed SSI analyses incorporating kinematic and inertial interaction may be considered for the estimation of seismic earth pressures on critical walls.

Whitman (1991) has suggested that SSI effects on basement walls of buildings reduce dynamic earth pressures and that M-O pressures may be used in design except where structures are founded on rock or hard soil (i.e., where no significant rocking occurs). In the latter case, the pressures given by the Ostadan (2005) method with the Wood (1973) formulation as the upper bound would appear to be more applicable. The effect of rocking in reducing the dynamic earth pressures on basement walls also has been suggested by Ostadan and White (1998). This condition may be explained if it is demonstrated that the dynamic displacements induced by kinematic and inertial components are out of phase. Chang et al. (1990) have found that dynamic earth pressures recorded on the wall of a large-scale model nuclear reactor containment building (e.g., 1/4 the size of a full-size power block) were consistent with dynamic pressures predicted by the M-O solution. Analyses by Chang et al. (1990) indicate that the dynamic wall pressures were strongly correlated with the rocking response of the structure.

Effect of Saturated Backfill on Wall Pressures. The previous discussions of yielding and nonyielding walls are limited to backfills that are not water-saturated. In current (2009) practice, drains typically are incorporated in the design to prevent groundwater from building up within the backfill. This is not practical or feasible, however, for waterfront structures (e.g., quay walls) where most of the earthquake-induced failures have been reported (Seed and Whitman, 1970; Ebeling and Morrison, 1992; ASCE-TCLEE, 1998) or for some types of structures located below groundwater.

During ground shaking, the presence of water in the pores of a backfill can influence the seismic loads that act on the wall in three ways (Ebeling and Morrison, 1992; Kramer, 1996): (a) by altering the inertial forces within the backfill, (b) by developing hydrodynamic pressures within the backfill, and (c) by generating excess porewater pressure due to cyclic straining. Effects of the presence of water in cohesionless soil backfill on seismic wall pressures can be estimated using formulations presented by Ebeling and Morrison (1992) and Kramer (1996). The effects of soil liquefaction associated with excess porewater pressure generation on wall pressures are treated in the discussion of increased lateral earth pressure in the liquefaction hazard section of this resource paper.

Resource Paper 13

LIGHT-FRAME WALL SYSTEMS WITH WOOD STRUCTURAL PANEL SHEATHING

This resource paper provides commentary on shear wall design, performance, and the state of practice for seismic-force-resisting systems using light-frame walls with wood structural panel sheathing as recognized in ASCE/SEI 7-05 (ASCE/SEI 7) Table 12.2-1, Items A13 and B23. This commentary is intended to supplement existing application-oriented commentary provided by the applicable American Iron and Steel Institute (AISI) and American Forest and Paper Association (AF&PA) standards and is being provided with the intent that applicable portions be integrated into relevant standards or other design guidance documents.

GLOBAL STRENGTH, DRIFT, AND DUCTILITY

Wood and cold-formed steel (CFS) light-frame structures using wood structural panel shear walls for seismic resistance rely on a significant level of ductility and displacement capacity in addition to strength. Vertical elements of the lateral-force-resisting system will often have strength-level (LRFD) calculated deflections of between 0.5 and 0.75 percent of the story height under the design-based earthquake (DBE), implying an expected real interstory drift (d_u) on the order of 2 to 3 percent of the story height for the DBE and more for the risk-targeted maximum considered earthquake (MCE_R). Although nonlinear time-history analysis, laboratory shake table testing (wood light-frame systems), and observed building performance suggest this level of drift can occur, all three also indicate that drifts can be substantially less (Cecotti and Karacabeyli, 2002; Christovasilis et. al., 2007; CUREE, 2001a, 2001b, 2002a, 2002b, and 2002c; Pryor et al., 2000). This wide variation in response is primarily attributable to the added strength and stiffness of finish materials on both the interior and exterior of the structure as well as other sources of redundancy. Several shake table studies have underscored this contribution of finish material (CUREE, 2001b; Christovasilis et al., 2007). Testing and analysis of structures with finishes included have also shown a tendency for drifts in multistory light-frame buildings to be concentrated in the lowest story which is typically the softest and weakest.

ELEMENTS IN THE LATERAL-FORCE-RESISTING SYSTEM

Laboratory shake table testing and observed building performance to date indicate that the primary seismic response of light-frame wood structural panel shear wall buildings is the in-plane racking displacement of the wall elements while the deformation demand on floor and roof diaphragms remains small. The few recorded instances of diaphragm failures in light-frame buildings have involved irregularly shaped diaphragms with re-entrant corners (CUREE, 2001a; Christovasilis et al., 2007). Consequently, the walls are the structural elements that determine the seismic response characteristics of light-frame shear wall buildings. Note that light-frame diaphragms can have a significant influence on the seismic behavior of concrete and masonry shear wall buildings, which are beyond the scope of this paper.

Wood structural panel sheathed shear wall systems are intended to be designed in accordance with ASCE/SEI 7-05, AF&PA *Special Design Provisions for Wind and Seismic* for wood construction, and AISI S213-07, *North American Standard for Cold-Formed Steel Framing – Lateral Design* for CFS construction. Structural assemblies in light-frame construction are formed by a system of closely spaced repetitive wood or cold-formed steel (CFS) floor, roof, and wall framing members. In wood structural panel shear wall systems, sheathing is most commonly installed in 4 foot by 8 to 10 foot sheets and fastened to wall framing with nails, screws, or similar small diameter dowel-type fasteners.

Seismic design in accordance with ASCE/SEI 7 anticipates cyclic loading of vertical shear wall elements in the inelastic range, often to or beyond peak capacity. The primary source of drift and energy dissipation of wood-frame shear walls is the bending and yielding of the shear wall sheathing to framing fasteners around the perimeter of each sheathing panel accompanied by slip between the sheathing and framing. In most wood-frame shear walls, the racking of the wall causes yielding of sheathing to framing fasteners, along with local crushing of the framing and sheathing due to fastener bearing. In most CFS frame shear walls, the racking of the wall causes fastener-related bearing deformations along with dimpling of the framing members. The sheathing in both wood and CFS walls rotates about its center of rigidity and the maximum number of fasteners is engaged in resisting the lateral loads.

Addressed here are the combinations of sheathing and fastening currently included in the American Forest and Paper Association (AF&PA) and American Iron and Steel Institute (AISI) standards. New combinations of sheathing and fastening should be tested in reverse-cyclic loading; some combinations of sheathing materials and methods of attachment (such as

adhesive) have not shown similar ductility levels in laboratory tests. This paper also reflects the behavior of shear walls with overturning restraint (tie-downs or similar) provided at each end as is common in an engineered structure; laboratory testing of shear walls without overturning restraint has shown increases in deflection and reductions in strength (CUREE, 2004; Dolan and Heine, 1997a and 1997b).

EFFECTS OF WALL FINISH MATERIALS

The effect of wall finish materials (gypsum wallboard, exterior stucco or siding, etc) on seismic performance varies with the seismic demand level. The shake table testing of a full-scale townhouse building as part of the NEESWood benchmark (Christovasilis et al., 2007) testing showed a significant influence of finish materials at a ground motion level of roughly 50 percent of the DBE, with resulting average interstory drift of approximately 0.75 percent. It is anticipated that the influence of finish materials will be somewhat less for the full DBE with anticipated interstory drifts on the order of 3 to 4 percent. For structures near collapse, estimated at approximately 7 percent interstory drift based on structures tested on Japan's E-Defense table, it is thought that there is little contribution of finish materials left in the structure. Nonetheless, the inclusion of finish materials in analytical studies for FEMA P695 (ATC, 2008) did improve the collapse margin to an acceptable level so wall finish materials can improve performance. More study of the influence of finish materials is needed.

The NEESWood benchmark testing showed that the reduction of drift due to finish materials was greatest for gypsum wallboard applied to walls detailed as shear walls (i.e., there was positive force transfer between the wall and the diaphragm and overturning restraint was provided). When gypsum wallboard was applied to nonstructural partition walls not detailed for force transfer from the diaphragms, the contribution was minimal. Several studies have also shown that stucco can be very effective in reducing interstory drift demand whereas the NEESWood benchmark testing showed only a modest effect from the stucco exterior finish.

When considering stucco as part of the seismic-force-resisting system, there are several limiting issues. There is concern over the long-term performance of the stucco since stucco in combination with building paper/barriers is the weather barrier for the structure. Staples often are used to attach the lath to the studs, but staple legs do not have much thickness to resist long-term corrosion. Galvanized or stainless steel staples would be more resistant to corrosion.

Finish materials such as gypsum wallboard and stucco have much lower displacement at peak capacity (around 0.5 to 1 percent of the story height) than the more ductile wood structural panel elements (1.5 to 5 percent of the story height). This prevents a simple summation of capacities and complicates estimated performance. Although not directly considered in the design, it seems clear that when a building is responding with interstory drifts on the order of 2 to 3 percent, well beyond the peak capacity of the gypsum or stucco, those elements can provide important hysteretic damping to help attenuate the movement of the structure. Similarly, CUREE shake table tests of a two-story wood-frame house examined the effects of fully sheathed walls (extra sheathing used in a segmented shear wall design above and below the openings). The shake table tests of segmented walls without the horizontal segments had increased wall displacements by a factor of more than two, suggesting that the sheathing above the below the openings has a significant effect on the performance of the structure (CUREE, 2001b) .

While not directly addressed in the *International Building Code* (IBC), the effect of finishes can be considered qualitatively. In contrast to moment frame construction, the mode shape of traditional light-frame multistory buildings tends to degrade to a single-degree-of-freedom system as a story reaches its ultimate strength and deforms predominately in shear. As a result, the majority of the displacement demand of the structure is concentrated in the weakest story. The other stories tend to remain in the elastic range. Finishes, which tend to be more concentrated in upper stories, contribute to this behavior and tend to cause significant displacement demand in the first story. Detailing of shear wall boundary members and anchorage connections is vital to adequate seismic performance of the soft or weak story of a structure.

ANALYTICAL MODELING

In order to evaluate the distribution of design forces and drifts, a building analytical model in accordance with ASCE/SEI 7 Section 12.7.3, is needed. Generally, the analysis uses either the simplified alternative structural design criteria (ASCE/SEI 7, Section 12.14) or equivalent lateral force procedure (ASCE/SEI 7, Section 12.8). The primary analysis model includes only those elements designated as structural shear walls and diaphragms.

Vertical distribution of forces should be in accordance with ASCE/SEI 7, which dictates a triangular (first mode) distribution for buildings under the equivalent lateral force procedure and a rectangular distribution with a slight increase in base shear under the simplified alternative structural design criteria.

Analytical modeling of the horizontal distribution of seismic forces at a theoretical level is based on the relative stiffness of the diaphragms, shear walls, and any other force resisting elements. Horizontal distribution should be in accordance with three categories identified in ASCE/SEI 7: diaphragms that are clearly very flexible relative to the vertical elements, diaphragms that are clearly very rigid relative to the vertical elements, and everything else. For "everything else," it is required that a semi-rigid diaphragm model be used for distribution of horizontal seismic forces.

ASCE/SEI 7 includes an exception permitting one- and two-family residential buildings with diaphragms of wood structural panel or untopped steel decking to be categorized as flexible. The simplified alternative structural design criteria of ASCE/SEI 7, Section 12.14, also permits assumption of a flexible diaphragm force distribution for wood structural panel diaphragms, untopped steel decking, or similar panelized construction (Section 12.4.5) with a small increase in base shear for multistory buildings.

Other buildings braced by wood and CFS light-frame shear walls fall into the "everything else" category. For these other buildings, one approach to meeting this requirement is evaluating force distribution using both rigid and flexible diaphragm models and designing each shear wall and diaphragm for the worst case force. For this approach, the flexible diaphragm model should be solved first, followed by an iterative rigid diaphragm distribution analysis.

Where nonuniform distribution of finish materials might trigger significant torsional behavior in the structure, additional analytical study including the effects of finish materials should be considered.

ADHESIVE ATTACHMENT OF SHEATHING IN WOOD AND CFS LIGHT-FRAME BUILDINGS

Ductility in wood-frame shear walls with wood structural panel sheathing is provided by the fasteners used to attach the sheathing to the framing members. Testing has shown brittle failure when adhesives are used for this attachment in place of mechanical fasteners. This is discussed further in *Recommended Lateral Force Requirements and Commentary* (SEAOC, 1999), Section C804.3. For this reason, the 2006 edition of IBC Section 2305.3.10 states: "Adhesive attachment of shear wall sheathing is not permitted as a substitute for mechanical fasteners, and shall not be used in shear wall strength calculations alone, or in combination with mechanical fasteners in Seismic Design Category D, E or F." The 2005 edition of AF&PA *Special Design Provisions for Wind and Seismic* (SDPWS) Section 4.3.6.3.1 states: "Adhesive attachment of shear wall sheathing shall not be used alone, or in combination with mechanical fasteners." Both of these provisions address adhesive attachment in wood-frame shear walls.

To date, adhesives are not known to have been used for structural attachment of wood structural panel sheathing to CFS stud walls. There is no discussion of adhesive attachment of CFS frame shear walls as of yet in either the IBC or AISI S213 (2007); however, a commentary note was added to AISI S213. Limited testing to date (Serrette, 2006) suggests some similarities to the brittle behavior seen in wood-frame shear walls with adhesives. For this reason, adhesive attachment to CFS studs should not be undertaken without adequate study of seismic behavior.

SHEATHING FASTENERS FOR WOOD AND CFS LIGHT-FRAME BUILDINGS

Overdriven Fasteners. Fasteners that are driven past the top of the sheathing have reduced bearing area on the sheathing. Consequently, this can lead to a shear load reduction of sheathed assemblies. APA Technical Note TT-012 states that no reduction is required for wood-sheathed shear walls or diaphragms when the fasteners are overdriven up to 1/16 in. under dry conditions. In addition, no reduction is necessary if no more than 20 percent of the perimeter fasteners are driven between 1/16 and up to 1/8 inch. Also, an article entitled "Capacity of Oriented Strand Board Shear Walls with Overdriven Sheathing Nails" reports on a testing program of overdriven oriented strand board (OSB) sheathing fasteners (Jones and Fonseca, 2002). The 2001 Canadian code, CSA O86 Cl. 9.5.3.4 states: "Nails shall be firmly driven into framing members but shall not be over-driven into sheathing. For structural wood-based sheathing, nails shall not be over-driven more than 15 percent of the panel thickness."

Significant reductions in strength have been observed in laboratory tests of CFS frame shear wall assemblies when the screw sheathing fasteners are overdriven. This may be due to the countersunk screw head removing or damaging more of the wood sheathing than an overdriven common sheathing nail. Additional testing is required to determine what effect overdriven screw fasteners may have on shear strength for CFS frame shear wall assemblies.

Fastener Locations. The location of the sheathing fasteners affects the performance of shear wall assemblies. If the sheathing fasteners are located too close to the panel edge, they may pull through the sheathing panel before the shear wall assembly reaches its expected capacity. In addition, if the fasteners penetrate into the framing member too close to the

framing member's edge or if the fasteners are spaced too close together, they may cause the wood framing member to split before the assembly obtains the expected load.

Wood Framing Considerations. The AF&PA NDS Commentary (American Forest and Paper Association, 2005b) includes spacing and edge distance recommendations for fasteners less than ¼ in. diameter used for wood framing. In addition, IBC Section 2305.1.2.1 (ICC 2006) and SDPWS Section 4.3.7 require that fasteners not be placed less than 3/8 in. from the panel edge. The IBC and AF&PA SDPWS wood-frame shear wall table require a minimum of a 3 in. nominal framing member at abutting panel edges and staggered placement of fasteners when fasteners are spaced at 2½ in. on center or closer or for 3 in. on center spacing when 10d commons penetrate in the framing members more than 1½ in.

CFS Framing Considerations. AISI S100 (American Iron and Steel Institute, 2007b) includes spacing and edge distance requirements for fasteners used for steel-to-steel connections. AISI S213, Section C2.2, requires that fasteners be 3/8 in. from the panel edge for all of the sheathing panels shown in the standard. The 2007 edition of AISI S21 incorporates a Canadian provision requiring minimum of ½ in. edge distance for wood-sheathed CFS frame shear wall assemblies based on edge distance used in the testing.

Salenikovich (2000) tested walls with different edge distances for the sheathing fasteners and found that the strength/capacity does not increase very much with increased edge distance, but the displacement capacity significantly increased and the building as a whole is toughened (displacement and load cycling ability). The edge distance of the fasters along the bottom of the wall (between the sheathing and the bottom plate of the wall framing) is especially important to achieve the toughening effect.

HOLD-DOWN CONNECTOR SLIP FOR WOOD AND CFS LIGHT-FRAME BUILDINGS

The aspect ratio of the shear wall affects how much horizontal wall drift is due to vertical deflection of the hold-down connection. Higher aspect ratio shear wall assemblies are more sensitive to hold-down connection slip or deformation. This slip/deformation-related drift is addressed in one part of the light-frame shear wall deflection equation that determines the horizontal wall drift due to the vertical deflection of the hold-down connection. Hold-down deflection may be comprised of fastener slip, device elongation/movement, and/or anchor bolt elongation.

COMBINATION OF MATERIALS FOR WOOD AND CFS LIGHT-FRAME BUILDINGS

Combining shear walls that have different sheathing materials is not permitted by either the IBC or ASCE/SEI 7. It is permitted to have one side opposite the wood sheathed side to be sheathed with gypsum board, and there are load values for that combination of sheathing materials on opposite sides of the same shear wall assembly. This prohibition is due to the difference in stiffness, strength, and performance of shear walls with different sheathing materials that, when combined, may result in unexpected load distribution and failure. However, if the gypsum is to be used to resist the lateral forces in the design, the walls included in the design must have the gypsum attached to the top and bottom plates of the wall framing. This is not the typical attachment used by most drywall installers. The concept of floating corners has been recommended by most drywall manufacturers to prevent cracking of the taped drywall wall-to-ceiling joint. If floating corners are used, the gypsum is totally ineffective in resisting any lateral loads unless the wall deformation causes the gypsum panel to bear on an adjacent structural element (e.g., in a corner).

ASPECT RATIO FOR WOOD AND CFS LIGHT-FRAME BUILDINGS

Shear wall aspect ratio also plays a role in the performance of light-frame shear wall assemblies. Although similar strength may be observed for shear walls of different aspect ratios, with ratios over 2:1 flexural bending of the wall becomes more dominant than shear/fastener deformation. Testing showed that these high aspect ratio walls are more flexible and will not satisfy the required seismic drift limit performance objective without a reduction in design capacity and corresponding design level drift. Therefore, a reduction factor, $2w/h$, was implemented in the AF&PA standard for those shear wall assemblies exceeding 2:1 but not exceeding 3.5:1. The same reduction is applied in the AISI standard for shear wall assemblies with aspect ratios not exceeding 4:1. Also, it should be noted that as walls get narrower, it is crucial to ensure proper installation of the shear wall components (e.g., hold-down connections) since poor installation will lower the performance significantly more (i.e., excessive top of wall drift) than would be seen by a lower aspect ratio wall.

WOOD MOISTURE ISSUES

Significant changes in moisture content (> 8 percent) can affect physical wood properties by swelling or shrinking wood fibers which, in turn, can affect wood connections. Testing by APA shows that wood-frame shear walls do not lose capacity due to moisture changes; however, nail slip is increased and, thus, shear wall deflections increase (APA, 2002). To minimize any negative effects of increased shear wall deflections, the designer should specify dry lumber or engineered wood products (which are typically dry) for optimized structures.

WOOD FRAMING FORCES AND CONNECTIVITY

Tension Failures of Wood Posts. It is unusual for tension posts in walls to fail in tension if the only tension force is the induced force associated with the racking and overturning of the wall segment itself. However, if the load path from upper stories causes significant additional tension forces in the post, failure can occur through three possible mechanisms: net section failure, combined bending and tension failure, and connection failure. Tension posts should be designed with checks for all three failure mechanisms.

Compression Failure of Wood Posts. Compression failures in wood posts are typically associated with high compression load due to accumulation of load due to load path considerations. The possible failure mechanisms are: traditional buckling and beam-column action.

Buckling of the post is usually restricted to the out-of-plane direction of the wall because of the continuous support provided by the sheathing in the plane of the wall. The designer must account for the entire load being supplied to the compression post including the compression induced by the racking and overturning of the wall element itself plus the compression forces being transferred to the post by the stories above and any headers attached to the post. Buckling of isolated, stand-alone posts must be checked in both directions.

Weak Axis Bending of Wood Studs. Shear failures in studs have been observed in wall tests and field studies where strong sheathing materials (e.g., stucco) fail at connections along the bottom of the wall. This causes the next row of fasteners from the bottom of the wall to transfer all of the lateral loads into the studs, thus loading the studs in bending about their weak axis. Typically, the failure occurs at about 1/3 the height of the stud.

Wood Cross-Grain Bending. Cross-grain bending of wood members leads to failure at relatively low loads. Of particular concern are locations where ledger boards are loaded perpendicular to their length and at shear wall foundation sill plates. For ledgers, the connection between the diaphragm and the masonry or concrete wall should connect the longitudinal diaphragm framing member (or a series of blocked joists) directly to the wall rather than to the ledger. In shear walls, wide steel plate washers and stiff hold-down connectors or straps should be used to reduce the cross-grain bending action.

Bearing Failure of Wood Plate. The failure of the bottom plate of the wall due to compression perpendicular to grain causes damage to the wood member holding sheathing fasteners along the bottom of the wall. Added deformation of walls with wood framing loaded perpendicular to grain at wood floor levels compared to walls located on slabs-on-grade has been observed in testing and should be accounted for in analysis of drift. Guidance on this effect needs to be developed.

Sheathing Connectors to Wood Studs. The primary source of drift and energy dissipation of wood-frame shear walls is the bending and yielding of the shear wall sheathing to framing fasteners around the perimeter of each sheathing panel accompanied by slip between the sheathing and framing. In most wood-frame shear walls, the racking of the wall causes yielding of sheathing to framing fasteners along with local crushing of the framing and sheathing due to fastener bearing. Other common sheathing fastener behaviors include nail heads pulled through the sheathing and withdrawal of the nail from the framing member. A less desirable behavior is the tear-out of the fastener through the edge of the sheathing; increasing the edge distance from the center of the fastener to the edge of the sheathing panel to not less than ½ in. can help to reduce the occurrence of this behavior.

COLD-FORMED STEEL MEMBER CONSIDERATIONS

Local Damage of Framing. The thin-walled nature (i.e., small thickness) of CFS framing members makes them vulnerable to physical damage that may have an adverse effect on the structural performance (AISI S200-07). Full damage assessment is not within the scope of the AISI standards and, consequently, when damage alters the cross-section geometry of a framing member beyond the specified tolerances, the designer should be consulted (American Iron and Steel Institute, 2007c).

Web Holes. As with any material, large holes may affect the structural performance of CFS framing members. Therefore, CFS framing standards (AISI S200-07) require that: "Holes in webs of studs, joists and tracks shall be in conformance with

an approved design, AISI S100, or an approved design standard. Webs with holes not conforming to the above shall be reinforced or patched in accordance with an approved design or approved design standard."

In CFS framing members, a "punchout" is defined as a hole made during the manufacturing process in the web of a steel framing member (AISI S200-07). Suitable dimensions and locations of standard punchouts are further defined (AISI S201-07; AISI, 2007d).

Nominal shear strengths for shear walls that have been included in industry design standards are based on tests with studs with 1.5-in. (38 mm) x 4-in. (100 mm) punch outs at a center-to-center spacing of 24 inches (600 mm) and, as a result, the use of studs with standard punch outs is permitted when using these values (AISI S213-07).

Local Buckling of CFS Framing Members. CFS framing members are susceptible to local buckling when loaded in compression. Consequently, local buckling is a necessary design consideration for CFS members. To that end, CFS framing standards (AISI S213-07) specify that: "The proportioning, design and detailing of cold-formed steel light-frame systems, members, connections and connectors … be in accordance with AISI S100."

AISI S100-07 considers local buckling of individual elements of CFS members as a major design criterion. As such, AISI S100-07 requires that the design of such members provide sufficient safety against the failure mode with due consideration to post-buckling strength. Post-buckling strength of plate elements was identified experimentally in 1928. In order to utilize the post-buckling strength for design purposes, AISI has used the effective design width approach to determine the section properties since 1946.

The designer should pay particular attention to the buckling performance for collectors and headers that are acting as drag struts. These members can have relatively high compression forces and must be designed for cyclic loading. The local transfer of forces into wall or diaphragm elements also becomes an area where localized buckling can occur.

Bending Failure of CFS Framing Members. The difference in local buckling behavior between stiffened and unstiffened elements results in a significant difference in the weak axis bending strength between stud and track members. Weak axis bending strength of a track member is typically lower than that of a stud. This makes proper design and detailing of wall anchorage important in order to minimize bending loads on track members. Connection of the anchorage device directly to the chord stud is a common detail that effectively eliminates bending loads on track members.

Bending Deformation of CFS Track Web. CFS framing members offer limited strength and stiffness to resist transverse concentrated loads such as would be applied by an anchor bolt with standard cut washer through the track web if used to resist wall uplift forces. This is similar to the concern regarding cross grain bending in a wood bottom plate with a similar anchorage detail.

Consequently, the AISI CFS framing standards (AISI S213-07) require that: "Studs or other vertical boundary members at the ends of wall segments, that resist seismic loads, braced with either sheathing or diagonal braces, … be anchored such that the bottom track is not required to resist uplift by bending of the track web."

Connection of the anchorage device directly to the chord stud is the most common detail that effectively eliminates transverse concentrated loads on track members. Use of a C-shape section (i.e., stud) reinforcement or a plate washer at anchor bolts are other ways to distribute transverse concentrated loads that may avoid this problem.

CFS Sheathing Connectors. As with wood-frame shear walls, in CFS shear walls inelastic behavior is primarily concentrated at the fasteners connecting the sheathing to the wall-framing members. However, the behavior of sheathing screw fasteners in CFS framing members is different from the behavior of sheathing nails in wood framing.

Nguyen et al. (1996) report: "In general, racking of the wall resulted in the screw fasteners rocking (tilting) about the plane of the stud flange material immediately around the screw. This behavior resulted in permanent lateral deflection of the wall and appears to be the main source of energy dissipation in the walls. As the lateral displacement of the wall increased, the panel pulled over the screw heads and became unzipped."

Screw size must be sufficient to preclude the screw shear failure mode. Thus, the screw size needs to be properly matched with framing member thickness to assure the desired behavior. The AISI CFS framing standards (AISI S213-07) require that: "Unless noted as (min.), substitution of a stud or track of a different designation thickness is not permitted."

For CFS framing, AISI S200-07 indicates: "Ends of structural wall studs shall have square end cuts and shall be seated tight against the tracks. For the purpose of this section, seated tight shall mean that a maximum gap tolerance of 1/8 inch (3.2 mm) will be acceptable between the end of wall framing member and the track." The CFS framing end gap does not adversely affect strength, but it is likely to contribute to system flexibility and shear wall deflection.

Testing has shown that a smaller gap tolerance may be suitable in some situations. For instance, testing of thicker materials (greater than 0.054 in.) showed that "the relative movement between the stud and track could result in shear failure of the screws." In these cases, a smaller gap tolerance of 1/16 in. (1.6 mm) may be more appropriate. AISI S200-07 further indicates: "a smaller gap tolerance may also be desirable in multi-story structures where the accumulation of these gap closures may become significant. Depending on track radius, it may be necessary to oversize the depth of the track to assure that the stud flanges do not prematurely engage the track radius and result in an excessive gap."

The designer should take the above into consideration when calculating shear wall deflections by considering the effect of the end gap in the fourth term of the deflection equation (i.e., lateral contribution from anchorage/hold-down deformation)(AISI S213-07).

Pull-Out Resistance of CFS Screw Fasteners. The pull-out resistance of screw fasteners may be reduced when the fasteners are cyclically loaded (Mahendran and Maharaachchi, 2000). Consequently, CFS framing standards (AISI S213-07) require that: "The pull-out resistance of screws … not be used to resist seismic forces."

2009 *NEHRP RECOMMENDED SEISMIC PROVISIONS* PROJECT PARTICIPANTS

2008-2009 BSSC BOARD OF DIRECTION

Chair

David R. Bonneville, PE, SE, Degenkolb Engineers, San Francisco, California

Vice Chair

Position vacant

Secretary

James Rinner, J. E. Dunn Construction Company, Topeka, Kansas (representing the Associated General Contractors of America)

Ex Officio

Jim. W. Sealy, FAIA, Architect/Consultant, Dallas, Texas

Members

Edwin Dean, PE, SE, Nishkian Dean, Portland, Oregon (representing the Applied Technology Council)

Cynthia J. Duncan, American Institute of Steel Construction, Chicago, Illinois

Jay W. Larson, PE, FASCE, American Iron and Steel Institute, Bethlehem, Pennsylvania

Joseph Messersmith, Portland Cement Association, Rockville, Virginia

Ronald E. Piester, RA, New York State Department, Division of Code Enforcement and Administration (representing the International Code Council)

Timothy Reinhold, Institute for Building and Home Safety, Tampa, Florida

James Rossberg, PE, American Society of Civil Engineers, Reston, Virginia

James "Tim" Ryan, CBO, City of Overland Park, Kansas (representing the National Institute of Building Sciences)

Gregory Schindler, PE, SE, KPFF Consulting Engineers, Seattle, Washington (representing the National Council of Structural Engineers Associations)

Charles Spitz, NCARB, AIA, CSI, Architect/Planner Code Consultant, Wall, New Jersey (representing the American Institute of Architects)

S. Shyam Sunder, National Institute of Standards and Technology, Gaithersburg, Maryland (representing the Interagency Committee for Seismic Safety in Construction)

Robert D. Thomas, National Concrete Masonry Association, Herndon, Virginia

David P. Tyree, PE, CBO, American Forest and Paper Association, Colorado Springs, Colorado

2007-2008 BSSC BOARD OF DIRECTION

Chair

Henry Green, Bureau of Construction Codes, State of Michigan Department of Consumer and Industry Services, Okemos, Michigan

Vice Chair

David R. Bonneville, PE, SE, Degenkolb Engineers, San Francisco (representing the Earthquake Engineering Research Institute)

Secretary

James Rinner, Kitchell CEM, Sacramento, California (representing the Associated General Contractors of America)

Ex Officio

Jim. W. Sealy, FAIA, Architect/Consultant, Dallas, Texas

Members

Bradford K. Douglas, PE, American Forest and Paper Association, Washington, DC

Edwin Dean, PE, SE, Nishkian Dean, Portland, Oregon (representing the Applied Technology Council)

Cynthia J. Duncan, American Institute of Steel Construction, Chicago, Illinois

Jay W. Larson, PE, FASCE, American Iron and Steel Institute, Bethlehem, Pennsylvania

Joseph Messersmith, Portland Cement Association, Rockville, Virginia

Ronald E. Piester, RA, New York State Department, Division of Code Enforcement and Administration (representing the International Code Council)

Timothy Reinhold, Institute for Building and Home Safety, Tampa, Florida

James Rossberg, PE, American Society of Civil Engineers, Reston, Virginia

Howard Simpson, ScD, PE, Simpson, Gumpertz and Heger, Arlington, Massachusetts (representing the National Council of Structural Engineers Associations)

Charles Spitz, NCARB, AIA, CSI, Architect/Planner Code Consultant, Wall, New Jersey (representing the American Institute of Architects)

S. Shyam Sunder, National Institute of Standards and Technology, Gaithersburg, Maryland (representing the Interagency Committee for Seismic Safety in Construction)

Robert D. Thomas, National Concrete Masonry Association, Herndon, Virginia

2006-2007 BSSC BOARD OF DIRECTION

Chair

Jim W. Sealy, FAIA, Architect/Consultant, Dallas, Texas

Vice Chair

David R. Bonneville, PE, SE, Degenkolb Engineers, San Francisco (representing the Earthquake Engineering Research Institute)

Secretary

James Rinner, Kitchell CEM, Sacramento, California (representing the Associated General Contractors of America)

2009 PROVISIONS UPDATE COMMITTEE

Chair

Ronald O. Hamburger, Senior Principal, Simpson Gumpertz and Heger, San Francisco, California

Ex Officio Voting Member

William Holmes, Vice President, Rutherford and Chekene Engineers, San Francisco, California

Representing Technical Subcommittee 1, Document Composition and Management

William Holmes, Vice President, Rutherford and Chekene Engineers, Oakland, California

John D. Gillengerten, Deputy Director, Office of Statewide Health and Planning and Development, Sacramento, California

Ronald O. Hamburger, Senior Principal, Simpson Gumpertz and Heger, San Francisco, California

James R. Harris, President, J. R. Harris and Company, Denver, Colorado

John D. Hooper, Director of Earthquake Engineering, Magnusson Klemencic, Seattle, Washington

E. V. Leyendecker, Research Civil Engineer, U.S. Geological Survey, Denver, Colorado

Representing Technical Subcommittee 2, Design Criteria and Analysis and Advanced Technologies

John D. Hooper, Director of Earthquake Engineering, Magnusson Klemencic, Seattle, Washington

Mark Aschheim, Professor, Santa Clara University, California

James R. Harris, President, J. R. Harris and Company, Denver, Colorado

Charles Kircher, Principal, Charles Kircher and Associates Consulting Engineers, Palo Alto, California

Representing Technical Subcommittee 3, Mapping, Foundations and Geotechnical Considerations

C. B. Crouse, Principal Engineer, URS Corporation, Seattle, Washington

Roger Borcherdt, Research Engineering Seismologist, U.S. Geological Survey, Menlo Park, California

E. V. Leyendecker, Research Civil Engineer, U.S. Geological Survey, Denver, Colorado

Jonathan P. Stewart, Professor, University of California, Los Angeles

Representing Technical Subcommittee 4, Concrete Structures

Neil Hawkins, Professor Emeritus, University of Illinois, Clyde Hill, Washington

S. K. Ghosh, Principal, S. K. Ghosh Associates, Palatine, Illinois

Sharon L. Wood, Professor of Civil Engineering, University of Texas, Austin

Representing Technical Subcommittee 5, Masonry Structures

Richard E. Klingner, Professor, University of Texas, Austin

Thomas A. Gangel, Principal, Wallace Engineering Structural Consultants, Tulsa, Oklahoma

Jason J. Thompson, Structural Engineer, National Concrete Masonry Association, Herndon, Virginia

Representing Technical Subcommittee 6, Steel and Composite Steel and Concrete Structures

James O. Malley, Senior Principal, Degenkolb Engineers, San Francisco, California

Roberto T. Leon, Professor, School of Civil and Environmental Engineering, Georgia Institute of Technology, Atlanta, Georgia

Bonnie Manley, Regional Director American Iron and Steel Institute, Norfolk, Massachusetts

Representing Technical Subcommittee 7, Wood Structures

Kelly Cobeen, Associate Principal, Wiss, Janney, Elstner Associates, Emeryville, California

J. Daniel Dolan, Professor, Washington State University, Pullman, Washington

Philip Line, Manager, Engineering Research, American Forest and Paper Association, Washington, DC

Representing Technical Subcommittee 8, Nonstructural Components and Nonbuilding Structures

J. G. (Greg) Soules, Principal Engineer, Chicago Bridge and Iron, The Woodlands, Texas

John D. Gillengerten, Deputy Director, Office of Statewide Health and Planning and Development, Sacramento, California

Harold Sprague, Structural Project Engineer, Black and Veatch Special Projects Corporation, Overland Park, Kansas

Representing Issue Team 1, Performance Criteria

William Holmes, Vice President, Rutherford and Chekene Engineers, Oakland, California

Representing Issue Team 2, Design Parameters

Robert E. Bachman, Principal, RE Bachman Consulting Engineers, Laguna Niguel, California
C. Mark Saunders, President, Rutherford and Chekene Consulting Engineers, San Francisco, California

Representing Issue Team 3, Foundation Design Requirements

Martin Johnson, Director ELSR Division, ABS Consulting, Irvine, California

Seismic Design Procedures Review Group

Charles Kircher, Principal, Charles Kircher and Associates Consulting Engineers, Palo Alto, California

PROVISIONS UPDATE PROJECT WORKING GROUPS

Technical Subcommittee 1, Document Composition and Management

Chair

William Holmes, Vice President, Rutherford and Chekene Engineers, San Francisco, California

Members

John D. Gillengerten, Deputy Director, Office of Statewide Health and Planning and Development, Sacramento, California
Ronald O. Hamburger, Structural Engineer, Simpson Gumpertz and Heger, San Francisco, California
James R. Harris, President, J. R. Harris and Company, Denver, Colorado
John D. Hooper, Director of Earthquake Engineering, Magnusson Klemencic, Seattle, Washington
E. V. Leyendecker, Research Civil Engineer, U.S. Geological Survey, Denver, Colorado

Technical Subcommittee 2, Design Criteria and Analysis and Advanced Technologies

Chair

John D. Hooper, Director of Earthquake Engineering, Magnusson Klemencic, Seattle, Washington

Members

Mark Aschheim, Professor, Santa Clara University, California
James R. Harris, President, J. R. Harris and Company, Denver, Colorado
Charles Kircher, Principal, Charles Kircher and Associates Consulting Engineers, Palo Alto, California
Finley Charney, Associate Professor, Virginia Polytechnic Institute and State University, Blacksburg
Michael Constantinou, Professor, State University of New York, Buffalo
Martin Johnson, Director ELSR Division, ABS Consulting, Irvine, California
Joe Maffei, Rutherford and Chekene Consulting Engineers, San Francisco, California
Alan Scott, Principal/Division Manager, KPFF Consulting Engineers, St. Louis, Missouri

Corresponding Members

Ian Aiken, Principal, Seismic Isolation Engineering, Piedmont, California
Mohammed Ettouney, Principal, Weidlinger Associates, New York, New York
Subhash Goel, Professor, University of Michigan, Ann Arbor
Husein Hasan, Senior Civil Engineer, Tennessee Valley Authority, Knoxville
Saif Hussain, Managing Principal, SHA Coffman Engineers, Encino, California
Marcelino Iglesias, Code Specialist, New Jersey Division of Codes and Standards, Trenton
Leonard Joseph, Senior Vice President, Thornton-Tomasetti Engineers, New York, New York
Sanj Malushte, Senior Engineering Specialist, Bechtel Corporation, Frederick, Maryland
Kit Miyamoto, President and CEO, Marr Chatter and Miyamoto, West Sacramento, California
Mark Pierepiekarz, MRP Engineering, Newcastle, Washington
Wenshen Pong, Assistant Professor, San Francisco State University, California
Andrei Reinhorn, Professor and Chairman, State University of New York, Buffalo
James Russell, Building Code Consultant, Concord, California
Gary Searer, Senior Engineer, Wiss, Janney, Elstner Associates, Emeryville, California
Sayed Stoman, Chief Engineer, Caldwell Tanks, Peactree City, Georgia

Andrew Taylor, Associate, KPFF Consulting Engineers, Seattle, Washington
Michael Valley, Associate, Magnusson Klemencic, Seattle, Washington
Andrew Whittaker, Associate Professor, State University of New York, Buffalo

Technical Subcommittee 3, Mapping, Foundations and Geotechnical Considerations

Chair

C. B. Crouse, Principal Engineer, URS Corporation, Seattle, Washington

Members

Roger Borcherdt, Research Engineering Seismologist, U.S. Geological Survey, Menlo Park, California
E. V. Leyendecker, Research Civil Engineer, U.S. Geological Survey, Denver, Colorado
Jonathan P. Stewart, Professor, University of California, Los Angeles
Donald Anderson, Principal Geotechnical Engineer, CH2M Hill, Bellevue, Washington
Kenneth Campbell, Vice President, ABS Consulting Group, Beaverton, Washington
Tom Hale, Structural Engineer, OSHPD, Sacramento, California
Jeffery Kimball, Technical Specialist, National Nuclear Security Administration, Germantown, Maryland
Nicholas Luco, USGS, Denver, Colorado
Mark Moore, Senior Associate, Rutherford and Chekene, Oakland, California
Farhang Ostradan, Chief Soils Engineer, Bechtel Corporation, San Francisco, California
Maurice Power, Principal Engineer, Geomatrix Consultants, Oakland, California
Mishac Yegian, Professor, Northeastern University, Boston, Massachusetts

Corresponding Members

Yousef Bozorginia, Associate Director, Pacific Earthquake Engineering Research (PEER), Richmond, California
Philip Caldwell, Staff Engineer, Square D/ Schneider Electric, Seneca, South Carolina
Susan Chang, Principal Engineer, Shannon and Wilson, Seattle, Washington
Paul Cloke, Professor Emeritus, University of Michigan, Prescott, Arizona
Craig Comartin, President, Comartin-Reis, Stockton, California
Ricardo Dobry, Professor, Rensselaer Polytechnic Institute, Troy, New York
Husein Hasan, Senior Civil Engineer, Tennessee Valley Authority, Knoxville
Tara Hutchinson, Associate Professor, University of California, San Diego
Jeffery Keaton, Senior Principal Engineering Geologist, MACTEC Engineering and Consulting, Los Angeles, California
Praveen Malhotra, Senior Research Scientist, FM Global, Norwood, Massachusetts
Geoffrey Martin, Professor Emeritus, University of Southern California, Los Angeles
Richard McConnell, Consultant, Springfield, Virginia
Adrian Rodriguez-Marek, Assistant Professor, Washington State University, Pullman
Dario Rosidi, Principal Technologist, CH2M Hill, Oakland, California

Technical Subcommittee 4, Concrete Structures

Chair

Neil Hawkins, Professor Emeritus, University of Illinois, Clyde Hill, Washington

Members

S. K. Ghosh, Principal, S. K. Ghosh Associates, Palatine, Illinois
Sharon L. Wood, Professor of Civil Engineering, University of Texas, Austin
David Arndt, Associate, KPFF Consulting Engineers, Seattle, Washington
Ned Cleland, president, Blue Ridge Design, Winchester, Virginia
W. Gene Corley, Senior Vice President, CTL Group, Skokie, Illinois
David Gustafson, Vice President of Engineering, Concrete Reinforcing Steel Institute, Schaumburg, Illinois

H.S. Lew, Senior Research Engineer, National Institute of Standards and Technology, Gaithersburg, Maryland
Joe Maffei, Rutherford and Chekene Consulting Engineers, San Francisco, California
Jack Moehle, Professor/Director of Civil Engineering Department, PEER Center, Richmond, California
John Silva, Director Codes and Approvals, Hilti, San Rafael, California
Richard Wollmershauser, Director of Technical Services, HILTI, Tulsa, Oklahoma

Corresponding Members

Husein Hasan, Senior Civil Engineer, Tennessee Valley Authority, Knoxville
Mervyn Kowalsky, Assistant Professor, North Carolina State University, Raleigh
Rene Luft, Principal, Simpson Gumpertz, and Heger, San Francisco, California
Antonio Nanni, Professor, University of Missouri, Rolla

Technical Subcommittee 5, Masonry Structures

Chair

Richard E. Klingner, Professor, University of Texas, Austin

Members

Thomas A. Gangel, Principal, Wallace Engineering Structural Consultants, Tulsa, Oklahoma
Jason J. Thompson, Structural Engineer, National Concrete Masonry Association, Herndon, Virginia
Daniel Abrams, Professor, University of Illinois MAE Center, Urbana
Ronald Barnett, Aercon Florida, Haines City
J. Gregg Borchelt, Vice President, Brick Industry Association, Reston, Virginia
Robert Chittenden, Principal, Chittenden Engineering, Auburn, California
Steve Dill, KPFF Consulting Engineers, Seattle, Washington
David Mclean, Department Chair, Washington State University, Pullman

Corresponding Members

Gregory Kingsley, President and CEO Principal Engineer, KL and A, Golden, Colorado
Robert Lyons, Associate, Brandow and Johnson Associates, Los Angeles, California
Max Porter, Professor, Iowa State University, Ames
Arturo Schultz, Associate Professor, University of Minnesota, Minneapolis
James Tauby, Chief Engineer, Mason Industries, Hauppauge, New York
John Tawresey, KPFF Consulting Engineers, Seattle, Washington
Diane Throop, Consultant, Cincinnati, Ohio
Terence Weigel, Associate Professor, University of Louisville, Kentucky

Technical Subcommittee 6, Steel and Composite Steel and Concrete Structures

Chair

James O. Malley, Senior Principal, Degenkolb Engineers, San Francisco, California

Members

Roberto T. Leon, Professor, School of Civil and Environmental Engineering, Georgia Institute of Technology, Atlanta, Georgia
Bonnie Manley, Regional Director American Iron and Steel Institute, Norfolk, Massachusetts
Michael Cochran, Associate principal, Weidlinger Associates, Inc., Los Angeles, California
Jerome Hajjar, Professor, University of Illinois at Urbana-Champaign, Urbana
C. Mark Saunders, President, Rutherford and Chekene Consulting Engineers, San Francisco, California
W. Lee Shoemaker, Director of Research and Engineering, Metal Building Manufactures Association, Cleveland, Ohio
Kurt Swensson, President, KSI / Structural Engineers, Atlanta, Georgia
Chia-Ming Uang, Professor, University of California-San Diego, La Jolla, California

Corresponding Members

Michel Bruneau, Professor, Department of Civil, Structural, and Environmental Engineering, State University of New York, Buffalo

Scott Civjan, Assistant Professor, University of Massachusetts, Amherst

Gregory Deierlein, Professor, Stanford University, Stanford, California

Cynthia Duncan, Director of Specifications, American Institute of Steel Construction, Chicago, Illinois

Jeff Ellis, Code Report and Branch Engineering Manager, Simpson Strong-Tie, Brea, California

Subhash Goel, Professor, University of Michigan, Ann Arbor

Husein Hasan, Senior Civil Engineer, TVA, Knoxville, Tennessee

Neil Hawkins, Professor Emeritus, Clyde Hill, Washington

Jay Larson, American Iron and Steel Institute, Bethlehem, Pennsylvania

Terry Lundeen, Principal, Coughlin Porter Lundeen, Seattle, Washington

Robert Lyons, Associate, Brandow and Johnston Associates, Los Angeles, California

Wenshen Pong, Assistant Professor, San Francisco State University, California

Rafael Sabelli, Director of Seismic Design, WALTER P. MOORE, San Francisco, California

Stephen Schneider, Kramer-Gehlen and Associates, Vancouver, Washington

Bahram Shahrooz, Associate Professor, University of Cincinnati, Ohio

Bozidar Stojadinovic, Assistant Professor, University of California, Berkeley

James Thomas, TLC Engineering for Architecture, Cocoa, Florida

Steven Thomas, Division Engineer, Butler Construction, Kansas City, Missouri

Technical Subcommittee 7, Wood Structures

Chair

Kelly Cobeen, Associate Principal, Wiss, Janney, Elstner Associates, Emeryville, California

Part 1 - Members

J. Daniel Dolan, Professor, Washington State University, Pullman, Washington

Philip Line, Manager, Engineering Research, American Forest and Paper Association, Washington, DC

Philip Brazil, Senior Engineer, Reid Middleton, Everett, Washington

Robert Chittenden, Principal, Chittenden Engineering, Auburn, California

Andre Filiatrault, Deputy Director MCEER, State University of New York, Buffalo

Robert George, Architect, South San Francisco, California

Erol Karacabeyli, Manager Wood Engineering Department, Forintek Canada Corporation, Vancouver, BC

Vladimir Kochkin, Research Engineer, National Association of Home Builders Research, Upper Marlboro, Maryland

James Mahaney, Principal, Wiss, Janney, Elstner Associates, Auburn, California

Gary Mochizuki, Principal Structural Engineer, Structural Solutions, Inc., Walnut Creek, California

Rawn Nelson, Structural Engineer, R.F. Nelson and Associates, Hermosa Beach, California

Steven Pryor, Building Systems R & D Manager, Simpson Strong-Tie, Pleasanton, California

Thomas Skaggs, Manager, Product Evaluation, APA-The Engineered Wood Association, Tacoma, Washington

Corresponding Members

David Adams, Structural Engineer, Tulare, California

Scott Beard, Structural Engineer, City of Tacoma, Washington

Kevin Cheung, Director, Technical Services, Western Wood Products Association, Portland, Oregon

Patrick Edwards, Vice President/Director of Engineering, TP Engineering, Trussville, Alabama

Jeff Ellis, Code Report & Branch engineering Manager, Simpson Strong-Tie, Brea, California

Rick Fine, Structural Engineer, Fine Engineering, Snohomish, Washington

Robert Johnson, President, R.I. Johnson and Associates, Wheaton, Illinois

Jay Larson, American Iron and Steel Institute, Bethlehem, Pennsylvania

Bonnie Manley, Regional Director, American Iron and Steel Institute, Walpole, Massachusetts

Zeno Martin, Engineer, APA-The Engineered Wood Association, Tacoma, Washington

Frank Park, Supervisor of Engineering/Construction Plan Review, County of Guilford, Greensboro, North Carolina

Marjan Popovski, Research Scientist - Building Systems Department, Forintek, Vancouver, BC, Canada

Douglas Rammer, Research Engineer, USDA Forest Products Laboratory, Madison, Wisconsin

Colin Rogers, Professor, McGill University, Montreal, QC, Canada

Richard Silva, Seismic Safety Program Manager, National Park Service, Denver, Colorado

Howard Smith, District Structural Engineer, Division of the State Architect, Department of General Services, Sacramento, California

Charles Spitz, Architect-Planner-Code Consultant, Wall, New Jersey

John van de Lindt, Associate Professor, Department of Civil Engineering, Colorado State University, Fort Collins

Technical Subcommittee 8, Nonstructural Components and Nonbuilding Structures

Chair

J. G. (Greg) Soules, Principal Engineer, Chicago Bridge and Iron, The Woodlands, Texas

Members

John D. Gillengerten, Senior Structural Engineer, Office of Statewide Health and Planning and Development, Sacramento, California

Harold Sprague, Structural Project Engineer, Black and Veatch Special Projects Corporation, Overland Park, Kansas

Robert E. Bachman, Principal, RE Bachman Consulting Engineers, Laguna Niguel, California

Victor Azzi, Consulting Structural Engineer, RMI, Rye, New Hampshire

Philip Caldwell, Staff Engineer, Square D / Schneider Electric, Seneca, South Carolina

Susan Dowty, Structural, Seismic and Code Consultant, S. K. Ghosh Associates, Laguna Niguel, California

James Lake, Fire Protection Engineer, NFPA International, Quincy, Massachusetts

Patrick Lama, Vice President, Mason Industries, Hauppage, New York

Ronald Haupt, Senior Consultant, Pressure Piping Engineering Associates, Foster City, California

Sanj Malushte, Senior Engineering Specialist, Bechtel Corporation, Frederick, Maryland

John Silva, Director Codes and Approvals, Hilti, San Rafael, California

Jeffery R. Soulages, Facilities Systems Engineering Manager, INTEL, Hillsboro, Oregon

Corresponding Members

David Adams, Structural Engineer, Tulare, California

Scott Ashford, Professor and Chair, Oregon State University, Corvallis

Antonia Braga, Senior Engineer, FM Global, Woodland Hills, California

Martin Eskijian, Supervisor Engineering Branch, California State Land Commission, Long Beach

Husein Hasan, Senior Civil Engineer, TVA, Knoxville, Tennessee

Douglas Honegger, Principal, D.G. Honegger Consulting, Arroyo Grande, California

Francis Jehrio, Engineering Specialist, York International Corporation, York, Pennsylvania

Brian Kehoe, Consultant, Emeryville, California

Theodore Lemoff, Principal Gases Engineer, NFPA International, Quincy, Massachusetts

John Loscheider, Principal, Loscheider Engineering Company, Renton, Washington

Panos G. Papavizas, Manager, Engineering Systems and Processes, Baltimore Aircoil Company, Jessup, Maryland

Rolf Pawski, Landmark Structures, Wheaton, Illinois

Mark Pierepiekarz, MRP Engineering, Newcastle, Washington

Denis Radecki, Senior Structural Engineer, Hamon Custodis, Brazil, Indiana

David Sheppard, Structural Engineer, D.A. Sheppard Consulting Engineer, Sonora, California

Richard Silva, Seismic Safety Program Manager, National Park Service, Denver, Colorado
Anthony Shelton, Mechanical Engineer, Kone, Inc., McKinney, Texas
Charles Spitz, Architect-Planner-Code Consultant, Wall, New Jersey
John Stevenson, Senior Consultant, Stevenson and Associates, Cleveland, Ohio
William Stewart, Architect, Stewart-Schaberg/Architects, Chesterfield, Missouri
Victoria Valentine, Manager of Product Standards, National Fire Sprinkler Association, Patterson, New Jersey
Michael Werner, Deputy public Works Director, Code Enforcement, County of St. Louis, Missouri
Peter Yin, Section Head, Structures, Port of Los Angeles, San Pedro, California

Seismic Design Procedures Review Group

Chair

FEMA

FEMA P-750
Catalog No. 09349-2

State of California ≈ Department of Justice
OFFICE of the ATTORNEY GENERAL
KAMALA D. HARRIS

ENVIRONMENTAL JUSTICE

“Environmental Justice" is the fair treatment of people of all races, cultures, and incomes with respect to the development, adoption, implementation, and enforcement of environmental laws, regulations, and policies.

The Attorney General is particularly concerned that local governments, in permitting new projects, consider potentially significant environmental impacts on communities already burdened with pollution, as required by the California Environmental Quality Act. The Attorney General also continues to lead in the fight against global warming; as a recent state agency report notes, global warming will hit our most vulnerable citizens the hardest.

The Attorney General considers environmental justice in all of her actions and uses the legal tools available to ensure that all Californians enjoy the benefits of a healthy, safe environment.

ATC-63

FEMA P-695 Quantification of Building Seismic Performance Factors

LATBSDC Annual Meeting
May 7, 2010

Jon A. Heintz
Applied Technology Council
Director of Projects

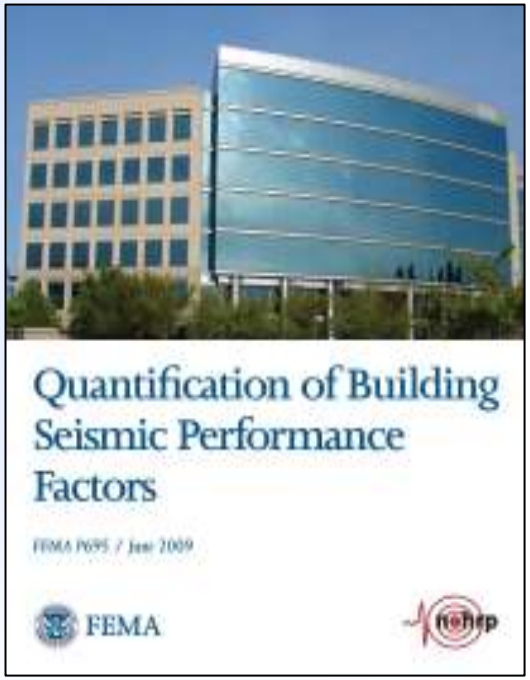
Outline

- Project Context
- Background/Scope/Basis of Methodology
- Methodology Overview
- Example Application to Concrete Moment Frame Systems
- General Findings and Observations

ATC-63 Project Context

ATC-63 Quantification of Building System Performance and Response Parameters

- FEMA funded project
- Multi-year effort beginning in 2004
- FEMA P695 *Quantification of Building Seismic Performance Factors* (FEMA, 2009)
- Genesis is rooted in *R*-factors
  - ✓ But Seismic Performance Factors (Ω_0, C_d) and design requirements are covered



ATC-63 Project Context

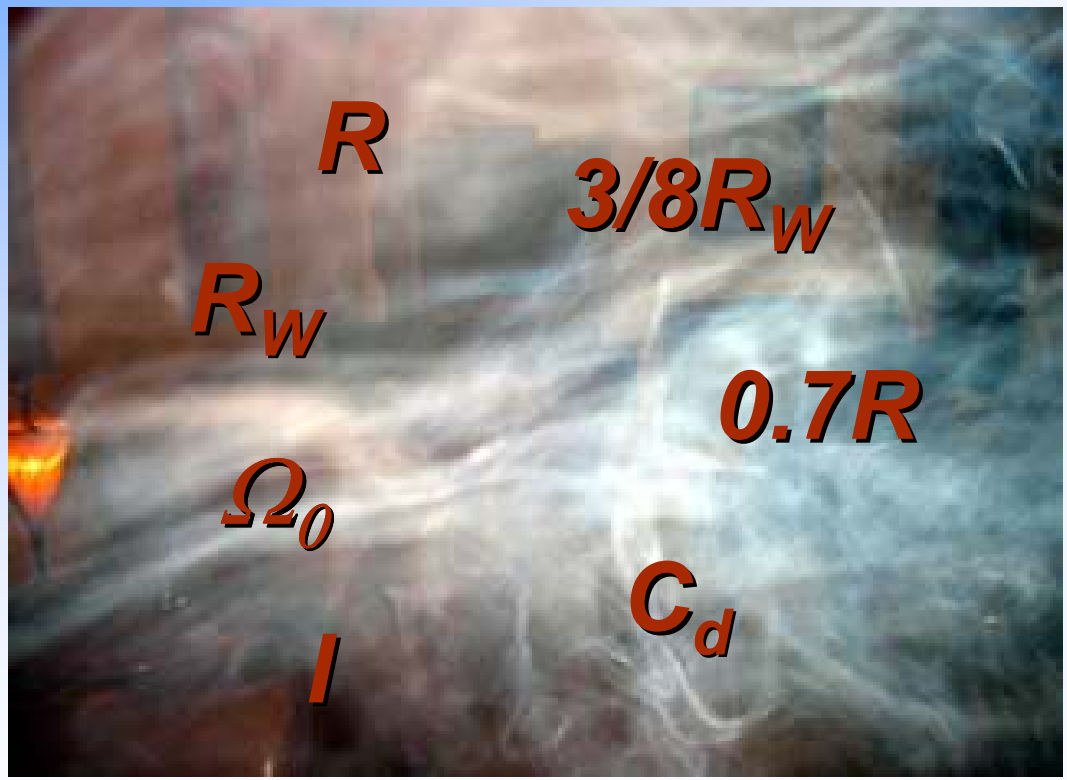
- R-factors were first introduced in 1978
  - ✓ ATC 3-06 *Tentative Provisions for the Development of Seismic Regulations for New Buildings*
- 1988 *NEHRP Recommended Provisions for the Development of Seismic Regulations for New Buildings*
- 1988 Uniform Building Code (UBC)
- 1985 UBC and earlier utilized *K*-factors

ATC-63 Project Context

- *K*-factors – there were essentially 4
  (frame, box, dual system, ductile moment frame)
- ATC 3-06 *R*-factors – there were 21
- 1988 NEHRP Provisions – there were 30
- Today in ASCE/SEI 7-05 – there are 83
- Critically important to seismic design
  - ✓ Set seismic design base shear
  - ✓ Account for system ductility and damping during inelastic response

ATC-63 Project Context

- But how were they determined?

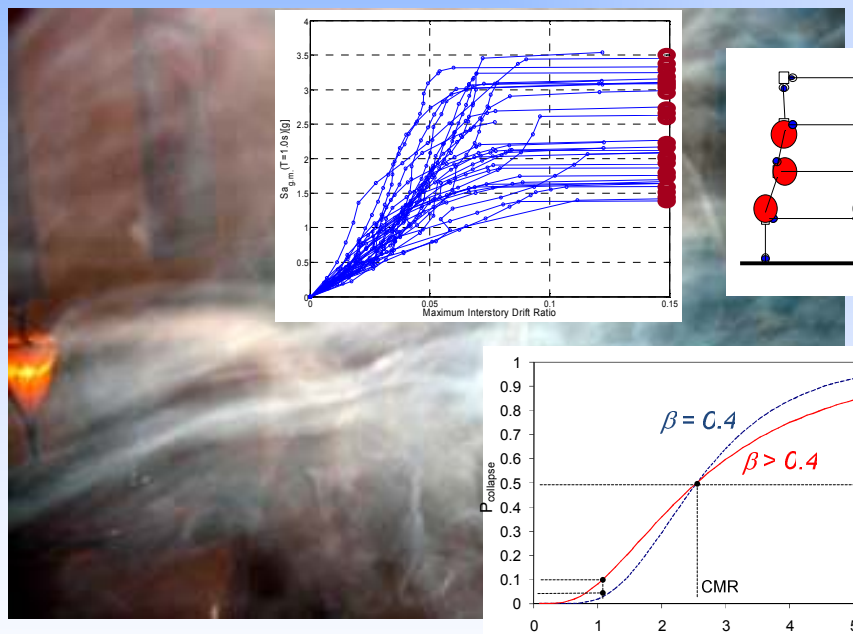


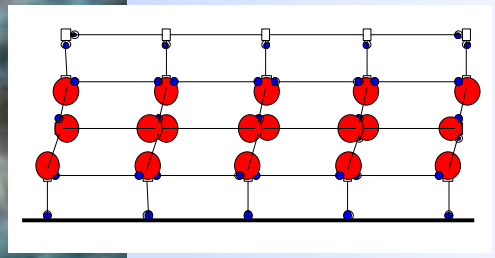
ATC-63 Project Context

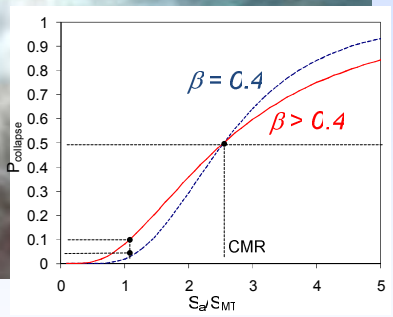
- That was then, this is now
- Advent of Performance Based Seismic Design
  - ✓ SEAOC Vision 2000 (1995)
  - ✓ FEMA 273 NEHRP Guidelines for the Seismic Rehabilitation of Buildings (1997)
- More than a decade of maturation and development of advanced analytical procedures
- We are now attempting to quantify the seismic performance of buildings

ATC-63 Project Context

- And asking the question: What performance goals do our building codes achieve?







$$\beta_{TOT} = \sqrt{\beta_{RTR}^2 + \beta_{DR}^2 + \beta_{TD}^2 + \beta_{MDL}^2}$$

- Objective - replace the smoke with science

Working Groups

Stanford – NDA **Krawinkler – AAC**
SUNY – NSA/NCA **Filiatrault – Wood**

ATC-63 Project Objectives

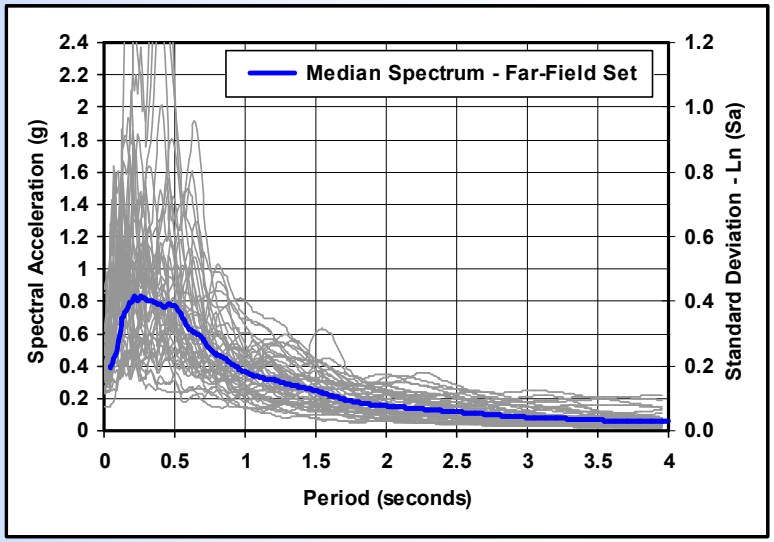
- Primary – Create a methodology for determining Seismic Performance Factors (SPF's) "that, when properly implemented in the design process, will result in the equivalent earthquake performance for buildings different lateral-force-resisting systems"

- Secondary – Evaluate a sufficient number of different lateral-force-resisting systems to provide a basis for Seismic Code committees (e.g., BSSC PUC) to develop a simpler set of lateral-force-resisting systems and more rational SPF's (and related design criteria) that would more reliably achieve the inherent earthquake safety performance objectives of building codes

Scope and Basis of the Methodology

- **New Buildings** – Methodology applies to the seismic-force-resisting system of new buildings and may not be appropriate for non-building structures and does not apply to nonstructural systems.
- ***NEHRP Provisions (ASCE 7-05)*** – Methodology is based on design criteria, detailing requirements, etc. of the *NEHRP Provisions* (i.e., *ASCE 7-05* as adopted by the BSSC for future *NEHRP Provisions* development) and, by reference, applicable design standards
- **Life Safety** – Methodology is based on life safety performance (only) and does not address damage protection and functionality issues (e.g., I = 1.0 will be assumed)
- **Structure Collapse** – Life safety performance is achieved by providing an acceptably low probability of partial collapse and global instability of the seismic-force-resisting system for MCE ground motions
- **MCE Ground Motions** – MCE ground motions are based on the spectral response parameters of the *NEHRP Provisions (ASCE 7-05)*, including site class effects

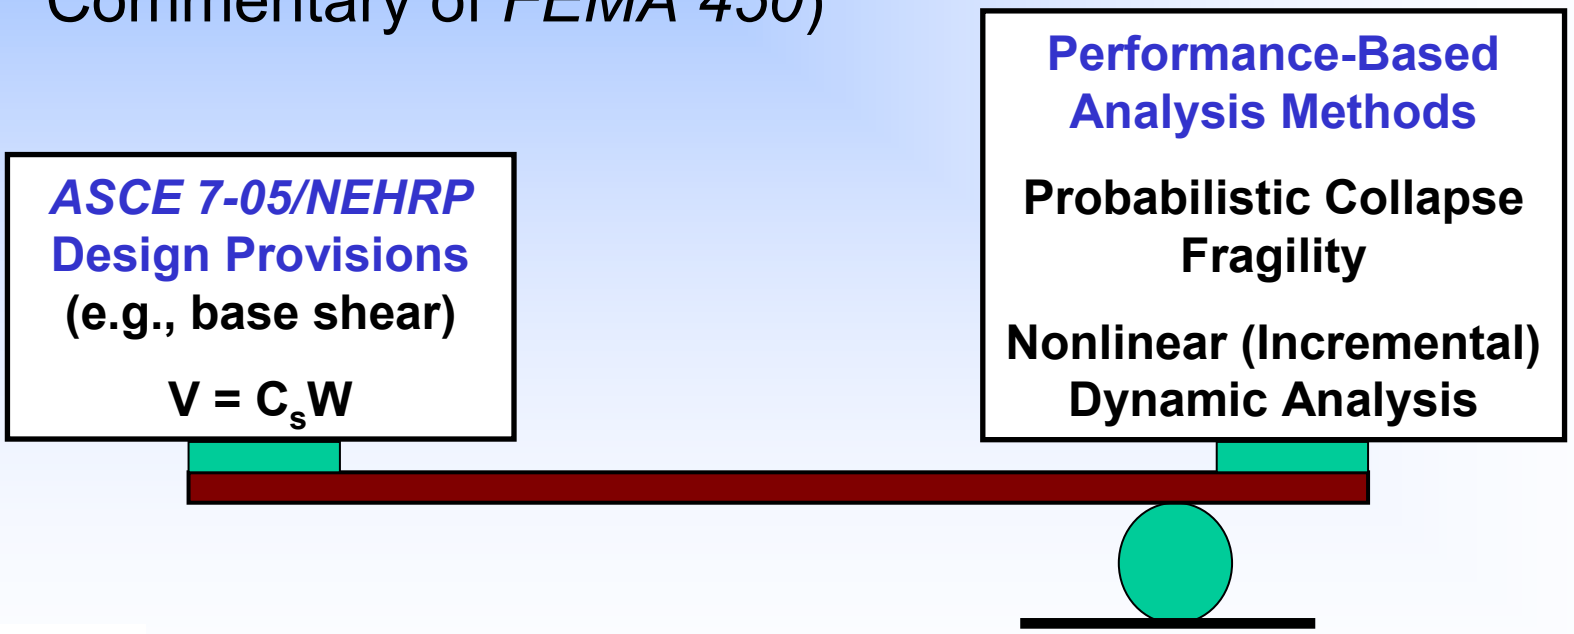
Ground Motion Record Set



- **Far-Field Record Set:**
  R > 10 km
- **Large Magnitude Events:**
  Moment magnitude, M > 6.5
- **Equal Weighting of Events:** ≤ 2 records per event
- **Strong Ground Shaking:** PGA > 0.2g /PGV > 15 cm/sec
- **Source Type:** Both Strike-Slip and Thrust Fault Sources
- **Site Conditions:** Rock or Stiff Soil Sites, Vs > 180 m/s

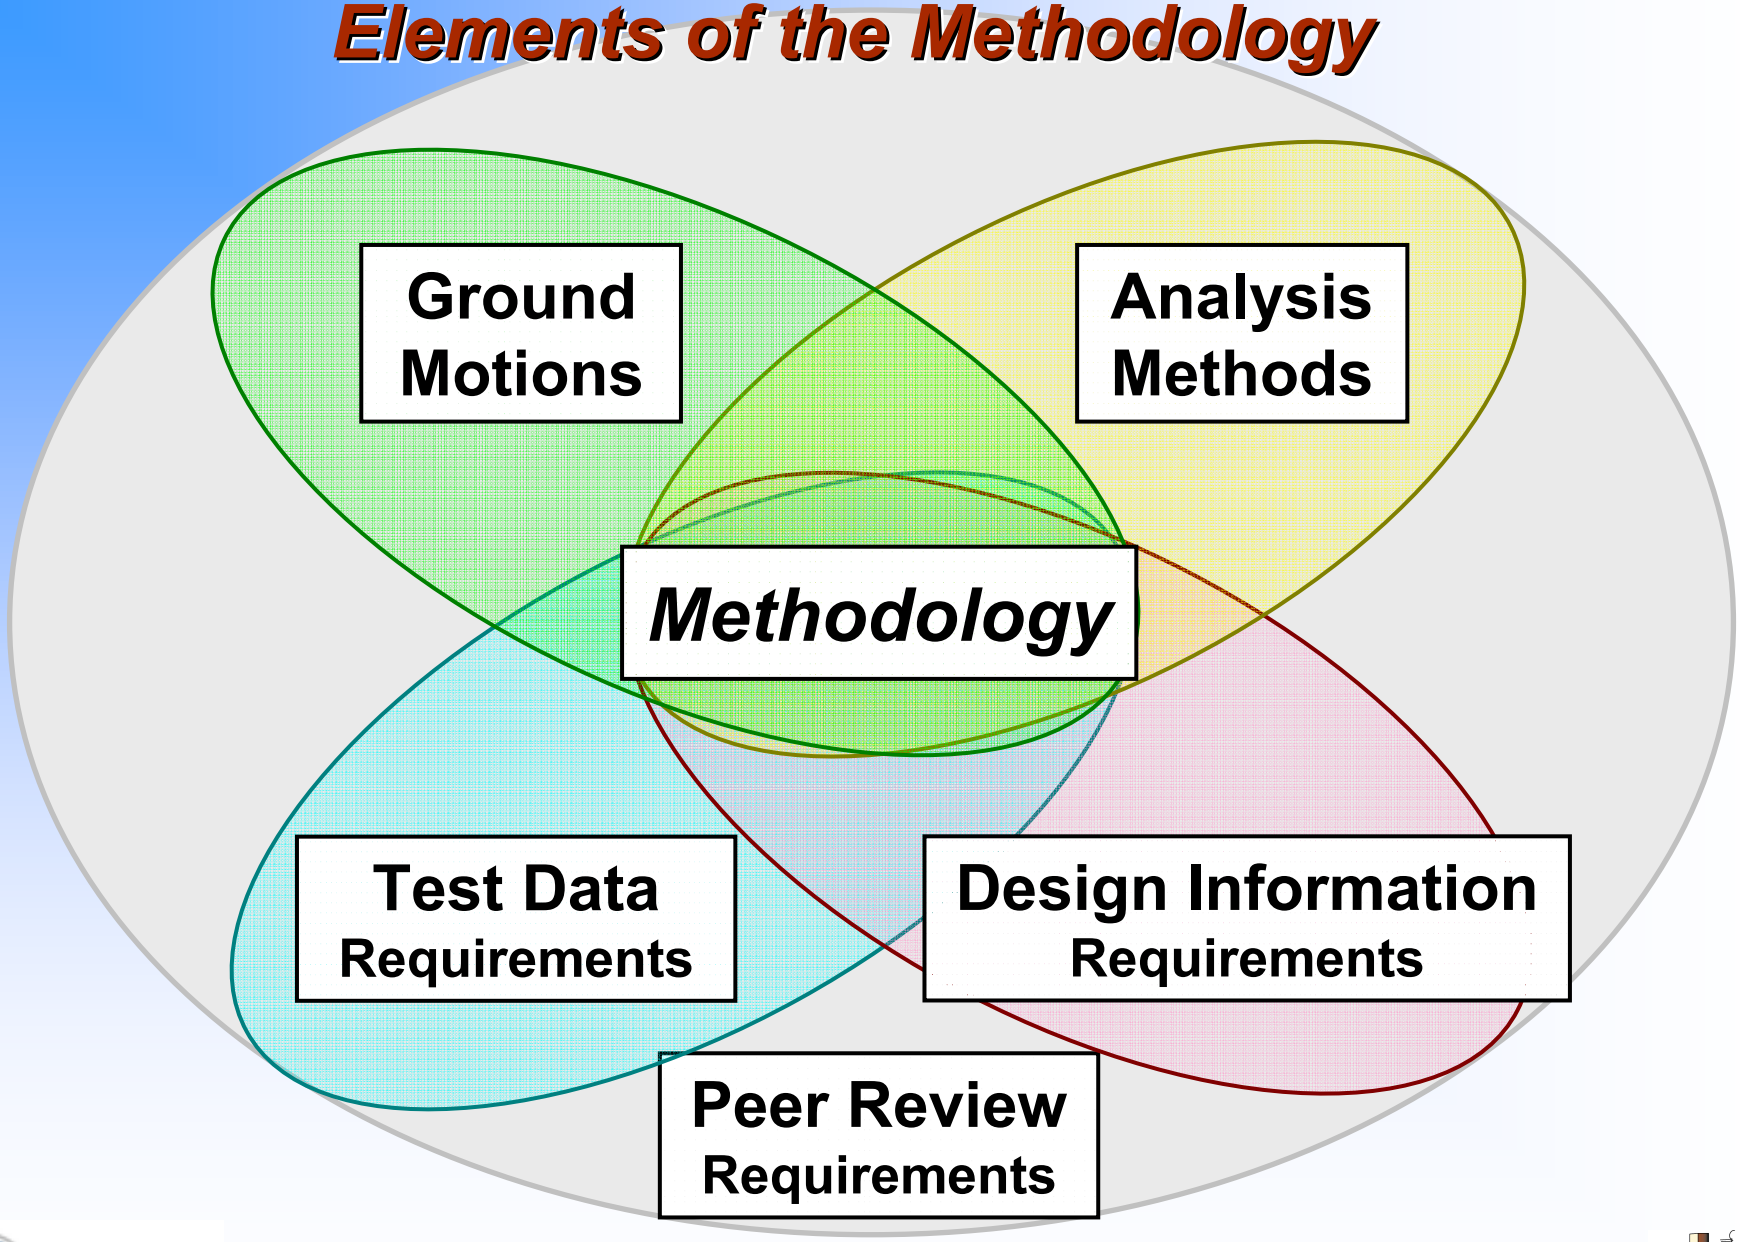
Technical Approach of the Methodology

- Conceptual Framework – Methodology incorporates cutting edge (nonlinear/probabilistic) performance-based analysis methods while remaining true to the basic concepts and definitions of seismic performance factors of *ASCE 7-05* and the *NEHRP Provisions* (e.g., global pushover concept as described in the Commentary of *FEMA 450*)

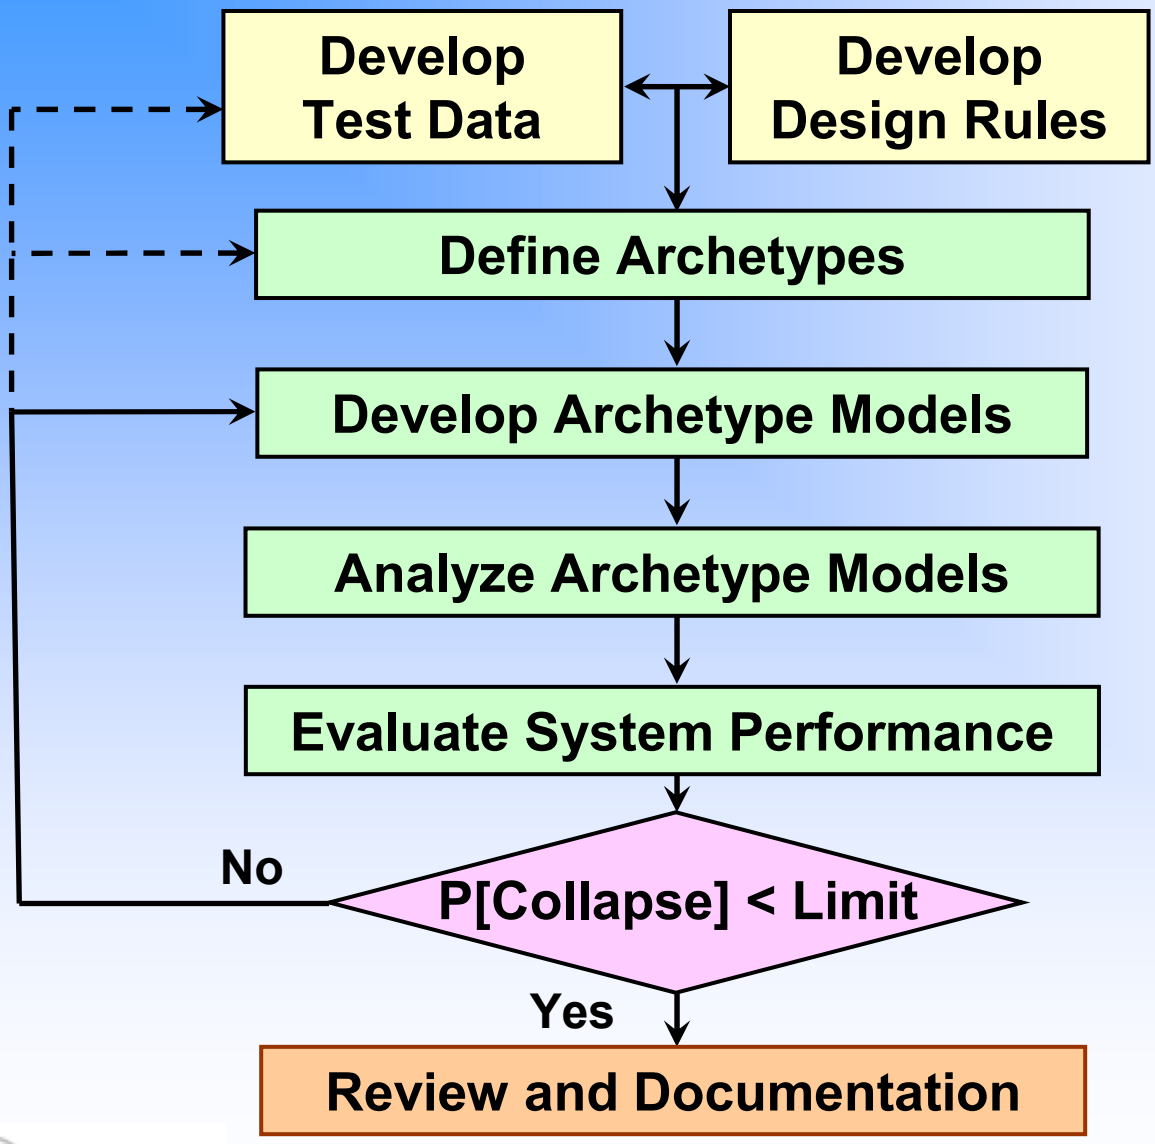


Overview of the Methodology

Elements of the Methodology



Notional Flowchart of Process

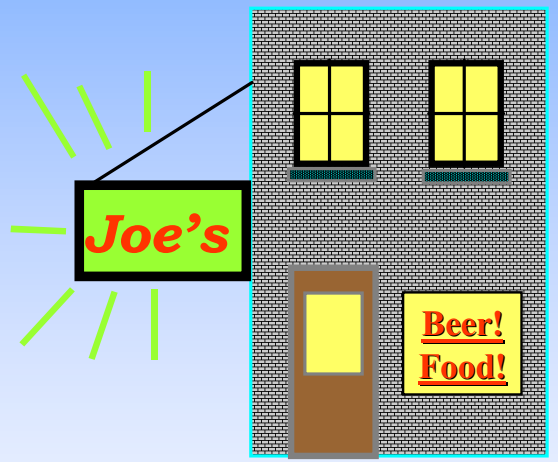


Notes

- "Homework" phase
- Characterize System Behavior
- Design archetypes (w/trial of *R* Factor)
- Perform Pushover and NDA
- Evaluate CMR values (and overstrength)
- Trial value of the *R* factor acceptable?
- Peer Review applies to total process

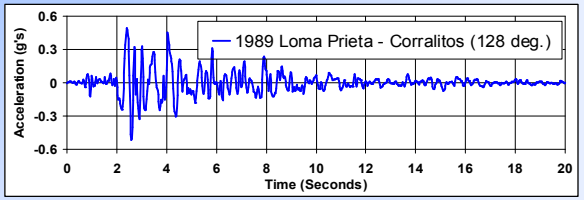
Notional Collapse Fragility – One Data Point

Building
(Joe's Bar)



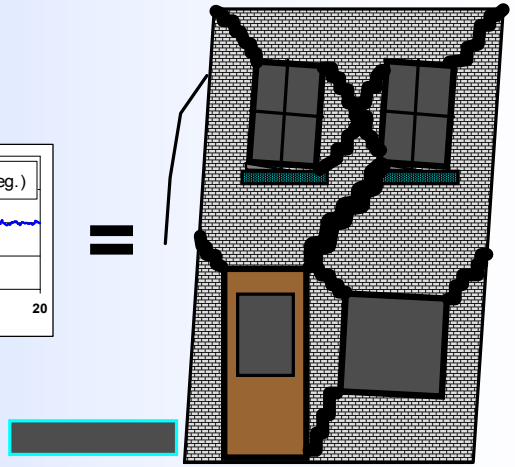
+

Scaled Ground
Motion Record



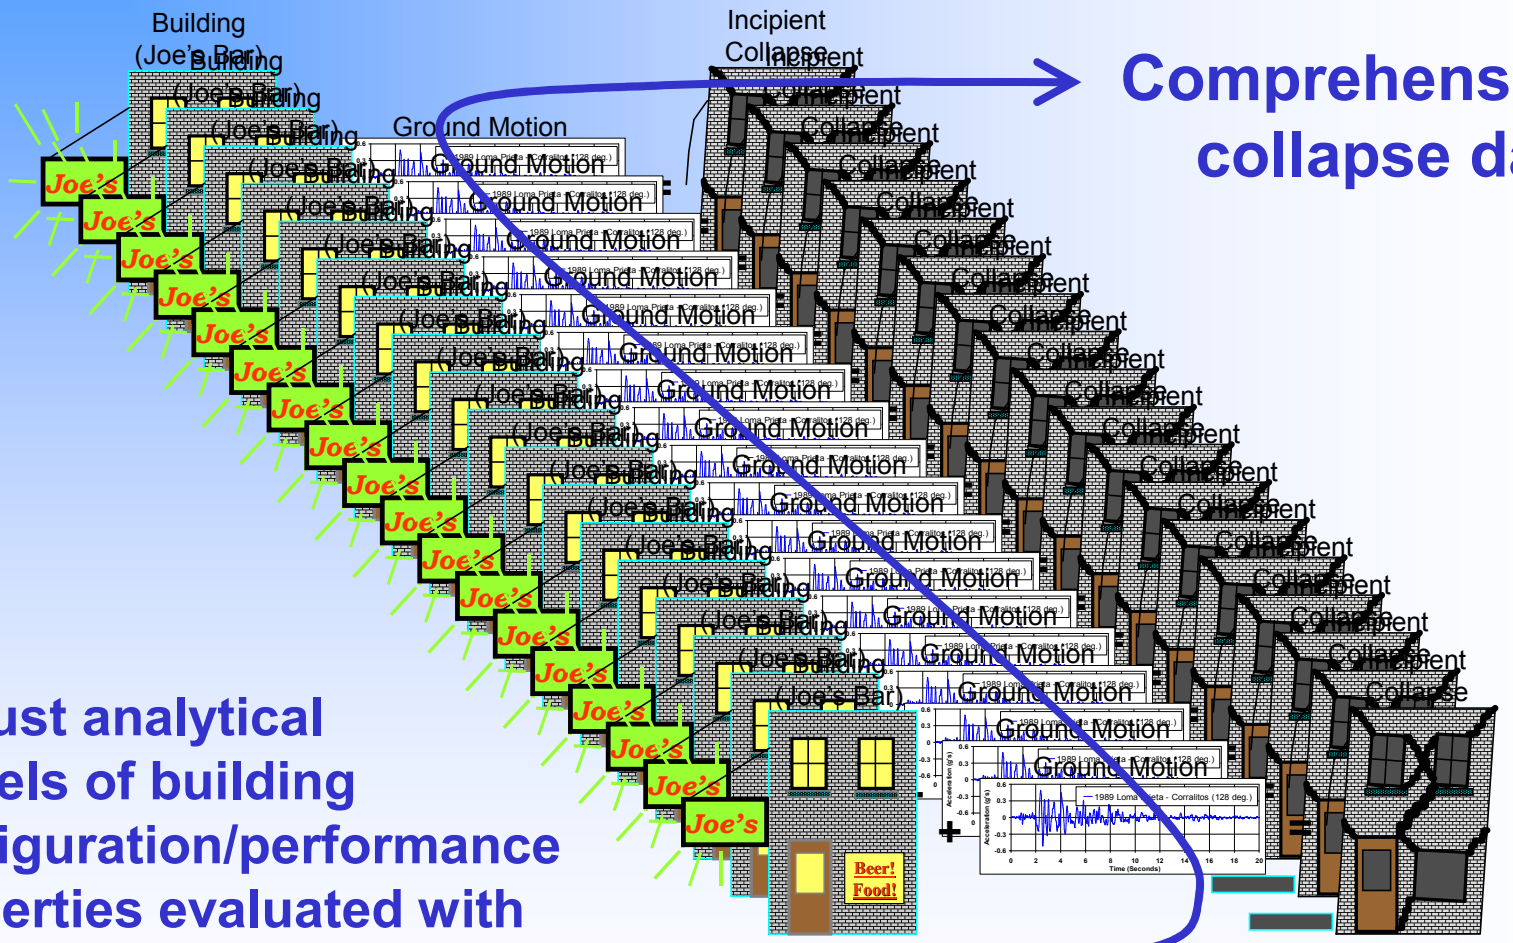
=

Incipient
Collapse



Evaluation of a individual structure (one configuration/set of performance properties) to failure using one ground motion record scaled to effect incipient collapse

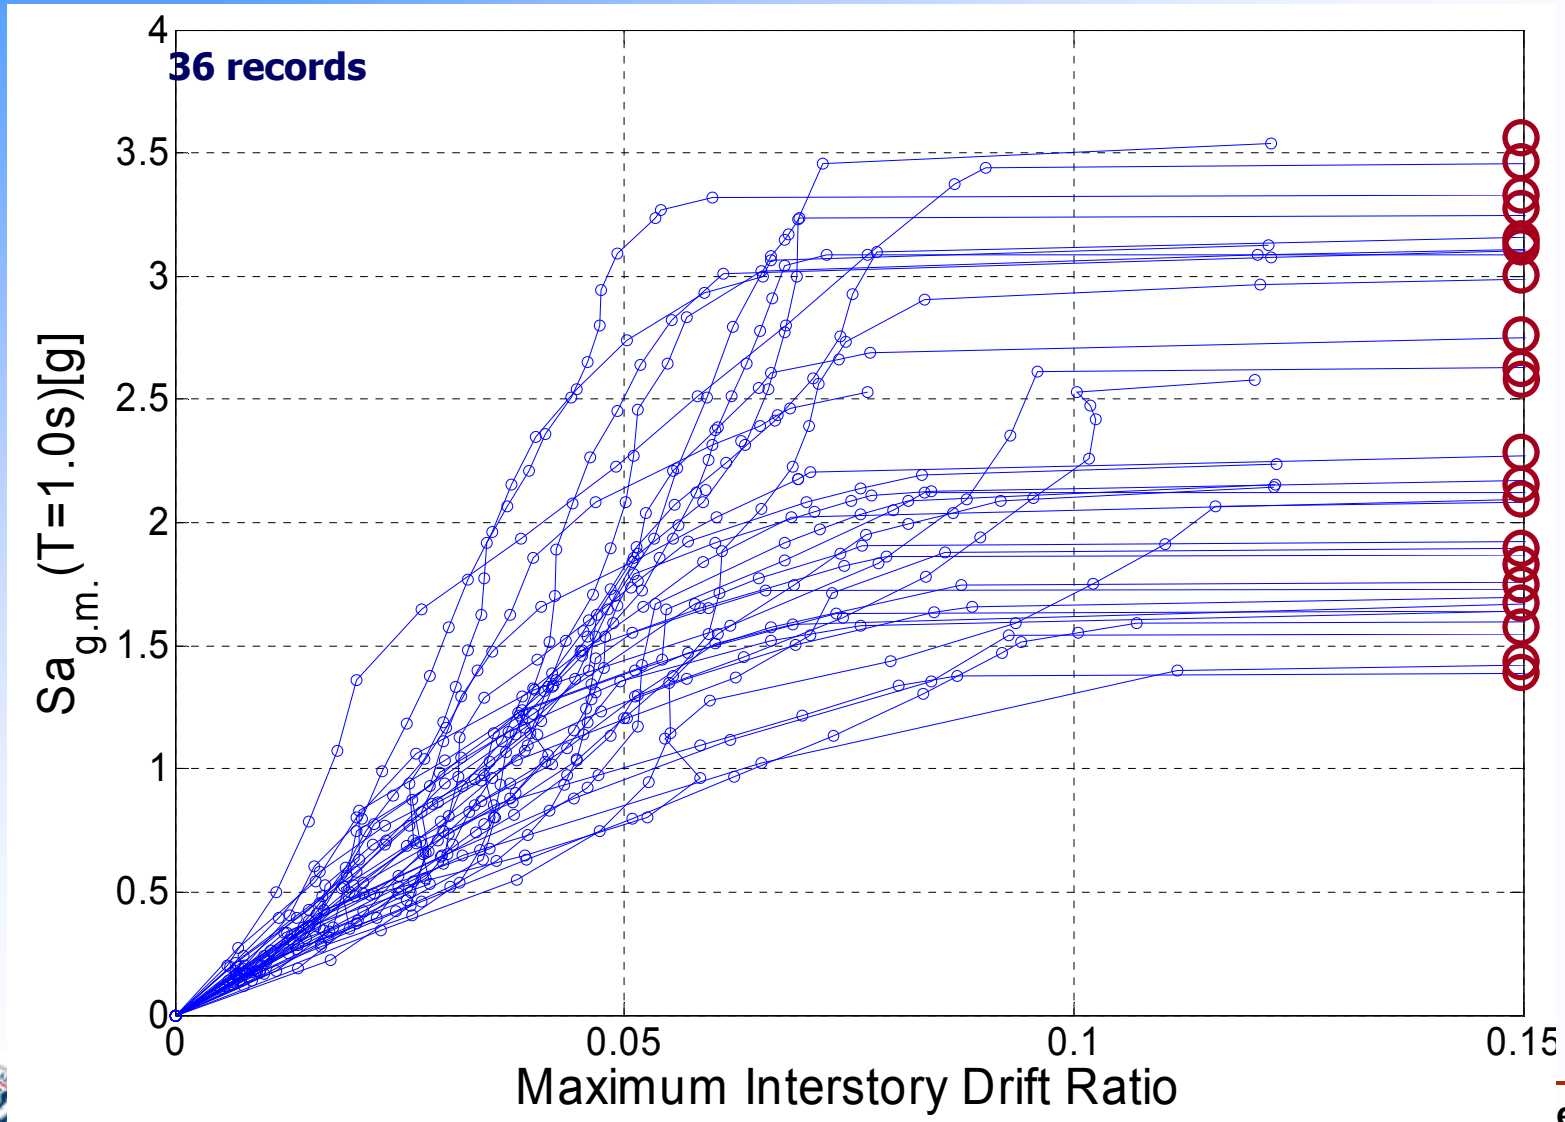
Notional Collapse Fragility – Comprehensive Data



Comprehensive collapse data

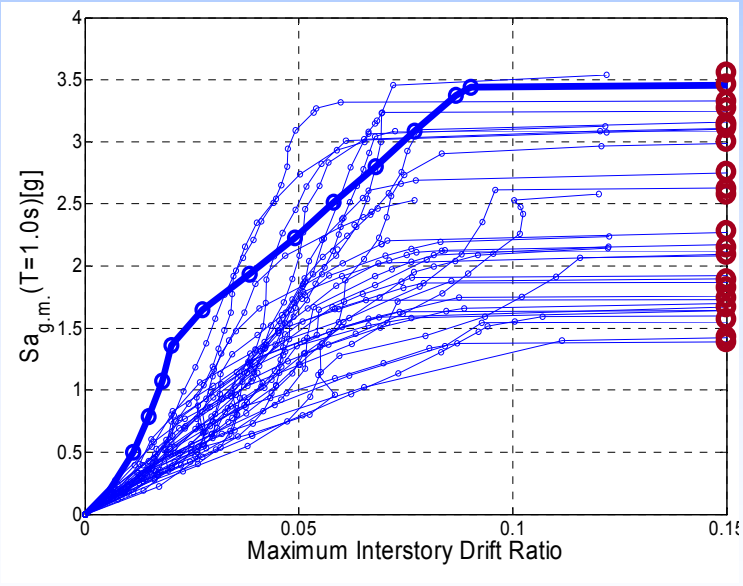
Robust analytical models of building configuration/performance properties evaluated with representative earthquake records

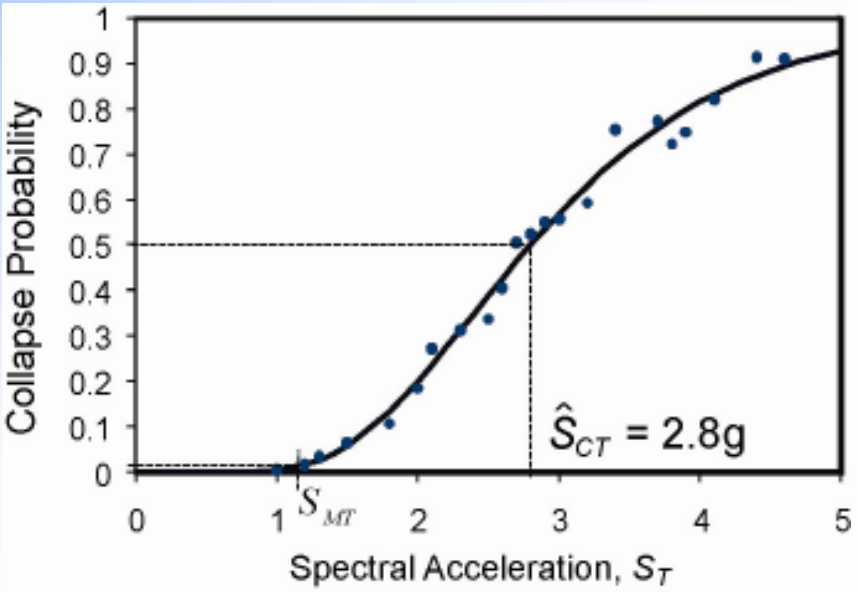
Notional Collapse Fragility



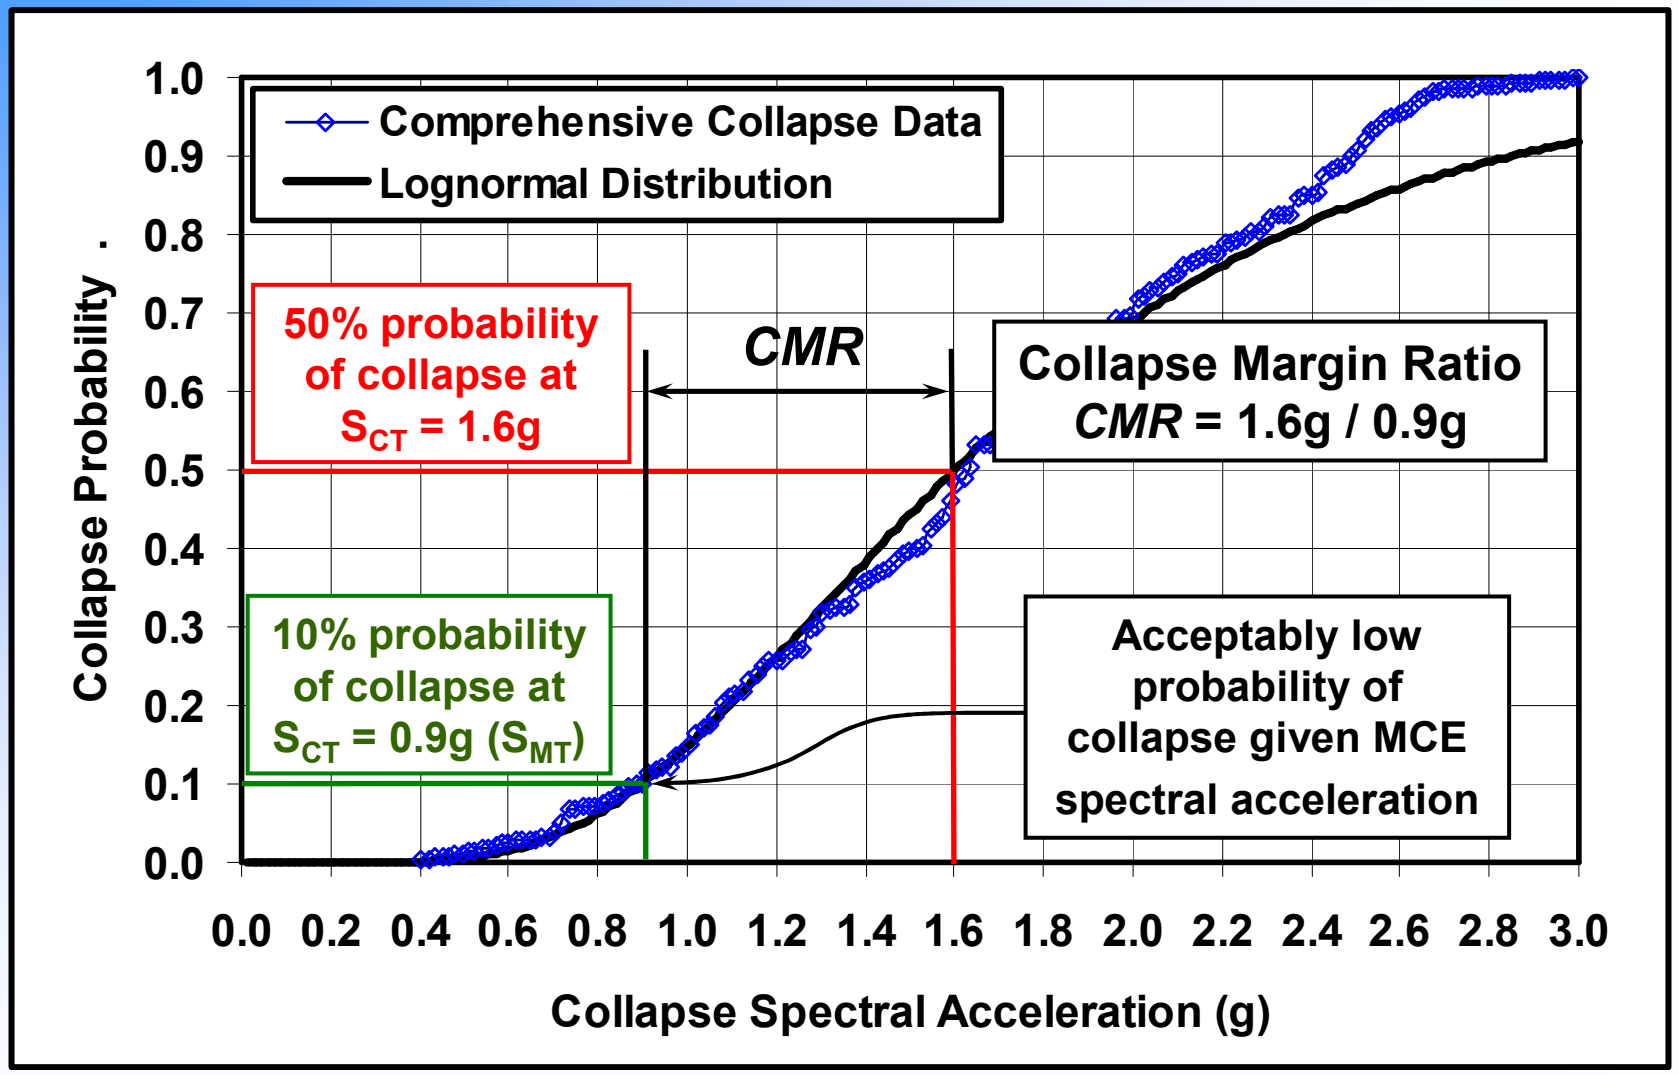
Notional Collapse Fragility

- Order collapse data from least to greatest
- Plot as a cumulative distribution function
  - ✓ Probability versus collapse intensity





Notional Collapse Fragility Curve

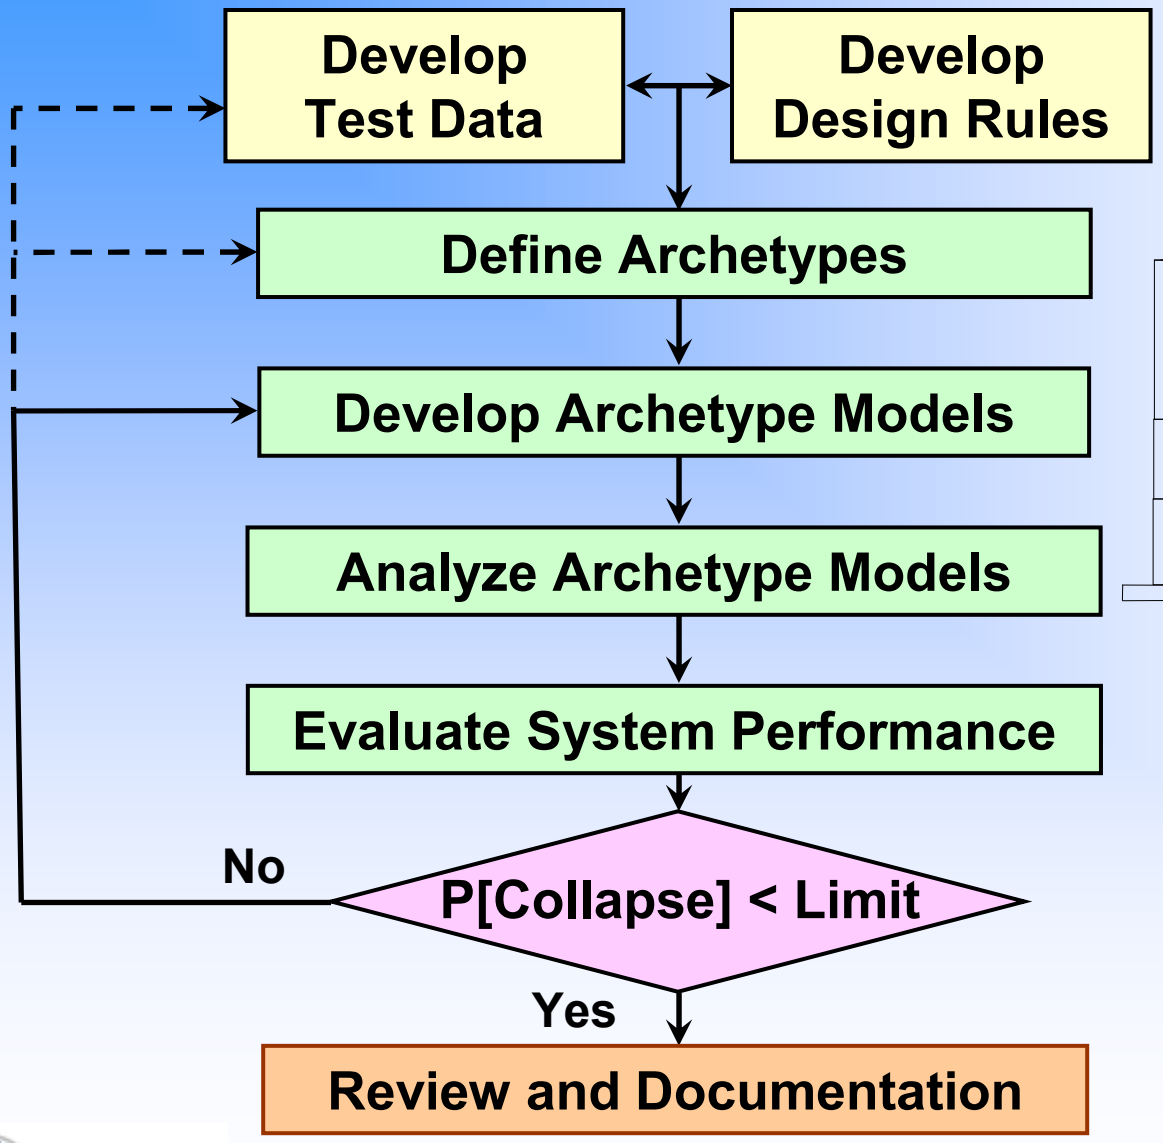


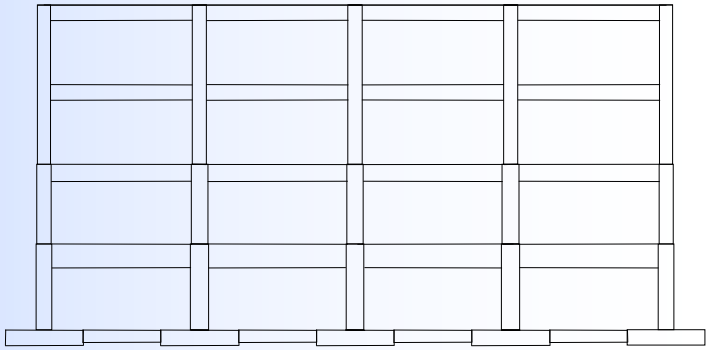
Performance Evaluation

- Simply…
  - ✓ Verify that calculated *CMR* < acceptable *CMR*
- But…
  - ✓ What is an acceptable probability of collapse?
  - ✓ How many data points are enough?
  - ✓ What is an appropriate analytical model?
  - ✓ How do we address uncertainty?
    - Ground motion, Design, Modeling, Testing

Illustrative Example

Example – RC SMF System





Reinforced Concrete Special Moment Frame System

System Conception

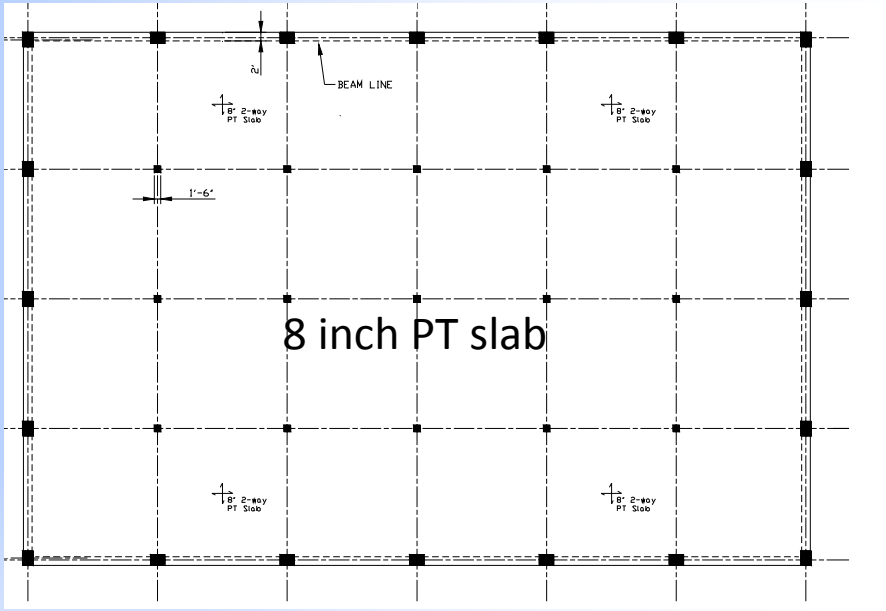
Typical Frame Members

Beams: 32” to 40” deep

Columns: 24”x28” to 30”x40”

Governing Design Parameters

- Beams: minimum strength
- Column size: joint strength
- Column strength: SCWB
- Drift: just meets limit

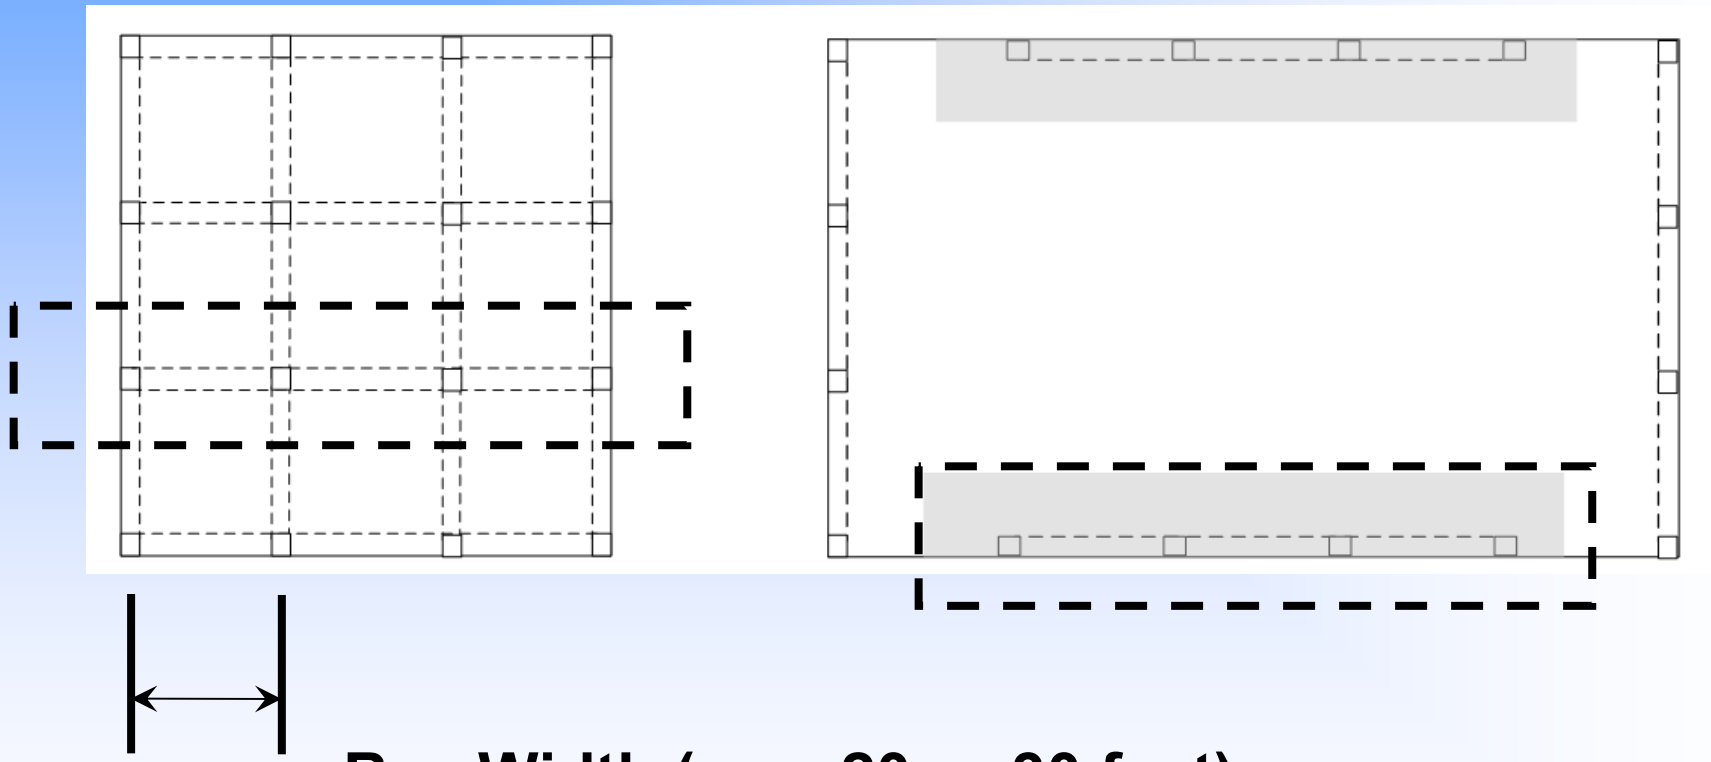


- Office occupancy
- Frame System
- High seismic regions
- Design Code: IBC / ACI / ASCE 7

System Configuration

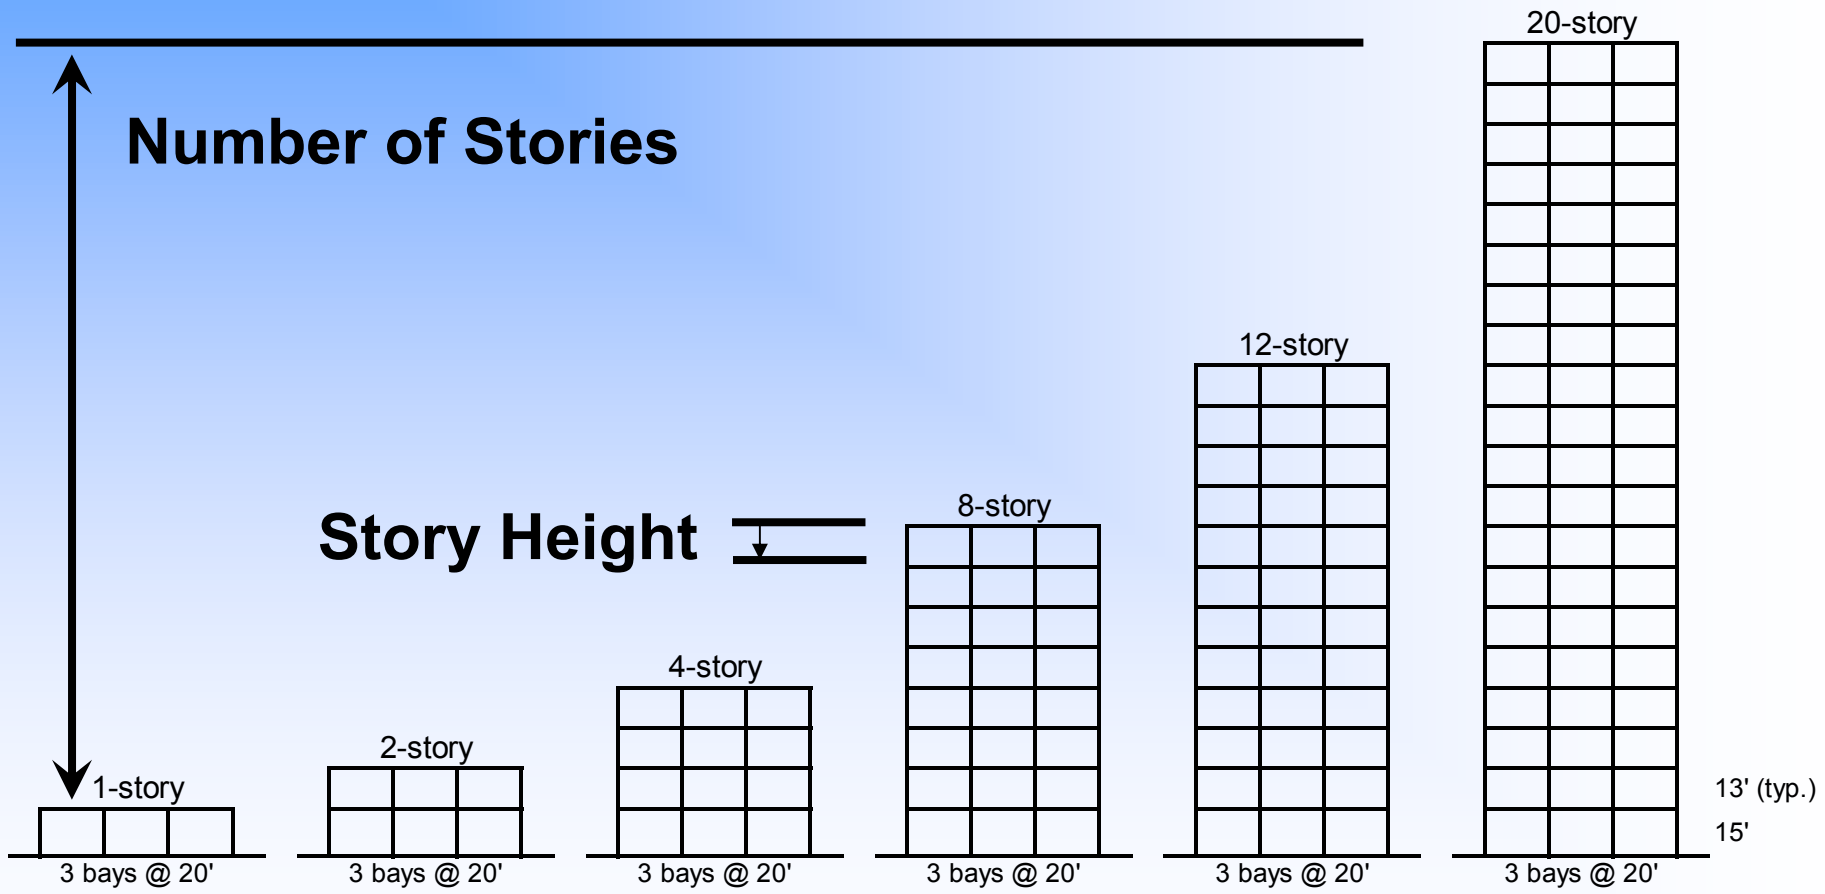
Space Frame

Perimeter Frame



Bay Width (e.g., 20 or 30 feet)

System Design Space



Performance Groups

20-foot bays

Space frame

High seismic design

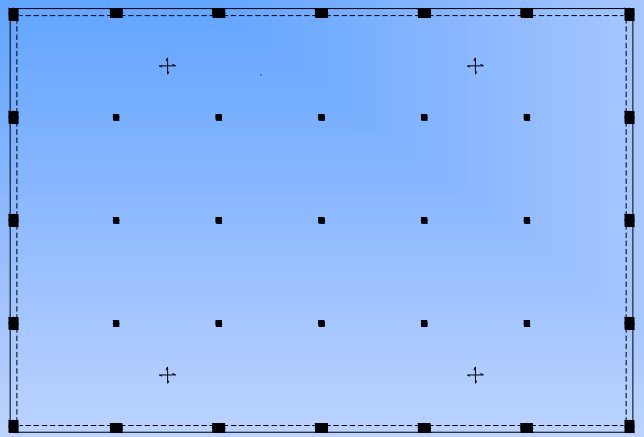
Performance Group Summary					
Group No.	Grouping Criteria				Number of Archetypes
	Basic Configuration	Design Load Level		Period Domain	
		Gravity	Seismic		
PG-1	Type 1	High	Max SDC	Short	≥ 3
PG-2				Long	≥ 3
PG-3			Min SDC	Short	≥ 3
PG-4				Long	≥ 3
PG-5		Low	Max SDC	Short	≥ 3
PG-6				Long	≥ 3
PG-7			Min SDC	Short	≥ 3
PG-8				Long	≥ 3

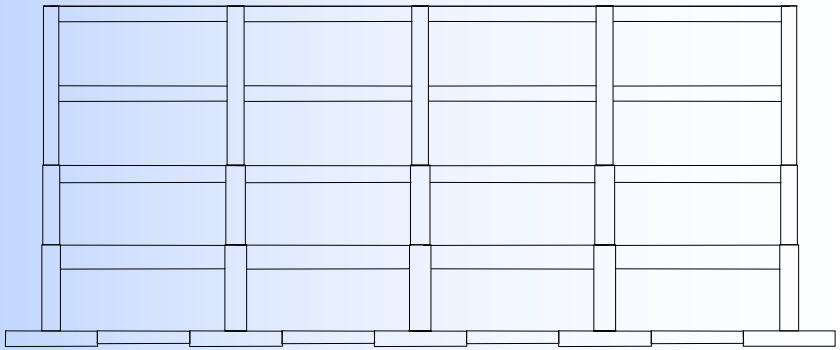
Repeat for 30-foot bays

Perimeter frame

Low seismic design

Deterioration Modes and Collapse Scenarios





1. **Deterioration Modes of RC Elements**
   - Shear, flexure, joint degradation
2. **Building System Collapse Scenarios**
   - Sidesway Collapse (SC)
   - Loss in Vertical Load Carrying Capacity (LVCC)
3. **Likelihood of Collapse Scenarios**

Deterioration Modes

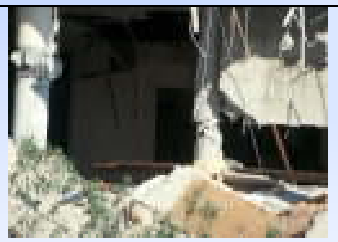
A Flexural hinging of beam-column elements

B Column compressive failure

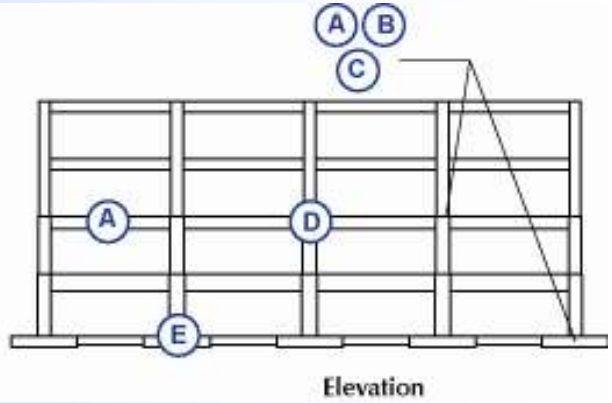
C Beam-column shear failure

D Joint shear failure

E Pull-out and bond-slip of rebar at connections



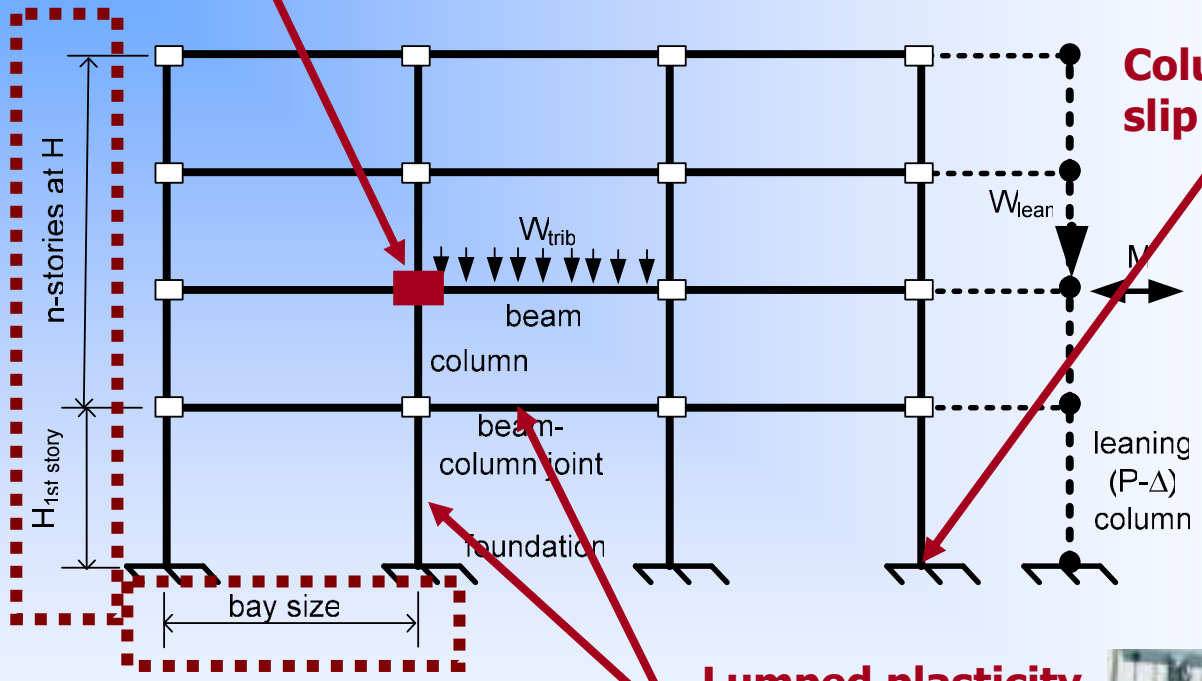
F Slab-column connection punching shear



Elevation

Nonlinear Analysis Models

Joints with both bond-slip springs and shear springs

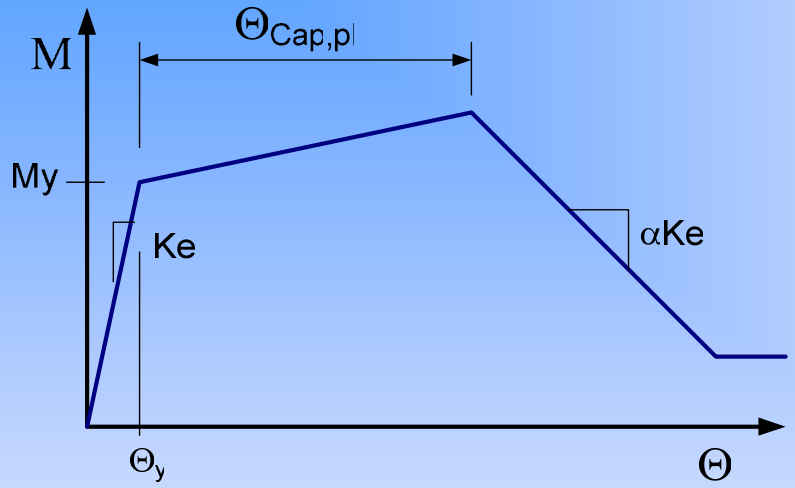


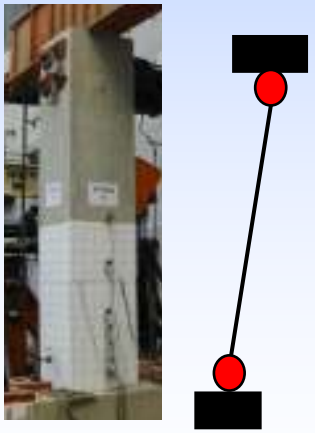
Column bond-slip springs

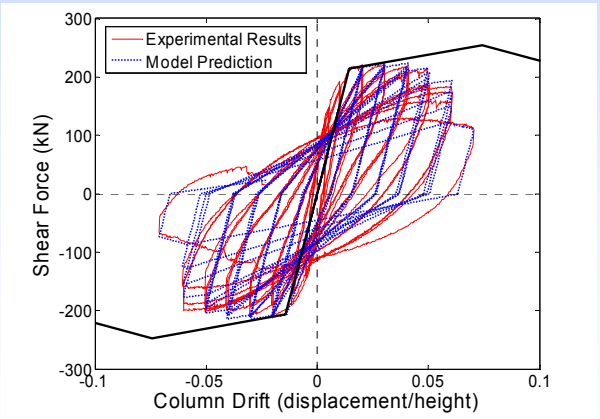
Lumped plasticity beam-columns

2D multistory model to capture likely sidesway collapse scenarios and component behavior

Concrete Hinge Model Calibration







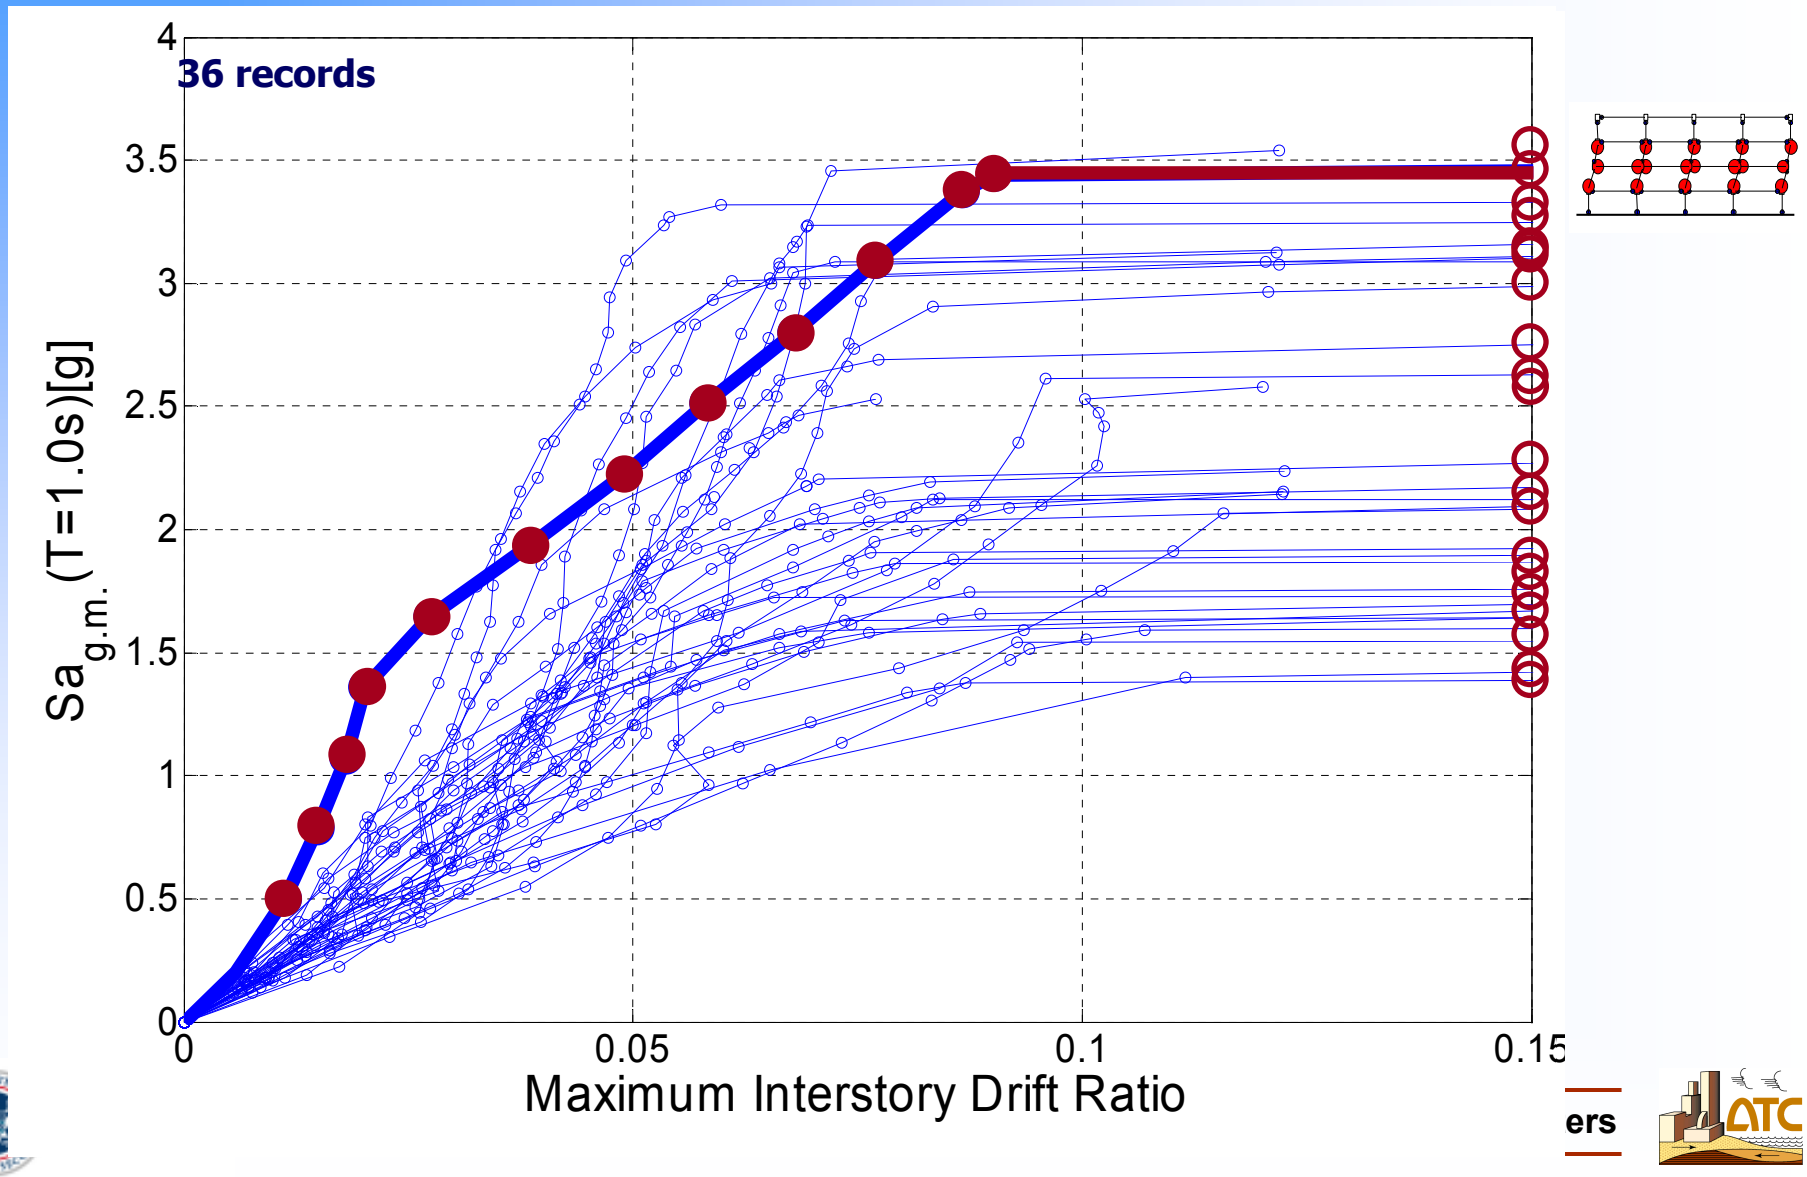
Identify and Test Key Parameters:

- strength
- initial stiffness
- post-yield stiffness
- plastic rotation (capping) capacity
- post-capping slope
- cyclic deterioration rate

Example Data Set:

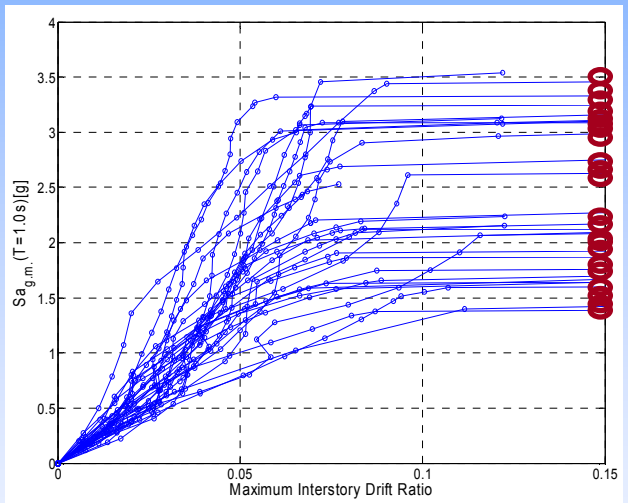
- 250+ columns (PEER database)
- flexure & flexure-shear dominant
- calibrated to ***median (characteristic)*** values

Simulation Results

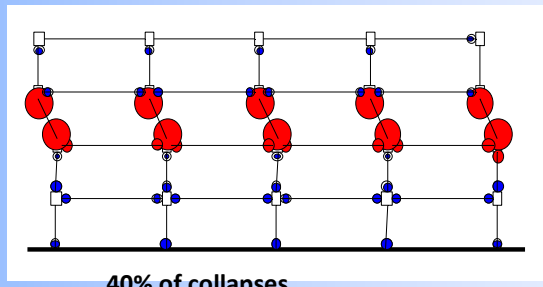


ers

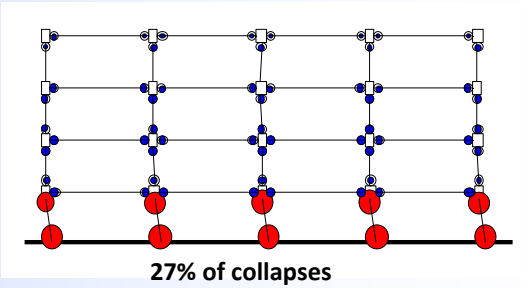
Simulation Results: Collapse Modes



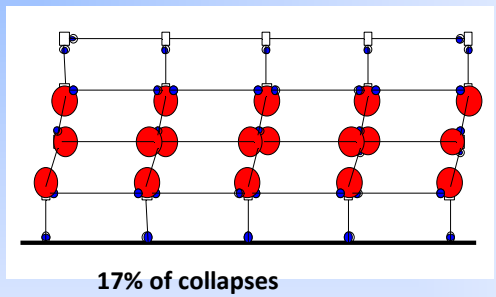
Incremental Dynamic Analysis



40% of collapses

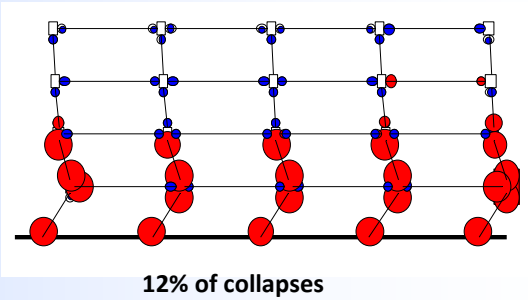


27% of collapses

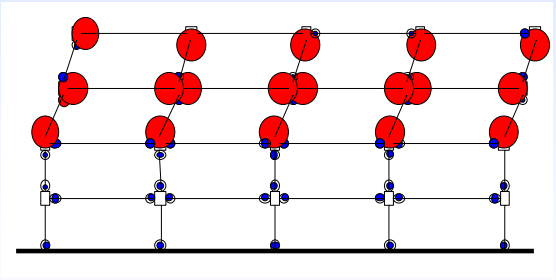


17% of collapses

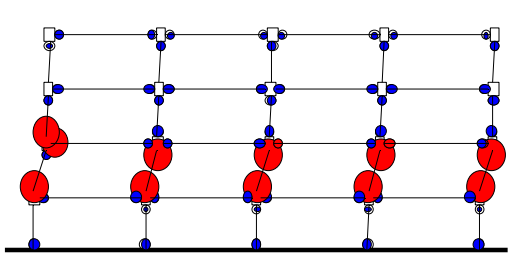
**Predicted by Static Pushover



12% of collapses

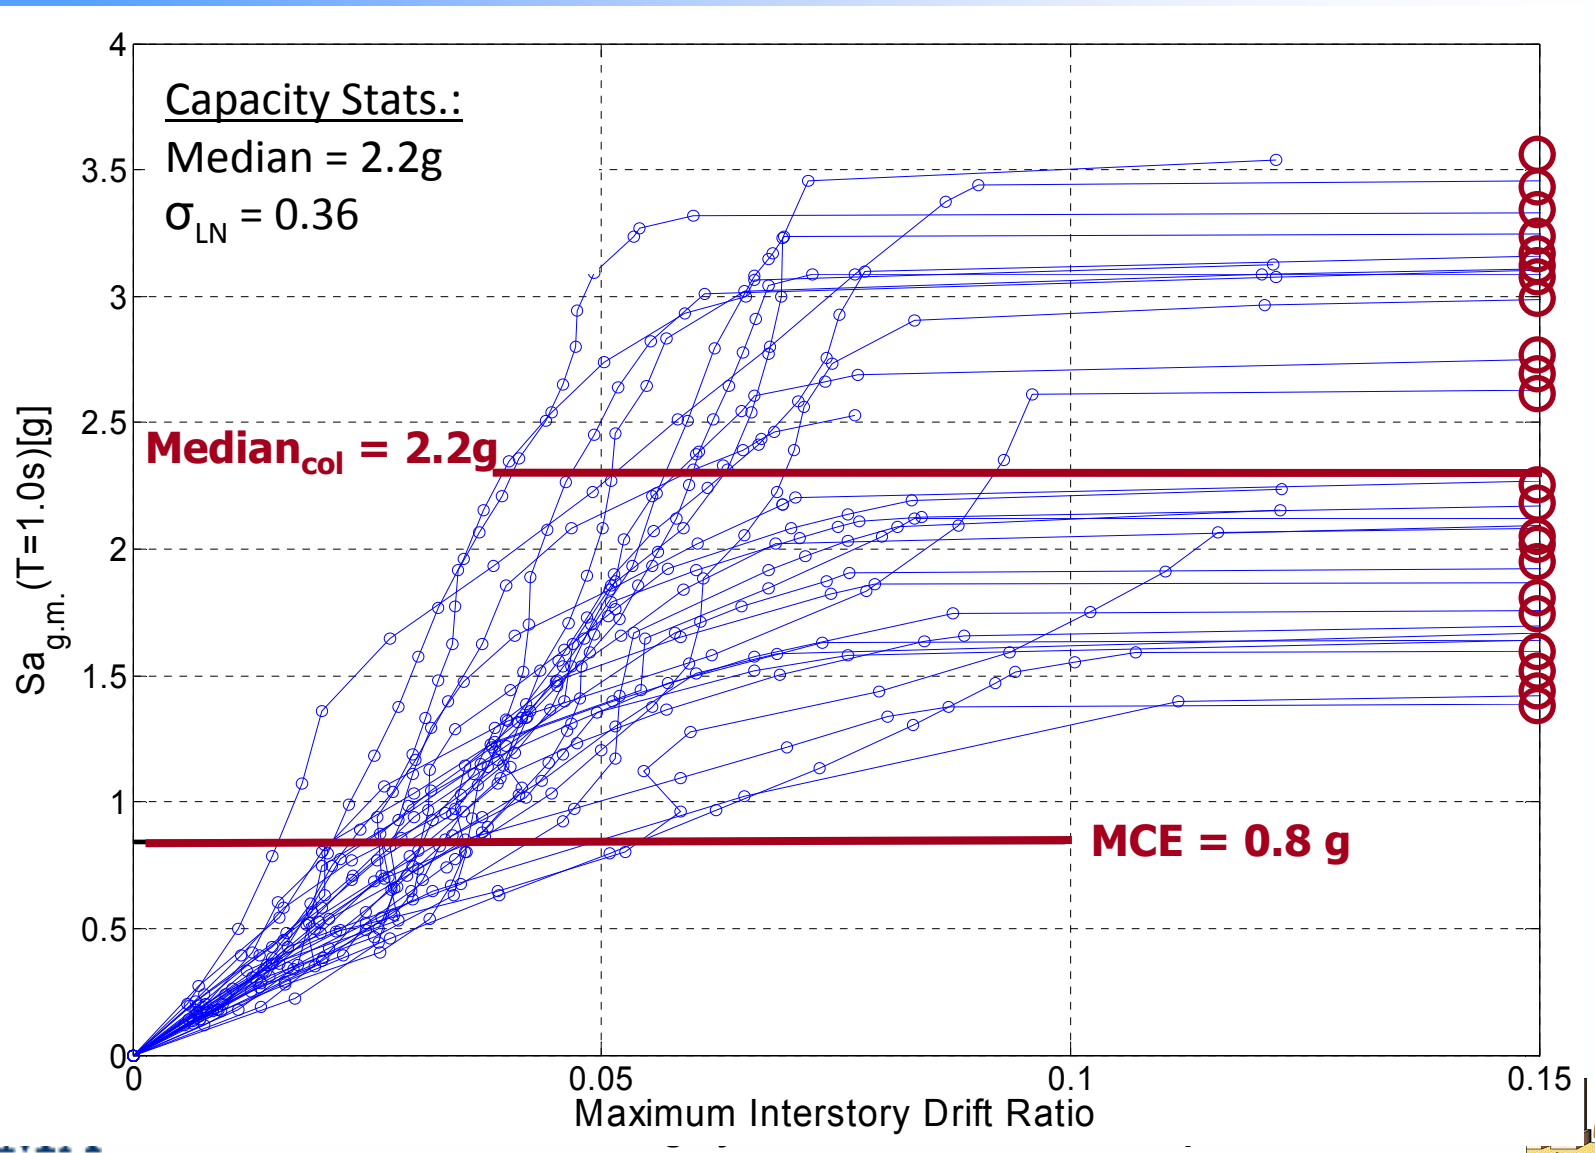


5% of collapses



2% of collapses

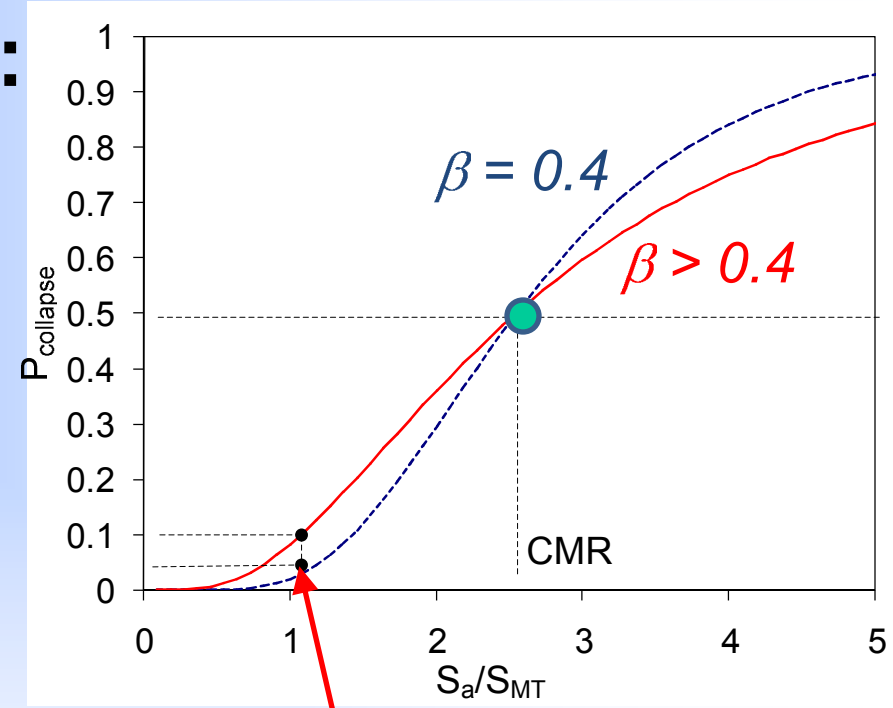
Simulation Results: Collapse Data



Effect of Uncertainties

FOUR CONTRIBUTORS:

1. **Record-to-Record Variability (β_{RTR} = 0.4)**
2. **Design Requirements**
3. **Quality of Test Data**
4. **Quality of Analytical Model**



$$\beta_{TOT} = \sqrt{\beta_{RTR}^2 + \beta_{DR}^2 + \beta_{TD}^2 + \beta_{MDL}^2}$$

Greater uncertainties will require larger median collapse margins to satisfy maximum collapse probability at MCE

Quality Ratings

Table 3-1 Quality Rating for Design Requirements

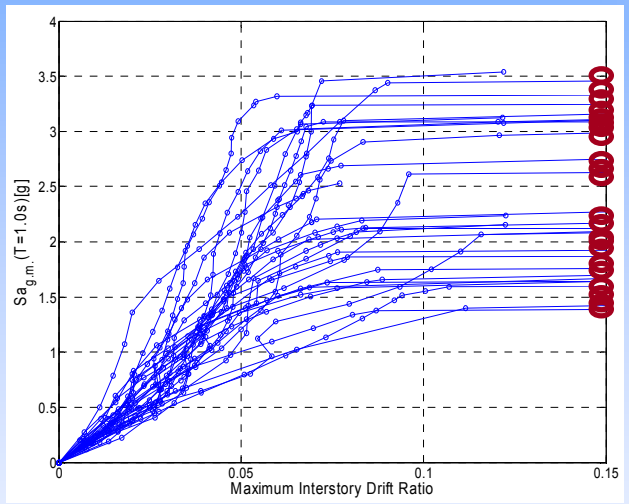
Completeness and Robustness	Confidence in Basis of Design Requirements		
	High	Medium	Low
High. Extensive safeguards against poor behavior. All important design and quality assurance issues are addressed.	(A) Superior	(B) Good	(C) Fair
Medium. Reasonable safeguards against poor behavior. Most of the important design and quality assurance issues are addressed.	(B) Good	(C) Fair	(D) Poor
Low. Questionable safeguards against poor behavior. Many important design and quality assurance issues are not addressed.	(C) Fair	(D) Poor	--

Total Collapse Uncertainty

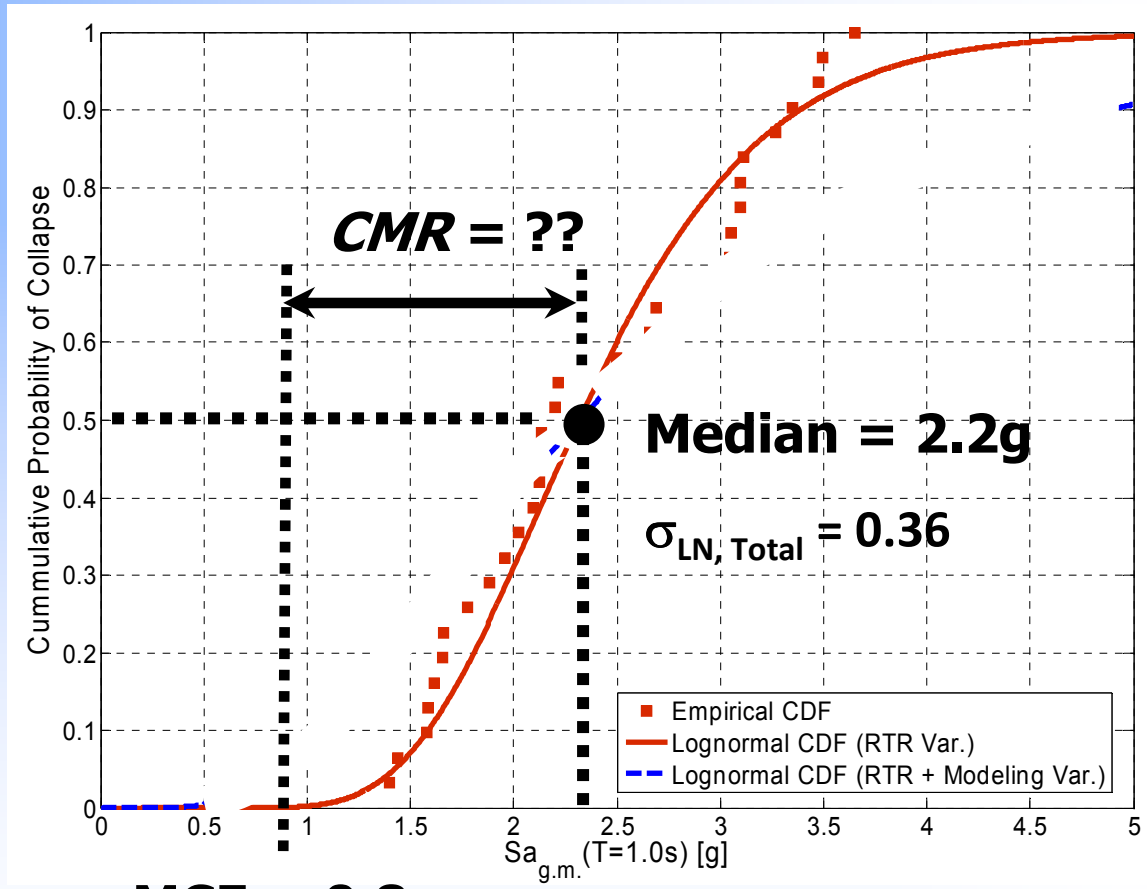
- Design Requirements: A-Superior
- Test Data: B-Good
- Nonlinear Model: A-Superior

Uncertainty - Nonlinear Model	**A - Superior**			
Uncertainty - Quality of Test Data	Uncertainty - Quality of Design Requirements			
	A - Super.	B - Good	C - Fair	D - Poor
A - Superior	0.55	0.55	0.65	0.80
B - Good	**0.55**	0.60	0.70	0.85
C - Fair	0.65	0.70	0.80	0.90
D - Poor	0.80	0.85	0.90	1.00

Adjusted Collapse Fragility Curve



Incremental Dynamic Analysis Results



MCE = 0.8g

Acceptable Collapse Margin Ratios

Total System Collapse Uncertainty	Collapse Probability				
	5%	10% ($ACMR_{10\%}$)	15%	20% ($ACMR_{20\%}$)	25%
0.275	1.57	**1.42**	1.33	**1.26**	1.20
0.300	1.64	**1.47**	1.36	**1.29**	1.22
0.500	2.28	**1.90**	1.68	**1.52**	1.40
0.525	2.37	**1.96**	1.72	**1.56**	1.42
0.550	2.47	**2.02**	1.77	**1.59**	1.45
0.575	2.57	**2.09**	1.81	**1.62**	1.47

On average per performance group

For any one archetype

Example Results – RC SMF System

Arch. Design ID Number	Design Configuration				Computed Collapse Margin				Acceptance Check	
	No. of Stories	Framing / Gravity Loads	Seismic SDC	Static Ω	*CMR*	μ_c	*SSF*	*ACMR*	Accept. *ACMR*	Pass/Fail
Maximum Seismic (D_{max}) and Low Gravity (Perimeter Frame) Designs, 20' Bay Width										
2069	1	P	D_{max}	1.6	1.18	16.1	1.34	1.58	1.59	Near Pass
2064	2	P	D_{max}	1.8	1.50	19.5	1.34	2.01	1.59	Pass

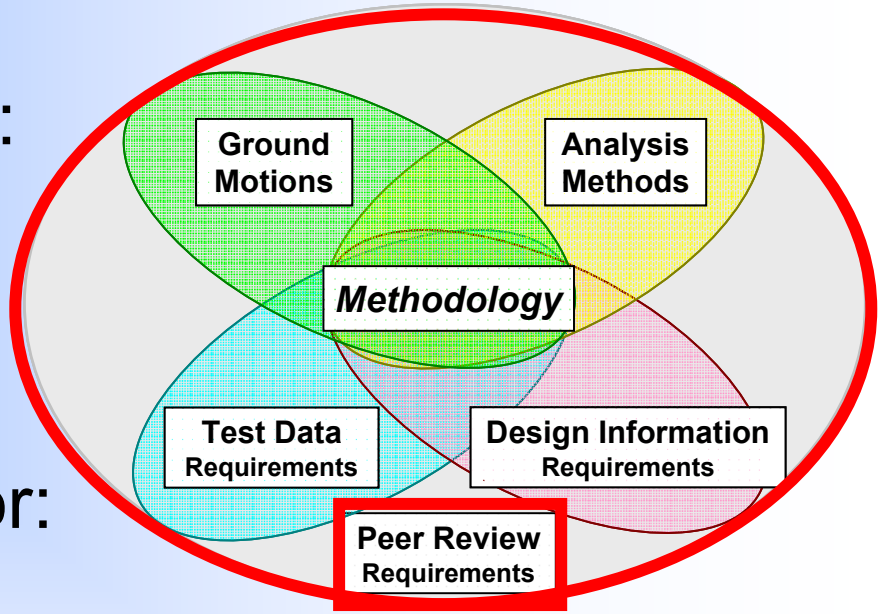
RC SMF Example - Conclusions

- A value of R=8 provides an acceptable level of collapse safety
- The Methodology is reasonably well-calibrated to current design provisions
  - ✓ RC SMF systems didn't fail miserably
  - ✓ RC SMF systems didn't pass easily
- This was true of all systems tested

Peer Review Considerations

- Implementation involves:
  - ✓ Uncertainty
  - ✓ Judgment
  - ✓ Potential for variation
- Peer Review is critical for:
  - ✓ Testing
  - ✓ Archetype development
  - ✓ Analytical modeling
  - ✓ Quality rating assessment



Observations and Findings

Observations and Findings

- Methodology was developed considering:
  - ✓ special concrete moment frames
  - ✓ ordinary concrete moment frames
  - ✓ special steel moment frames
  - ✓ wood shear walls
- Some trends in our current design process have become apparent…

Observations and Findings

- Performance assessment is a difficult challenge fraught with much uncertainty
- Buildings located in the near-field have higher collapse probabilities
- Short period buildings have higher collapse probabilities
- Collapse performance varies by Seismic Design Category
- Secondary systems influence collapse capacity
- There is no practical difference in performance between *R*=6 and *R*=6.5

Summary

- Recommended Methodology provides a rational basis for establishing global seismic performance factors (e.g., *R* factors)
- Intended to support and improve Seismic Codes:
  - ✓ Adoption of new systems that must be assigned values of seismic performance factors
  - ✓ Improvement of current values of seismic performance factors of existing systems
  - ✓ Collapse evaluation of a specific building designed using alternative "performance-based" methods (App. F)
- FEMA P-695 is now available online and in print

Thank you!

2014 *NEHRP RECOMMENDED SEISMIC PROVISIONS FOR NEW BUILDINGS AND OTHER STRUCTURES:*

PART 1, PROVISIONS

~~*Work on this 2009 edition of the NEHRP (National Earthquake Hazards Reduction Program) Recommended Seismic Provisions for New Buildings and Other Structures began in September 2004 when the National Institute of Building Sciences, the parent organization of the Building Seismic Safety Council (BSSC), entered into a contract with Federal Emergency Management Agency (FEMA) for initiation of the 2009 Provisions update effort. During 2005, the BSSC member organization representatives and alternate representatives and the BSSC Board of Direction were asked to identify individuals to serve on the 2009 Provisions Update Committee (PUC) and its Technical Subcommittees (TSs) and to suggest topics for concentrated study by ad hoc Issue Teams.*~~

~~*The 2009 PUC and its eight Technical Subcommittees (TS) then were established to address document composition and management; design criteria and analysis and advanced technologies; mapping, foundations, and geotechnical considerations; concrete structures; masonry structures; steel and composite steel and concrete structures; wood structures; nonstructural components and nonbuilding structures. Three Issue Teams (ITs) also were established to focus on performance criteria, design parameters, and foundation design requirements. Further, given ongoing work by the U.S. Geological Survey (USGS) to update its seismic hazard maps, a Seismic Design Procedures Review Group (SDPRG) was established to consider the emerging maps and to re-examine the existing design maps and procedures that were introduced in the 1997 edition of the Provisions and that remained essentially unchanged for the 2000 and 2003 editions of the Provisions.*~~

~~*Work already done and decisions made prior to initiation of the 2009 Provisions update project recognized that the codes and standards arena has changed over the past decade and that those changes called for a refocusing of the Provisions on exploration of new technologies and procedures and less consideration of format and editorial changes. To this end, the initial efforts of the 2009 PUC and its TSs focused on adoption of the national load standard, Minimum Design Loads for Building and Other Structures, ASCE/SEI 7-05 (including Supplements No. 1 and No. 2), as the primary reference standard of the Provisions and the identification of parts of the 2003 Provisions that should be maintained as modifications to the standard or otherwise revised to reflect new knowledge and experience data. The result of this effort was a vote by the BSSC member organizations to adopt ASCE/SEI 7-05 by reference and for it to serve as the base document for the update cycle. Three modifications to the standard, originally appendices to various chapters of the 2003 Provisions, had been deemed needed by the PUC and TSs and were approved as part of this vote by the membership for inclusion in the 2009 Provisions. As the update cycle progressed, additional modifications to the standard were prepared and voted on by the membership in three separate ballots. All these modifications appear in Part 1 of this document and, together with ASCE/SEI 7-05 and the references cited therein, constitute the 2009 Provisions. (A summary of the results of the member organization ballots and comment resolution process is available from the BSSC upon written request and will be posted on the BSSC website at www.bssconline.org.)*~~

~~*A major effort also was made to rewrite the commentary to the Provisions. Until now, the commentary was published in a separate volume and tended to explain the development of the requirements. For 2009, the commentary appears in Part 2 of this Provisions volume and explains how to apply the Provisions requirements as articulated in ASCE/SEI 7-05 and the references cited therein. (Note that the Part 1 modifications to the standard are accompanied by appropriate commentary text included in Part 1.)*~~

~~*Part 3 of this Provisions volume introduces new procedures or provisions not currently contained in the referenced standards for consideration and experimental use by the design community, researchers, and standards and code development organizations and feedback from these users is encouraged. Part 3 also presents individual summaries of*~~

~~*ongoing committee work that awaits additional research before being submitted to the BSSC membership for consensus approval and provides useful guidance on the application of Part 1 requirements, either as a discussion of an overall approach or as a detailed procedure.*~~

1.1 INTENT

The *NEHRP Recommended Seismic Provisions for New Buildings and Other Structures* presents the minimum recommended requirements necessary for the design and construction of new buildings and other structures to resist earthquake ground motions throughout the United States. The intent of these provisions is to provide reasonable assurance of seismic performance that will:

1. Avoid serious injury and life loss,
2. Avoid loss of function in critical facilities, and
3. Minimize structural and nonstructural repair costs where practical to do so.

These objectives are addressed by seeking to avoid structural collapse in very rare, extreme ground shaking and by seeking to provide reasonable control of damage to structural and nonstructural systems that could lead to injury and economic or functionality losses for more moderate and frequent ground shaking. These design requirements include minimum lateral strength and stiffness for structural systems and guidance for anchoring, bracing, and accommodation of structural drift for nonstructural systems.

Occupancy Category III or IV structures intended to provide enhanced safety and functionality are required to have more strength than Occupancy Category I or II structures in an effort to reduce damage to the structural system. Allowable drifts are reduced to control damage to building components connected to multiple floor levels. Nonstructural system performance is enhanced by strengthening the anchorage and bracing requirements, and important equipment must be shown to be functional after being shaken.

The degree to which these goals can be achieved depends on a number of factors including structural framing type, building configuration, materials, as-built details, and overall quality of design. In addition, large uncertainties as to the intensity and duration of shaking and the possibility of unfavorable response of a small subset of buildings or other structures may prevent full realization of the intent.

1.2 REFERENCE DOCUMENT

Design for seismic resistance of structural elements including foundation elements and nonstructural components shall conform to the requirements of ASCE/SEI 7-05, *Minimum Design Loads for Buildings and Other Structures,* including Supplements No. 1 and No. 2 (referred to hereinafter as ASCE/SEI 7-05), as modified herein.[1]

COMMENTARY TO SECTIONS 1.1 AND 1.2

The primary intent of the *NEHRP Recommended Seismic Provisions for New Buildings and Other Structures* is to prevent, for typical buildings and structures, serious injury and life loss caused by damage from earthquake ground shaking. Most earthquake injuries and deaths are caused by structural collapse; therefore, the major thrust of the *Provisions* is to prevent collapse for very rare, intense ground motion, termed the maximum considered earthquake (MCE) ground motion.[2] The intent remains the same in the 2009 *Provisions*; however, the prevention of collapse is redefined in terms of risk-targeted maximum considered earthquake (MCE_R) ground motions. This change is explained fully in the commentary to the Part 1 modification to ASCE/SEI 7-05 Section 11.2.

Falling exterior walls and cladding and falling interior ceilings, light fixtures, pipes, equipment, and other nonstructural components also cause deaths and injuries. The *Provisions* minimizes this risk using requirements for anchoring and bracing nonstructural components, although this level of protection generally is aimed at ground motions less severe than the MCE_R ground motion. This anchoring and bracing of nonstructural systems coupled with reasonable limitations on differential movement between floors (i.e., story drift limits) also serve to control damage that may be costly to repair or that would result in lengthy building closures, particularly for moderate shaking levels.

[1] Supplement No. 2 of the standard is available for download at http://content.seinstitute.org/files/pdf/SupplementNo2ofthe2005Editionof ASCE7.pdf.

[2] The derivation of MCE ground motion was described in detail in Commentary Appendix A of the 2003 *NEHRP Recommended Provisions* (FEMA 450-2), and this appendix, "Development of Maximum Considered Earthquake Ground Motion Maps Figures 3.3-1 through 3.3-14," can be downloaded from http://www.nigs.org/index.php/bssc/publications/fema450nehrp2003/.

Stricter story drift limits can further limit damage to components connected to more than one floor (e.g., walls, cladding and stairways) but, at the same time, can create higher acceleration levels in the building that could increase damage to nonstructural components braced or anchored to a single floor (e.g., ceilings, light fixtures, and pipes). Achieving an optimum balance between the cost and performance of the structural system and the effect of structural stiffness on performance of the nonstructural systems is impossible using the prescriptive rules of a building code, particularly given the variety of structural systems used in the United States.

Buildings deemed to have higher importance due to hazardous contents or critical occupancy are assigned to higher Occupancy Categories (see ASCE/SEI 7-05 Table 1-1). The damage level in these buildings is intended to be reduced by decreasing nonlinear demand using an importance factor, *I*, to reduce the response modification coefficient, *R*. The resulting increased strength will reduce structural damage, or increase reliability of acceptable performance, for a given level of shaking. Some authorities having jurisdiction subject the design and construction of such buildings to a higher level of scrutiny.

The performance of critical occupancy structures in past earthquakes indicates that the increase in the importance factor controls structural damage in moderate shaking. In strong shaking associated with the design level of two-thirds the maximum considered earthquake or higher, the values of *I* have not been well tested for their effect on either functionality for critical buildings or increased reliability of life safety protection for high occupancy buildings.

The importance factor also increases the design anchorage and bracing load for nonstructural systems, which should increase the reliability of their staying in place and, thus, remaining undamaged. In addition, certain critical equipment must remain operable after strong shaking. Experience data show that some nonstructural components will remain functional if they stay in position, but other components will require testing to show that they will function following strong shaking. The emphasis to date has been on the seismic qualification of individual components. However, the nonstructural systems of many buildings are, in reality, complex networks that can be shut down by a single failure. For example, a break in a pressurized pipe can flood part or all of a building forcing it to close, and failure of the anchorage (or internal workings) of a battery, day tank, fuel lines, muffler, or main engine can shut down an emergency generator. Therefore, the special regulations for seismic protection of nonstructural systems represent a rational approach to achieving performance appropriate for the various occupancies, but experience data to confirm their adequacy are lacking.

When the hazard definition for design was changed from motion with a 2 percent chance of exceedance in 50 years to the 1 percent chance of collapse in 50 years, the primary intended performance was retained. The design basis ground motion is still two-thirds of the risk-targeted maximum considered earthquake (MCE_R) ground motion. The increase in the importance factor is intended to ensure a lower probability of collapse for the performance of higher occupancy and critical buildings.

The *Provisions* requirements are not intended to prevent damage due to earth slides (such as those that occurred in Anchorage, Alaska) or tsunami (such as occurred in Hilo, Hawaii, and the Indian Ocean). They provide only for required resistance to earthquake ground shaking without significant settlement, slides, subsidence, or faulting in the immediate vicinity of the structure. In most cases, practical engineering solutions are available to resist other potential earthquake hazards, but they must be developed on a case-by-case basis.

Although the *Provisions* sets the minimum performance goals described in Section 1.1, earthquake performance of buildings and other structures is highly variable. The characteristics of the shaking itself are highly uncertain and even different sets of motions defined to qualify as maximum considered earthquake ground motions can result in significantly different responses. Additional uncertainty is created by the wide variety of systems and configurations allowed under the regulations as well as by the various interpretations and implementation practices of individual designers. Thus, a small percentage of buildings designed to the requirements of the *Provisions* may not meet the performance intent when exposed to earthquake ground motions. The commentary the *Tentative Provisions for the Development of Seismic Regulations for Buildings* (Applied Technology Council, 1978), upon which the first edition of the *NEHRP Recommended Provisions* (1985) was based, suggested a less than 1 percent chance of collapse in a 50-year period for a building designed using the tentative requirements. More recent studies (e.g., *Quantification of Building Seismic Performance Factors*, FEMA P-695, 2009) suggest a 10 percent chance of collapse with shaking at the maximum considered earthquake level, which is roughly equivalent to the 1978 estimations.

1.3 MODIFICATIONS TO ASCE/SEI 7-05

With only a few exceptions (such as the changes to Table 12.2-1 shown in underline and strikeout), modifications are presented as replacements for existing sections of ASCE/SEI 7-05 or as new sections to be added to the standard. Commentary, if any, to the modifications that appear in the remainder of this part of the 2009 Provisions is presented at the end of each chapter of modifications. Commentary to the seismic chapters (Chapters 11 through 22) of the unmodified reference document itself, ASCE/SEI 7-05, is presented in Part 2 of the 2009 Provisions.

Modifications to Chapter 11
Seismic Design Criteria

Replace with the following:

SECTION 11.1.2, SCOPE

11.1.2 Scope. Every structure, and portion thereof, including nonstructural components, shall be designed and constructed to resist the effects of earthquake motions as prescribed by the seismic requirements of this standard. Certain nonbuilding structures, as described in Chapter 15, are also within the scope and shall be designed and constructed in accordance with the requirements for Chapter 15. Requirements concerning alterations, additions, and change of use are set forth in Appendix 11B. Existing structures and alterations to existing structures need only comply with the seismic requirements of this standard where required by Appendix 11B. The following structures are exempt from the seismic requirements of this standard:

1. Detached one- and two-family dwellings that are located where the mapped, short period, spectral response acceleration parameter, S_S, is less than 0.4 or where the Seismic Design Category determined in accordance with Section 11.6 is A, B or C.
2. Dwellings of wood-frame construction satisfying the limitations of and constructed in accordance with the *International Residential Code*.
3. Buildings of wood-frame construction satisfying the limitations of and constructed in accordance with Section 2308 of the *International Building Code*.
4. Agricultural storage structures that are intended only for incidental human occupancy.
5. Structures that require special consideration of their response characteristics and environment that are not addressed in Chapter 15 and for which other regulations provide seismic criteria, such as vehicular bridges, electrical transmission towers, hydraulic structures, buried utility lines and their appurtenances, and nuclear reactors.

Commentary to Chapter 11 Modifications

COMMENTARY TO SECTION 11.1.2

C11.1.2 Scope. The scope statement establishes in general terms the applicability of the standard as a base of reference. Certain structures are exempt and need not comply. The reasons for each are described below.

Note that it is not acceptable to use a combination of *International Building Code* (IBC) and *International Residential Code* (IRC) conventional construction provisions. Conventional requirements of either the IBC or the IRC can be combined with engineered design of elements in accordance with IBC engineered design requirements. Elements designed using the IBC engineered design requirements are not exempt from the seismic requirements of ASCE/SEI 7.

Exemption 1 – Detached one- and two-family dwellings in Seismic Design Categories A, B, and C, along with those located where $S_s < 0.4$g, are exempt because they represent low seismic risks.

Exemption 2 – This exemption recognizes that the wood-frame seismic design requirements of the *International Residential Code* (IRC) substantially meet the intent of conventional construction (wood-frame) provisions included in the *NEHRP Recommended Seismic Provisions* through the 2003 Edition.

Exemption 3 – This exemption recognizes that wood-frame seismic design requirements of *International Building Code* (IBC) Section 2308 substantially meet the intent of conventional construction (wood-frame) provisions included in the *NEHRP Recommended Seismic Provisions* through the 2003 Edition.

Exemption 4 – Agricultural storage structures generally are exempt from most code requirements because of the exceptionally low risk to life involved.

Exemption 5 – Bridges, transmission towers, nuclear reactors, and other structures with special configurations and uses are not covered because regulations developed to apply to buildings and building-like structures do not adequately address their design and performance issues.

The standard is not retroactive and usually applies to existing structures only where there is an addition, change of use, or alteration. Minimum acceptable seismic resistance of existing buildings is a policy issue normally set by the authority having jurisdiction. Appendix 11B of the standard contains rules of application for basic conditions. ASCE 31*, Seismic Evaluation of Buildings,* and ASCE 41, *Seismic Rehabilitation of Existing Buildings,* are available for technical guidance but do not contain policy recommendations. The International Code Council includes a chapter in the IBC to control the alteration, repair, addition, and change of occupancy of existing buildings and also maintains the *International Existing Building Code* (IEBC) and an associated commentary.

Modifications to Chapter 12 Seismic Design Requirements for Building Structures

SECTION 12.8.7, P-DELTA LIMIT

Replace with the following:

12.8.7 P-delta Limit. Stability coefficient, θ, as determined for each level of the structure by the following equation, shall not exceed 0.10:

$$\theta = \frac{P_x \Delta I}{V_x h_{sx} C_d} \qquad (12.8\text{-}16)$$

where:

P_x = the total vertical design load at and above Level x. Where calculating the vertical design load for purposes of determining P-delta effects, the individual load factors need not exceed 1.0.
Δ = the design story drift calculated in accordance with Section 12.8.6.
I = the occupancy importance factor determined in accordance with Section 11.5.1.
V_x = the seismic shear force acting between Level x and x - 1.
h_{sx} = the story height below Level x.
C_d = the deflection amplification factor from Table 12.2-1

EXCEPTION: The stability coefficient, θ, shall be permitted to exceed 0.10 if either of the following applies:

1. The resistance to lateral forces is determined to increase continuously in a monotonic nonlinear static (pushover) analysis according to ASCE/SEI 41 Section 3.3.3.3.2 using S_a defined as a MCE_R spectral response acceleration according to the *Provisions* at the effective fundamental period. Modeling and analysis-shall conform to ASCE/SEI 41 Section 3.3.3, except that the analysis shall be done for seismic actions occurring simultaneously with the effects of dead load in combination with not less than 25 percent of the required design live loads, reduced as permitted for the area of a single floor. Degradation shall be modeled and P-delta effects shall be included in the analysis. A review of the nonlinear static analysis shall be performed by an independent team having experience in seismic analysis methods and the theory and application of nonlinear seismic analysis and structural behavior under earthquake loading. The review team shall be composed of at least two members including at least one registered design professional.
2. Compliance with the provisions of the nonlinear response history procedure in Chapter 16 is demonstrated.

SECTION 12.11.2.2.1, TRANSFER OF ANCHORAGE FORCES INTO DIAPHRAGM

Replace with the following:

12.11.2.2.1 Transfer of Anchorage Forces into Diaphragm. Diaphragms shall be provided with continuous ties or struts between diaphragm chords to distribute these anchorage forces into the diaphragm.

EXCEPTION: In buildings with diaphragms of light-frame construction, continuous cross-ties are not required provided all of the following are satisfied:

1. The unsupported height of the wall does not exceed 12 feet,
2. Anchorages are spaced no more than 4 feet on center,
3. The length of the diaphragm in the direction parallel to the wall being anchored does not exceed 2.5 times the length of the diaphragm in the orthogonal direction, and
4. The anchorage connection extends far enough into the diaphragm to transfer the anchorage force into the diaphragm.

Diaphragm connections shall be positive, mechanical, or welded. Added chords are permitted to be used to form subdiaphragms to transmit the anchorage forces to the main continuous cross-ties. The maximum length-to-width ratio of the structural subdiaphragm shall be 2.5 to 1. Connections and anchorages capable of resisting the prescribed forces shall be provided between the diaphragm and the attached components. Connections shall extend into the diaphragm a sufficient distance to develop the force transferred into the diaphragm.

SECTION 12.11.2.2.3, WOOD DIAPHRAGMS

Replace with the following:

12.11.2.2.3 Wood Diaphragms. In wood diaphragms, the continuous ties shall be in addition to the diaphragm sheathing.

EXCEPTION: Where continuous cross-ties are not required by Section 12.11.2.2.1 and the anchorage connections extend into the diaphragm a sufficient distance to develop the force transferred into the diaphragm sheathing.

Anchorage shall not be accomplished by use of toenails or nails subject to withdrawal nor shall wood ledgers or framing be used in cross-gain bending or cross-grain tension. The diaphragm sheathing shall not be considered effective as providing the ties or struts required by this section.

SECTION 12.14.7.5.1, TRANSFER OF ANCHORAGE FORCES INTO DIAPHRAGM

Replace with the following:

12.14.7.5.1 Transfer of Anchorage Forces into Diaphragm. Diaphragms shall be provided with continuous ties or struts between diaphragm chords to distribute these anchorage forces into the diaphragm.

EXCEPTION: In buildings with diaphragms of light-framed construction, continuous cross-ties are not required provided all of the following are satisfied:

1. The unsupported height of the wall does not exceed 12 feet,
2. Anchorages are spaced no more than 4 feet on center,
3. The length of the diaphragm in the direction parallel to the wall being anchored does not exceed 2.5 times the length of the diaphragm in the orthogonal direction, and
4. The connection extends far enough into the diaphragm to transfer the anchorage force into the diaphragm.

Added chords are permitted to be used to form subdiaphragms to transmit the anchorage forces to the main continuous cross-ties. The maximum length-to-width ratio of the structural subdiaphragm shall be 2.5 to 1. Connections and anchorages capable of resisting the prescribed forces shall be provided between the diaphragm and the attached components. Connections shall extend into the diaphragm a sufficient distance to develop the force transferred into the diaphragm.

SECTION 12.14.7.5.2, WOOD DIAPHRAGMS

Replace with the following:

12.14.7.5.2 Wood Diaphragms. In wood diaphragms, the continuous ties shall be in addition to the diaphragm sheathing.

EXCEPTION: Where continuous cross-ties are not required by Section 12.14.7.5.1 and the anchorage connections extend into the diaphragm a sufficient distance to develop the force transferred into the diaphragm sheathing.

Anchorage shall not be accomplished by use of toenails or nails subject to withdrawal nor shall wood ledgers or framing be used in cross-gain bending or cross-grain tension. The diaphragm sheathing shall not be considered effective as providing the ties or struts required by this section.

Commentary to Chapter 12 Modifications

COMMENTARY TO SECTION 12.8.7

C12.8.7 P-delta Limit. ASCE/SEI 7-05 allows amplified forces to be used in a linear elastic analysis where the stability coefficient, exceeds 0.10. By comparison, FEMA 350 requires explicit modeling of P-delta effects for steel moment-resisting frames where exceeds approximately 0.04. Where the tangent stiffness of the structure may become negative, dynamic displacement demands can increase significantly (Gupta and Krawinkler, 2000). Structures with not greater than 0.10 generally are expected to have a positive tangent stiffness, depending on the progression of plastic hinging and strain hardening. The 2009 *Provisions* allows structures to exceed this limit only if a nonlinear static analysis including P-delta effects demonstrates that the tangent stiffness remains positive up to the target displacement computed for the MCE_R or if nonlinear dynamic analysis demonstrates adequate resistance to instability.

The occupancy importance factor, *I*, is inserted into Equation 12.8-16 to correct an error in ASCE/SEI 7. In this way, the stability coefficient is based on the elastic stiffness of the system.

Modifications to Chapter 13
Seismic Design Requirements for Nonstructural Elements

There are no exceptions/modifications for this chapter

Modifications to Chapter 14
Material Specific Seismic Design and Detailing Requirements

NEW SECTION 14.2.4, ACCEPTANCE CRITERIA FOR SPECIAL PRECAST STRUCTURAL WALLS BASED ON VALIDATION TESTING

Add the following new section:

14.2.4 Acceptance Criteria for Special Precast Structural Walls Based on Validation Testing

14.2.4.1 Notation

Symbols additional to those in ACI 318 Chapter 2 are defined.

E_{max} = maximum lateral resistance of test module determined from test results (forces or moments)

E_n = nominal lateral resistance of test module calculated using specified geometric properties of test members, specified yield strength of reinforcement, specified compressive strength of concrete, a strain compatibility analysis or deformation compatibility analysis for flexural strength and a strength reduction factor of 1.0

E_{nt} = calculated lateral resistance of test module using the actual geometric properties of test members, the actual strengths of reinforcement, concrete, and coupling devices, obtained by testing per Sections 14.2.4.7.7, 14.2.4.7.8, and 14.2.4.7.9, and a strength reduction factor of 1.0

θ = drift ratio

β = relative energy dissipation ratio

14.2.4.2 Definitions

Definitions additional to those in ACI 318 Chapter 2 are defined.

14.2.4.2.1 Coupling Elements. Devices or beams connecting adjacent vertical boundaries of structural walls and used to provide stiffness and energy dissipation for the connected assembly greater than the sum of those provided by the connected walls acting as separate units.

14.2.4.2.2 Drift Ratio. Total lateral deformation of the test module divided by the height of the test module.

14.2.4.2.3 Global Toughness. The ability of the entire lateral force resisting system of the prototype structure to maintain structural integrity and continue to carry the required gravity load at the maximum lateral displacements anticipated for the ground motions of the maximum considered earthquake.

14.2.4.2.4 Prototype Structure. The concrete wall structure for which acceptance is sought.

14.2.4.2.5 Relative Energy Dissipation Ratio. Ratio of actual to ideal energy dissipated by test module during reversed cyclic response between given drift ratio limits, expressed as the ratio of the area of the hysteresis loop for that cycle to the area of the circumscribing parallelograms defined by the initial stiffnesses during the first cycle and the peak resistances during the cycle for which the relative energy dissipation ratio is calculated. See Section 14.2.4.9.1.3.

14.2.4.2.5 Test Module. Laboratory specimen representing the critical walls of the prototype structure. See Section 14.2.4.5.

14.2.4.3 Scope and General Requirements

14.2.4.3.1 These provisions define minimum acceptance criteria for new precast structural walls, including coupled precast structural walls, designed for regions of high seismic risk or for structures assigned to high seismic performance or design categories, where acceptance is based on experimental evidence and mathematical analysis.

14.2.4.3.2 These provisions are applicable to precast structural walls, coupled or uncoupled, with height to length, $h_w/l_{w,}$ ratios equal to or greater than 0.5. These provisions are applicable for either prequalifying precast structural walls for a specific structure or prequalifying a new precast wall type for construction in general.

14.2.4.3.3 Precast structural walls shall be deemed to have a response that is at least equivalent to the response of monolithic structural walls designed in accordance with ACI 318 Sections 21.1 and 21.9, and the corresponding structural walls of the prototype structure shall be deemed acceptable, when all of the conditions in Sections 14.2.4.3.3.1 through 14.2.4.3.3.5 are satisfied.

14.2.4.3.3.1 The prototype structure satisfies all applicable requirements of these provisions and of ACI 318 except Section 21.9.

14.2.4.3.3.2 Tests on wall modules satisfy the conditions in Sections 14.2.4.4 and 14.2.4.9.

14.2.4.3.3.3 The prototype structure is designed using the design procedure substantiated by the testing program.

14.2.4.3.3.4 The prototype structure is designed and analyzed using effective initial properties consistent with those determined in accordance with Section 14.2.4.7.11, and the prototype structure meets the drift limits of these provisions.

14.2.4.3.3.5 The structure as a whole, based on the results of the tests of Section 14.2.4.3.3.2 and analysis, is demonstrated to have adequate global toughness (the ability to retain its structural integrity and support its specified

gravity loads) through peak displacements equal to or exceeding the story-drift ratios specified in Section 14.2.4.7.4, 14.2.4.7.5 or 14.2.4.7.6, as appropriate.

14.2.4.4 Design Procedure

14.2.4.4.1 Prior to testing, a design procedure shall be developed for the prototype structure and its walls. That procedure shall account for effects of material non-linearity, including cracking, deformations of members and connections, and reversed cyclic loading. The design procedure shall include the procedures specified in Sections 14.2.4.4.1.1 through 14.2.4.4.1.4 and shall be applicable to all precast structural walls, coupled and uncoupled, of the prototype structure.

14.2.4.4.1.1 Procedures shall be specified for calculating the effective initial stiffness of the precast structural walls, and of coupled structural walls, that are applicable to all the walls of the prototype structure.

14.2.4.4.1.2 Procedures shall be specified for calculating the lateral strength of the precast structural walls, and of coupled structural walls, applicable to all precast walls of the prototype structure.

14.2.4.4.1.3 Procedures shall be specified for designing and detailing the precast structural walls so that they have adequate ductility capacity. These procedures shall cover wall shear strength, sliding shear strength, boundary tie spacing to prevent bar buckling, concrete confinement, reinforcement strain, and any other actions or elements of the wall system that can affect ductility capacity.

14.2.4.4.1.4 Procedures shall be specified for determining that an undesirable mechanism of nonlinear response, such as a story mechanism due to local buckling of the reinforcement or splice failure, or overall instability of the wall, does not occur.

14.2.4.4.2 The design procedure shall be used to design the test modules and shall be documented in the test report.

14.2.4.4.3 The design procedure used to proportion the test specimens shall define the mechanism by which the system resists gravity and earthquake effects and shall establish acceptance values for sustaining that mechanism. Portions of the mechanism that deviate from code requirements shall be contained in the test specimens and shall be tested to determine acceptance values.

14.2.4.5 Test Modules

14.2.4.5.1 At least two modules shall be tested. At least one module shall be tested for each limiting engineering design criteria (shear, axial load and flexure) for each characteristic configuration of precast structural walls, including intersecting structural walls or coupled structural walls. If all the precast walls of the structure have the same configuration and the same limiting engineering design criterion, then two modules shall be tested. Where intersecting precast wall systems are to be used, the response for the two orthogonal directions shall be tested.

14.2.4.5.2 Where the design requires the use of coupling elements, those elements shall be included as part of the test module.

14.2.4.5.3 Modules shall have a scale large enough to represent the complexities and behavior of the real materials and of the load transfer mechanisms in the prototype walls and their coupling elements, if any. Modules shall have a scale not less than one half and shall be full-scale if the validation testing has not been preceded by an extensive analytical and experimental development program in which critical details of connections are tested at full scale.

14.2.4.5.4 The geometry, reinforcing details, and materials properties of the walls, connections, and coupling elements shall be representative of those to be used in the prototype structure.

14.2.4.5.5 Walls shall be at least two panels high unless the prototype structure is one for which a single panel is to be used for the full height of the wall.

14.2.4.5.6 Where precast walls are to be used for bearing wall structures, as defined in ASCE/SEI 7-05, the test modules shall be subject during lateral loading to an axial load stress representative of that anticipated at the base of the wall in the prototype structure.

14.2.4.5.7 The geometry, reinforcing, and details used to connect the precast walls to the foundation shall replicate those to be used in the prototype structure.

14.2.4.5.8 Foundations used to support the test modules shall have geometric characteristics, and shall be reinforced and supported, so that their deformations and cracking do not affect the performance of the modules in a way that would be different than in the prototype structure.

14.2.4.6 Testing Agency. Testing shall be carried out by an independent testing agency approved by the Authority Having Jurisdiction. The testing agency shall perform its work under the supervision of a registered design professional experienced in seismic structural design.

14.2.4.7 Test Method

14.2.4.7.1 Test modules shall be subjected to a sequence of displacement-controlled cycles representative of the drifts expected under earthquake motions for the prototype structure. If the module consists of coupled walls, approximately equal drifts (within 5 percent of each other) shall be applied to the top of each wall and at each floor level. Cycles shall be to predetermined drift ratios as defined in Sections 14.2.4.7.2 through 14.2.4.7.6.

14.2.4.7.2 Three fully reversed cycles shall be applied at each drift ratio.

14.2.4.7.3 The initial drift ratio shall be within the essentially linear elastic response range for the module. See 14.2.4.7.11. Subsequent drift ratios shall be to values not less than 5/4 times, and not more than 3/2 times, the previous drift ratio.

14.2.4.7.4 For uncoupled walls, testing shall continue with gradually increasing drift ratios until the drift ratio in percent equals or exceeds the larger of : (a) 1.5 times the drift ratio corresponding to the design displacement or (b) the following value:

$$0.80 \le 0.67\left[h_w/l_w\right] + 0.5 \le 2.5 \qquad (14.2.4\text{-}1)$$

where h_w = height of entire wall for prototype structure (in inches) and l_w = length of entire wall in direction of shear force (in inches).

14.2.4.7.5 For coupled walls, h_w/l_w in Equation 14.2.4-1 shall be taken as the smallest value of h_w/l_w for any individual wall of the prototype structure.

14.2.4.7.6 Validation by testing to limiting drift ratios less than those given by Equation 14.2.4-1 shall be acceptable provided testing is conducted in accordance with this document to drift ratios equal or exceeding of those determined for the response to a suite of nonlinear time history analyses conducted in accordance with the 2009 *NEHRP Recommended Seismic Provisions* for risk-targeted maximum considered earthquake ground motions.

14.2.4.7.7 Actual yield strength of steel reinforcement shall be obtained by testing coupons taken from the same reinforcement batch as used in the test module. Two tests, conforming to the ASTM specifications cited in ACI 318 Section 3.8, shall be made for each reinforcement type and size.

14.2.4.7.8 Actual compressive strength of concrete shall be determined by testing of concrete cylinders cured under the same conditions as the test module and tested at the time of testing the module. Testing shall conform to the applicable requirements of ACI 318 Sections 5.6.1 through 5.6.4.

14.2.4.7.9 Where strength and deformation capacity of coupling devices does not depend on reinforcement tested as required in Section 14.2.4.7.7, the effective yield strength and deformation capacity of coupling devices shall be obtained by testing independent of the module testing.

14.2.4.7.10 Data shall be recorded from all tests such that a quantitative interpretation can be made of the performance of the modules. A continuous record shall be made of test module drift ratio versus applied lateral force, and photographs shall be taken that show the condition of the test module at the peak displacement and after each key testing cycle.

14.2.4.7.11 The effective initial stiffness of the test module shall be calculated based on test cycles to a force between $0.6E_{nt}$ and $0.9E_{nt}$, and using the deformation at the strength of $0.75E_{nt}$ to establish the stiffness.

14.2.4.8 Test Report

14.2.4.8.1 The test report shall contain sufficient evidence for an independent evaluation of all test procedures, design assumptions, and the performance of the test modules. As a minimum, all of the information required by Sections 14.2.4.8.1.1 through 14.2.4.8.1.11 shall be provided.

14.2.4.8.1.1 A description shall be provided of the design procedure and theory used to predict test module strength, specifically the test module nominal lateral resistance, E_n, and the test module actual lateral resistance E_{nt}.

14.2.4.8.1.2 Details shall be provided of test module design and construction, including fully dimensioned engineering drawings that show all components of the test specimen.

14.2.4.8.1.3 Details shall be provided of specified material properties used for design, and actual material properties obtained by testing in accordance with Section 14.2.4.7.7.

14.2.4.8.1.4 A description shall be provided of test setup, including fully dimensioned diagrams and photographs.

14.2.4.8.1.5 A description shall be provided of instrumentation, its locations, and its purpose.

14.2.4.8.1.6 A description and graphical presentation shall be provided of applied drift ratio sequence.

14.2.4.8.1.7 A description shall be provided of observed performance, including photographic documentation, of the condition of each test module at key drift ratios including, (as applicable), the ratios corresponding to first flexural cracking or joint opening, first shear cracking, and first crushing of the concrete for both positive and negative loading directions, and any other significant damage events that occur. Photos shall be taken at peak drifts and after the release of load.

14.2.4.8.1.8 A graphical presentation shall be provided of lateral force versus drift ratio response.

14.2.4.8.1.9 A graphical presentation shall be provided of relative energy dissipation ratio versus drift ratio.

14.2.4.8.1.10 A calculation shall be provided of effective initial stiffness for each test module as observed in the test and as determined in accordance with Section 14.2.4.7.11 and a comparison made as to how accurately the design procedure has been able to predict the measured stiffness. The design procedure shall be used to predict the overall structural response and a comparison made as to how accurately that procedure has been able to predict the measured response.

14.2.4.8.1.11 The test date, report date, name of testing agency, report author(s), supervising registered design professional, and test sponsor shall be provided.

14.2.4.9 Test Module Acceptance Criteria

14.2.4.9.1 The test module shall be deemed to have performed satisfactorily when all of the criteria Sections 14.2.4.9.1.1 through 14.2.4.9.1.3 are met for both directions of in-plane response. If any test module fails to pass the validation testing required by these provisions for any test direction, then the wall system has failed the validation testing.

14.2.4.9.1.1 Peak lateral strength obtained shall be at least $0.9E_{nt}$ and not greater than $1.2\ E_{nt}$.

14.2.4.9.1.2 In cycling up to the drift level given by Sections 14.2.4.7.4 through 14.2.4.7.6, fracture of reinforcement or coupling elements, or other significant strength degradation, shall not occur. For a given direction, peak lateral strength during any cycle of testing to increasing displacement shall not be less than 0.8 times E_{max} for that direction.

14.2.4.9.1.3 For cycling at the given drift level for which acceptance is sought in accordance with Section 14.2.4.7.4, 14.2.4.7.5 or 14.2.4.7.6, as applicable, the parameters describing the third complete cycle shall have satisfied the following:

1. The relative energy dissipation ratio shall not be less than 1/8 and
2. The secant stiffness between drift ratios of -1/10 and +1/10 of the maximum applied drift shall not be less than 0.10 times the stiffness for the initial drift ratio specified in Section 14.2.4.7.3.

Commentary to Chapter 14 Modifications

COMMENTARY TO SECTION 14.2.4

C14.2.4 Acceptance Criteria for Special Precast Structural Walls Based on Validation Testing

C14.2.4.1 Notation. Symbols additional to those in ACI 318 Chapter 2 are defined:

A_h = area of hysteresis loop.
E_1, E_2 = peak lateral resistance for positive and negative loading, respectively, for third cycle of loading sequence.
f_1 = live load factor defined in Section 14.2.4.2.3.
h_w = height of column of test module, in. or mm.
K, K' = initial stiffness for positive and negative loading, respectively, for first cycle.
θ_1, θ_2 = drift ratios at peak lateral resistance for positive and negative loading, respectively, for third cycle of loading sequence.

$\theta 1', \theta 2'$ = drift ratios for zero lateral load for unloading at stiffness K, K' from peak positive and negative lateral resistance, respectively, for third cycle of loading sequence.

Δ = lateral displacement, in. or mm. See Figures. C14.2.4.2.2-1, C14.2.4.2.2-2, and C14.2.4.2.2-3.

Δ_a = allowable story drift, in. or mm. See Table 12.12-1 of ASCE/SEI 7-05.

C14.2.4.2 Definitions

C14.2.4.2.1 Coupling elements. Coupling elements are connections provided at specific intervals along the vertical boundaries of adjacent structural walls. Coupled structural walls are stiffer and stronger than the same walls acting independently. For cast-in-place construction effective coupling elements are typically coupling beams having small span-to-depth ratios. The inelastic behavior of such beams is normally controlled by their shear strength. For precast construction, effective coupling elements can be precast beams connected to the adjacent structural walls either by post-tensioning, ductile mechanical devices, or grouted-in-place reinforcing bars. The resultant coupled construction can be either emulative of cast-in-place construction or non-emulative (jointed). However, for precast construction coupling beams can also be omitted and mechanical devices used to connect directly the vertical boundaries of adjacent structural walls.[2,3]

C14.2.4.2.2 Drift ratio. The definition of the drift ratio, θ, is illustrated in Figure C14.2.4.2.2-1 for a three panel wall module. The position of the module at the start of testing, with only its self-weight acting, is indicated by broken lines. The module is set on a horizontal foundation support that is centered at A and is acted on by a lateral force H applied at the top of the wall. The self-weight of the wall is distributed uniformly to the foundation support. However, under lateral loading, that self-weight and any axial gravity load acting at the top of the wall cause overturning moments on the wall that are additional to the overturning moment Hh_w and can affect deformations. The chord AB of the centroidal axis of the wall is the vertical reference line for drift measurements.

For acceptance testing a lateral force H is applied to the wall through the pin at B. Depending on the geometric and reinforcement characteristics of the module that force can result in the module taking up any one, or a combination, of the deformed shapes indicated by solid lines in Figures C14.2.4.2.2-1, C14.2.4.2.2-2 and C14.2.4.2.2-3.

Figure C14.2.4.2.2-2 illustrates several possible components of the displacement Δ for a wall that is effectively solid while Figure C14.2.4.2.2-3 illustrates two possibly undesirable components of the displacement Δ. Regardless of the mode of deformation of the wall, the lateral force causes the wall at B to displace horizontally by an amount Δ. The drift ratio is the angular rotation of the wall chord with respect to the vertical and for the setup shown equals Δ / h_w where h_w is the wall height and is equal to the distance between the foundation support at A and the load point at B. Where prestressing steel is used in wall members, the stress f_{ps} in the reinforcement at the nominal and the probable lateral resistance shall be calculated in accordance with ACI 318 Section 18.7.

C14.2.4.2.3 Global toughness. These provisions describe acceptance criteria for special precast structural walls based on validation testing. The requirements of Section 21.1.1.8 of ACI 318 concerning toughness cover both to the energy dissipation of the wall system which, for monolithic construction, is affected primarily by local plastic hinging behavior and the toughness of the prototype structure as a whole. The latter is termed "global toughness" in these provisions and is a condition that does not apply to the walls alone. That global toughness requirement can be satisfied only though analysis of the performance of the prototype structure as a whole when the walls perform to the criteria specified in these provisions.

The required gravity load for global toughness evaluations is the value given by these provisions. For conformity with Section 9.2.1 of ACI 318-08, UBC 1997, IBC 2006 and NFPA 5000, the required gravity load is $1.2D + f_1L$ where the seismic force is additive to gravity forces and 0.9D where the seismic force counteracts gravity forces. D is the effect of dead loads, L is the effect of live loads, and f_1 is a factor equal to 0.5 except for garages, areas occupied as places of public assembly, and all areas where the live load is greater than 100 psf (4.79 kN/m^2) where f_1 equals 1.0.

C14.2.4.2.5 Relative energy dissipation ratio. This concept is illustrated in Figure C14.2.4.2.2-1 for the third loading cycle to the limiting drift ratio required by Section 14.2.4.7.4, 14.2.4.7.5 or 14.2.4.7.6, as appropriate.

Figure 14.2.4.2.2-2 illustrates several possible components of the displacement Δ for a wall that is effectively solid while Figure C14.2.4.2.2-3 illustrates two possibly undesirable components of the displacement Δ. Regardless of the mode of deformation of the wall, the lateral force causes the wall at B to displace horizontally by an amount Δ. The drift ratio is the angular rotation of the wall chord with respect to the vertical and for the setup shown equals Δ / h_w where h_w is the wall height and is equal to the distance between the foundation support at A and the load point at B.

Where prestressing steel is used in wall members, the stress f_{ps} in the reinforcement at the nominal and the probable lateral resistance shall be calculated in accordance with Section 18.7 of ACI 318.

C14.2.4.2.3 Global toughness. These provisions describe acceptance criteria for special precast structural walls based on validation testing. The requirements of ACI 318 Section 21.1.1.8 concerning toughness cover both to the energy dissipation

of the wall system which, for monolithic construction, is affected primarily by local plastic hinging behavior and the toughness of the prototype structure as a whole. The latter is termed "global toughness" in these provisions and is a condition that does not apply to the walls alone. That global toughness requirement can be satisfied only though analysis of the performance of the prototype structure as a whole when the walls perform to the criteria specified in these provisions.

The required gravity load for global toughness evaluations is the value given by these provisions. For conformity with Section 9.2.1 of ACI 318-08, UBC 1997, IBC 2006 and NFPA 5000, the required gravity load is $1.2D + f_1L$ where the seismic force is additive to gravity forces and 0.9D where the seismic force counteracts gravity forces. D is the effect of dead loads, L is the effect of live loads, and f_1 is a factor equal to 0.5 except for garages, areas occupied as places of public assembly, and all areas where the live load is greater than 100 psf (4.79 kN/m^2) where f_1 equals 1.0.

C14.2.4.2.5 Relative energy dissipation ratio. This concept is illustrated in Figure C14.2.4.2.5 for the third loading cycle to the limiting drift ratio required by Section 14.2.4.7.4, 14.2.4.7.5 or 14.2.4.7.6, as appropriate. For Figure C14.2.4.2.5, it is assumed that the test module has exhibited different initial stiffnesses, K and K', for positive and negative lateral forces and that the peak lateral resistances for the third cycle for the positive and negative loading directions, E_1 and E_2, also differ. The area of the hysteresis loop for the third cycle, A_h, is hatched. The circumscribing figure consists of two parallelograms, ABCD and DFGA. The slopes of the lines AB and DC are the same as the initial stiffness, K, for positive loading and the slopes of the lines DF and GA are the same as the initial stiffness, K , for negative loading. The relative energy dissipation ratio concept is similar to the equivalent damping concept used in Section 17.8.3 of the ASCE/SEI 7-05 for required tests of seismic isolation systems.

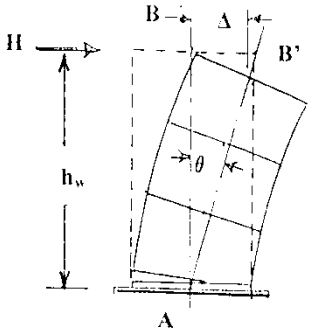

Figure C14.2.4.2.2-1 Definition of drift ratio θ.

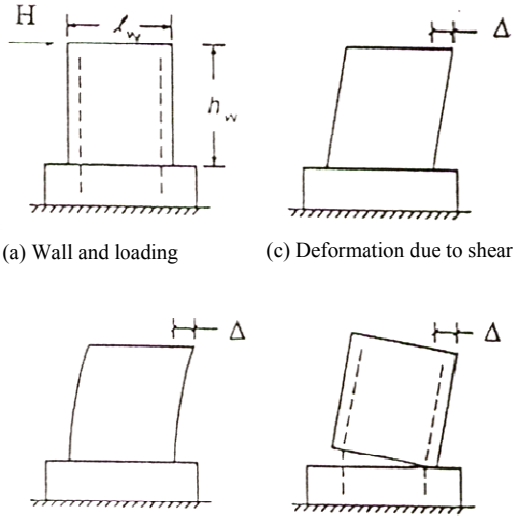

(a) Wall and loading

(c) Deformation due to shear

(b) Deformation due to flexure

(d) Deformation due to extension of reinforcement at foundation to wall interface

Figure C14.2.4.4.2.2-2 Typical wall deformation components.

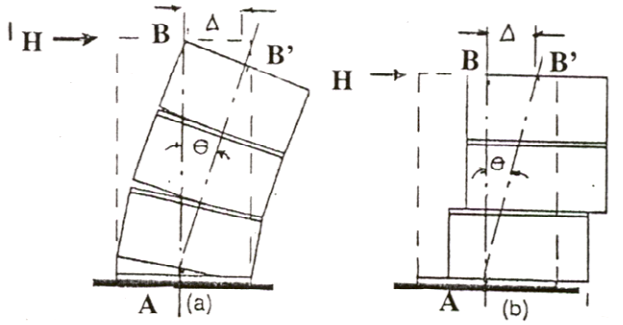

Figure C14.2.4.4.2.2-3 Undesirable deformations along horizontal joints: (a) excessive gap opening between panels and (b) shear slip.

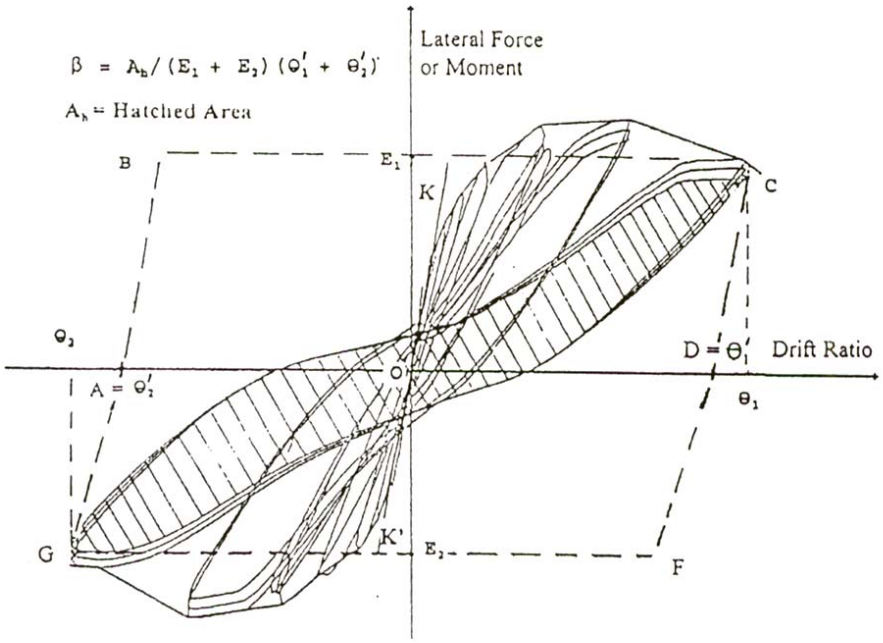

Figure C14.2.4.4.2.5 Relative energy dissipation ratio.

For a given cycle the relative energy dissipation ratio, β, is the area, A_h, inside the lateral force-drift ratio loop for the module, divided by the area of the effective circumscribing parallelograms ABCD and DFGA. The areas of the parallelograms equal the sum of the absolute values of the lateral force strengths, E_1 and E_2, at the drift ratios θ_1 and θ_2 multiplied by the sum of the absolute values for the drift ratios θ_1' and θ_2'.

C14.2.4.3 Scope and general requirements. While only ACI Committee 318 can determine the requirements necessary for precast walls to meet the provisions of ACI 318 Section 21.1.1.8, ACI 318 Section 1.4 already permits the building official to accept wall systems, other than those explicitly covered by ACI 318 Chapter 21, provided specific tests, load factors, deflection limits, construction procedures and other pertinent requirements have been established for acceptance of such systems consistent with the intent of the code. The purpose of these provisions is to provide a framework that establishes the specific tests, load factors, deflection limits and other pertinent requirements appropriate for acceptance, for regions of high seismic risk or for structures assigned to high seismic performance or design categories, of precast wall systems, including coupled wall systems, not satisfying all the requirements of ACI 318 Chapter 21. For regions of moderate

seismic risk or for structures assigned to intermediate seismic performance or design categories, less stringent provisions than those specified here are appropriate.

These provisions assume that the precast wall system to be tested has details differing from those prescribed by ACI 318 Section 21.9 for conventional monolithic reinforced concrete construction. Such walls may, for example, involve the use of precast elements, precast prestressed elements, post-tensioned reinforcement, or combinations of those elements and reinforcement.

For monolithic reinforced concrete walls a fundamental design requirement of ACI 318 Chapter 21 is that walls with h_w/l_w exceeding1.0 be proportioned so that their inelastic response is dominated by flexural action on a critical section located near the base of the wall. That fundamental requirement is retained in these provisions. The reason is that tests on modules, as envisioned in these provisions, cannot be extrapolated with confidence to the performance of panelized walls of proportions differing from those tested for the development of ACI 318 Chapter 21 if the shear-slip displacement pattern of Figure C14.2.4.2.2.3, or the shear deformation response of Figure C14.2.4.2.2.2, governs the response developed in the test on the module. Two other fundamental requirements of ACI 318 Chapter 21 are for ties around heavily strained boundary element reinforcement and the provision of minimum amounts of uniformly distributed horizontal and vertical reinforcement in the web of the wall. Ties around boundary element reinforcement to inhibit its buckling in compression are required where the strain in the extreme compression fiber is expected to exceed some critical value. Minimum amounts of uniformly distributed horizontal and vertical reinforcement over the height and length of the wall are required to restrain the opening of inclined cracks and allow the development of the drift ratios specified in Sections 14.2.4.7.4, 14.2.4.7.5 and 14.2.4.7.6. Deviations from those tie and distributed reinforcement requirements are possible only if a theory is developed that can substantiate reasons for such deviations and that theory is tested as part of the validation testing.

C14.2.4.3.1. These provisions are not intended for use with existing construction or for use with walls that are designed to conform to all the requirements of ACI 318 Section 21.9. The criteria of these provisions are more stringent than those for walls designed to ACI 318 Section 21.9. Some walls designed to Section 21.9, and having low height to length ratios, may not meet the drift ratio limits of Equation 14.2.4-1 because their behavior may be governed by shear deformations. The height to length ratio of 0.5 is the least value for which Equation 14.2.4-1 is applicable.

C14.2.4.3.3 For acceptance, the results of the tests on each module must satisfy the acceptance criteria of Section 14.2.4.9. In particular, the relative energy dissipation ratio calculated from the measured results for the third cycle between the specified limiting drift ratios must equal or exceed 1/8. For uncoupled walls, relative energy dissipation ratios increase as the drift ratio increases. Tests on slender monolithic walls have shown relative energy dissipation ratios, derived from rotations at the base of the wall, of about 40-45 percent at large drifts. The same result has been reported even where there has been a significant opening in the web of the wall on the compression side. For 0.020 drift ratios and walls with height to length ratios of 4, relative energy dissipation ratios have been computed as 30, 18, 12, and 6 percent, for monolithic reinforced concrete, hybrid reinforced/post-tensioned prestressed concrete with equal flexural strengths provided by the prestressed and deformed bar reinforcement, hybrid reinforced/post-tensioned prestressed concrete with 25 percent of the flexural strength provided by deformed bar reinforcement and 75 percent by the prestressed reinforcement, and post-tensioned prestressed concrete special structural walls, respectively. Thus, for slender precast uncoupled walls of emulative or non-emulative design it is to be anticipated that at least 35 percent of the flexural capacity at the base of the wall needs to be provided by deformed bar reinforcement if the requirement of a relative energy dissipation ratio of 1/8 is to be achieved. However, if more than about 40 percent of the flexural capacity at the base of the wall is provided by deformed bar reinforcement, then the self-centering capability of the wall following a major event is lost and that is one of the prime advantages gained with the use of post-tensioning. For squat walls with height to length ratios between 0.35 and 0.69 the relative energy dissipation has been reported as remaining constant at 23 percent for drifts between that for first diagonal cracking and that for a post-peak capacity of 80 percent of the peak capacity. Thus, regardless of whether the behavior of a wall is controlled by shear or flexural deformations a minimum relative energy dissipation ratio of 1/8 is a realistic requirement.

For coupled wall systems, theoretical studies and tests have demonstrated that the 1/8 relative energy dissipation ratio can be achieved by using central post-tensioning only in the walls and appropriate energy dissipating coupling devices connecting adjacent vertical wall boundaries.

C14.2.4.3.3.4. The ASCE/SEI 7-05 allowable story drift limits are the basis for the drift limits of IBC 2006 and NFPA 5000. Allowable story drifts, Δ_a, are specified in Table 1617.3 of IBC 2006 and likely values are discussed in the Commentary to Section 14.2.4.7.4. The limiting initial drift ratio consistent with Δ_a equals $\Delta_a / C_d h_w$, where is the strength reduction factor appropriate to the condition, flexure or shear, that controls the design of the test module. For example, for Δ_a/h_w equal to 0.015, the required deflection amplification factor C_d of 5, and equal to 0.9, the limiting initial drift ratio, corresponding to B in Figure C14.2.4.9.1, is 0.0033. The use of a value is necessary because the allowable story drifts of the IBC are for the design seismic load effect, E, while the limiting initial drift ratio is at the nominal strength, E_n , which must be greater than

E/ . The load-deformation relationship of a wall becomes significantly non-linear before the applied load reaches E_{nl}. While the load at which that non-linearity becomes marked depends on the structural characteristics of the wall, the response of most walls remains linear up to about 75 percent of E_{nl}.

C14.2.4.3.3.5. The criteria of Section 14.2.4.9 are for the test module. In contrast, the criterion of Section 14.2.4.3.3.5 is for the structural system as a whole and can be satisfied only by the philosophy used for the design and analysis of the building as a whole. The criterion adopted here is similar to that described in the last paragraph of R21.1.1 of ACI 318 and the intent is that test results and analyses demonstrate that the structure, after cycling three times through both positive and negative values of the limiting drift ratio specified in Section 14.2.4.7.4, 14.2.4.7.5 or 14.2.4.7.6, as appropriate, is still capable of supporting the gravity load specified as acting on it during the earthquake.

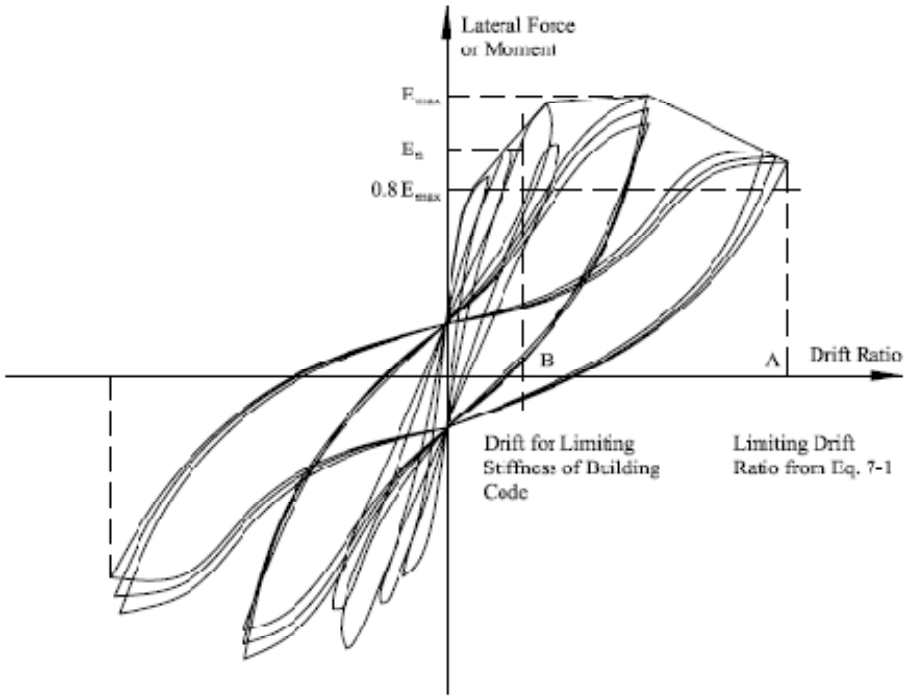

Figure C14.2.4.9.1 Quantities used in evaluating acceptance criteria.

C14.2.4.4 Design Procedure.

C14.2.4.4.1. The test program specified in these provisions is intended to verify an existing design procedure for precast structural walls for a specific structure or for prequalifying a generic type of special precast wall system for construction in general. The test program is not for the purpose of creating basic information on the strength and deformation properties of such systems for design purposes. Thus, the test modules should not fail during the validation testing, a result that is the opposite of what is usually necessary during testing in the development phase for a new or revised design procedure. For a generic precast wall system to be accepted based on these provisions, a rational design procedure is to have been developed prior to this validation testing. The design procedure is to be based on a rational consideration of material properties and force transfer mechanisms, and its development will usually require preliminary and possibly extensive physical testing that is not part of the validation testing. Because special wall systems are likely to respond inelastically during design-level ground shaking, the design procedure must consider wall configuration, equilibrium of forces, compatibility of deformations, the magnitudes of the lateral drifts, reversed cyclic displacements, the relative values of each limiting engineering design criteria (shear, flexure and axial load) and use appropriate constitutive laws for materials that include considerations of effects of cracking, loading reversals and inelasticity.

The effective initial stiffness of the structural walls is important for calculating the fundamental period of the prototype structure. The procedure used to determine the effective initial stiffness of the walls is to be verified from the validation test results as described in Section 14.2.4.7.11.

Provisions Sections 14.2.4.4.1.1 through 14.2.4.4.1.3 state the minimum procedures to be specified in the design procedure prior to the start of testing. The Authority Having Jurisdiction may require that more details be provided in the design procedure than those of Sections 14.2.4.4.1.1 through 14.2.4.4.1.3 prior to the start of testing.

C14.2.4.4.2. The justification for the small number of test modules, specified in Section 14.2.4.5.1 is that a previously developed rational design procedure is being validated by the test results. Thus, the test modules for the experimental program must be designed using the procedure intended for the prototype wall system and strengths must be predicted for the test modules before the validation testing is started.

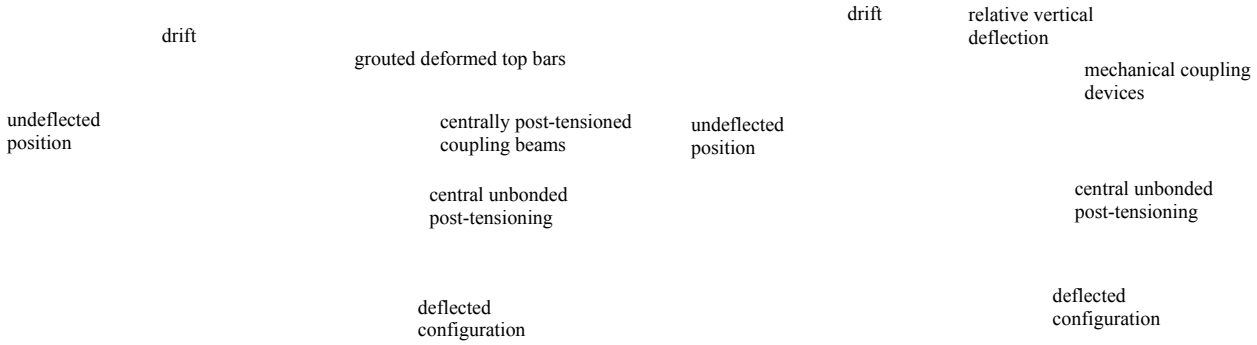
C14.2.4.5 Test Modules.

C14.2.4.5.1. One module must be tested for each limiting engineering design criterion, such as shear, or axial load and flexure, for each characteristic configuration of walls. Thus, in accordance with Section 14.2.4.4.3 if the test on the module results in a maximum shear stress of $3\sqrt{f_c'}$ then the maximum shear stress that can be used in the prototype is that same value. Each characteristic in-plane configuration of walls, or coupled walls, in the prototype structure must also be tested. Thus, as a minimum for one-way structural walls, two modules with the configuration shown in Figure C14.2.4.2.2-1, and, for one way coupled walls, two modules with the configuration shown in either Figure C14.2.4.5.1(a) or in Figure C14.2.4.5.1(b), must be tested. In addition, if intersecting wall systems are to be used then the response of the wall systems for the two orthogonal directions needs to be tested. For two-way wall systems and coupled wall-frame systems, testing of configurations other than those shown in Figures C14.2.4.2.2-1 and C14.2.4.5.1 may be appropriate when it is difficult to realistically model the likely dominant earthquake deformations using orthogonal direction testing only.

This provision should not be interpreted as implying that only two tests will need to be made to qualify a generic system. During the development of that system it is likely that several more tests will have been made, resulting in progressive refinements of the mathematical model used to describe the likely performance of the generic structural wall system and its construction details. Consequently, only one test of each module type for each limiting engineering design condition, at a specified minimum scale and subjected to specific loading actions, may be required to validate the system. Further, as stated in Section 14.2.4.9.1, if any one of those modules for the generic wall system fails to pass the validation testing required by these provisions, then the generic wall system has failed the validation testing

In most prototype structures, a slab is usually attached to the wall and, as demonstrated by the results of the PRESSS building test, the manner in which the slab is connected to the wall needs to be carefully considered. The connection needs to be adequate to allow the development of story drifts equal to those anticipated in these provisions. However, in conformity with common practice for the sub-assemblage tests used to develop the provisions of Chapter 21of ACI 318, there is no requirement for a slab to be attached to the wall of the test module. The effect of the presence of the slab should be examined in the development program that precedes the validation testing.

C14.2.4.5.3. Test modules need not be as large as the corresponding walls in the prototype structure. The scale of the test modules, however, must be large enough to capture all the complexities associated with the materials of the prototype wall, its geometry and reinforcing details, load transfer mechanisms, and joint locations. For modules involving the use of precast elements, for example, scale effects for load transfer through mechanical connections should be of particular concern. The issue of the scale necessary to capture fully the effects of details on the behavior of the prototype should be examined in the development program that precedes the validation testing.



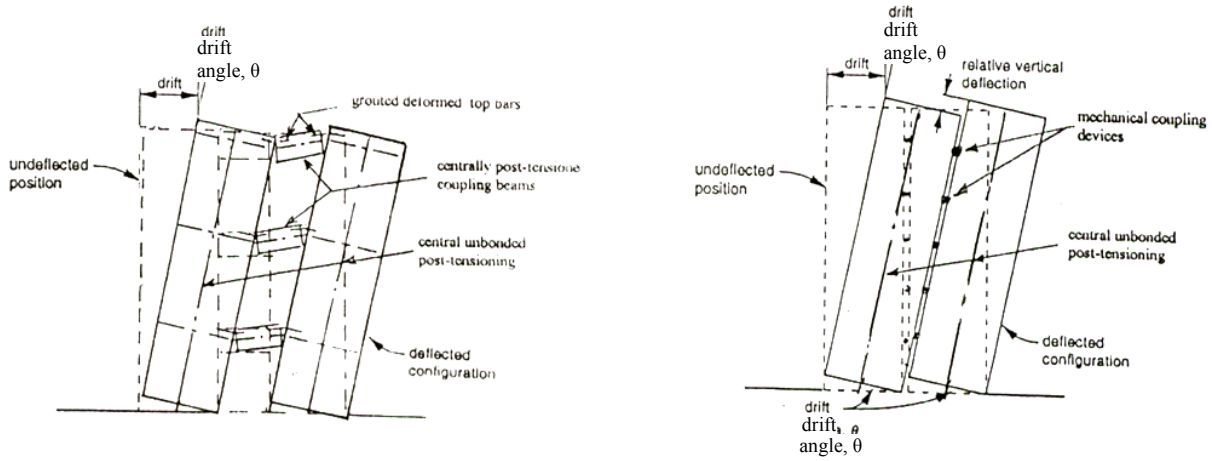


Figure C14.2.4.5.1 (a) Coupled wall test module with coupling beams; (b) Coupled wall test module with vertical mechanical couplers.

C14.2.4.5.4. It is to be expected that for a given generic precast wall structure, such as an unbonded centrally post-tensioned wall constructed using multiple precast or precast pretensioned concrete wall panels, validation testing programs will initially use specific values for the specified strength of the concrete and reinforcement in the walls, the layout of the connections between panels, the location of the post-tensioning, the location of the panel joints, and the design stresses in the wall. Pending the development of an industry standard for the design of such walls, similar to the standard for special hybrid moment frames, specified concrete strengths, connection layouts, post-tensioning amounts and locations, etc., used for such walls will need to be limited to the values and layouts used in the validation testing programs.

C14.2.4.5.5. For walls constructed using precast or precast/prestressed panels and designed using non-emulative methods, the response under lateral load can change significantly with joint opening (Figure C14.2.4.2.2-2d and Figure C14.2.4.2.2-3a). The number of panels used to construct a wall depends on wall height and design philosophy. If, in the prototype structure, there is a possibility of horizontal joint opening under lateral loading at a location other than the base of the wall, then the consequences of that possibility need to be considered in the development and validation test programs. Joint opening at locations other than the base can be prevented through the use of capacity design procedures.

C14.2.4.5.6. The significance of the magnitude of the gravity load that acts simultaneously with the lateral load needs to be addressed during the validation testing if the development program suggests that effect is significant.

C14.2.4.5.7. Details of the connection of walls to the foundation are critical, particularly for non-emulative wall designs. The deformations that occur at the base of the wall due to plastic hinging or extension of the reinforcing bars or post-tensioning steel crossing the wall to foundation interface, (Figure C14.2.4.2.2-2d), are in part determined by details of the anchorage and the bonding of those reinforcements on either side of the interface. Grout will be normally used to bed panels on the foundation and the characteristics of that grout in terms of materials, strength and thickness, can have a large effect on wall performance. The typical grout pad with a thickness of 1 inch (25 mm) or less can be expected to provide a coefficient of friction of about 0.6 under reversed loadings. Pads with greater thickness and without fiber reinforcement exhibit lesser coefficients of friction. Adequate frictional resistance is essential to preventing undesirable shear-slip deformations of the type shown in Figure C14.2.4.2.2.3(b).

C14.2.4.5.8. The geometry of the foundations need not duplicate that used in the prototype structure. However, the geometric characteristics of the foundations (width, depth and length) need to be large enough that they do not influence the behavior of the test module.

C14.2.4.6 Testing Agency. In accordance with the spirit of the requirements of Sections 1.3.5 and 1.4 of ACI 318, it is important that testing be carried out by a recognized independent testing agency, approved by the agency having jurisdiction and that the testing and reporting be supervised by a registered design professional familiar with the proposed design procedure and experienced in testing and seismic structural design.

C14.2.4.7 Test Method. The test sequence is expressed in terms of drift ratio, and the initial ratio is related to the likely range of linear elastic response for the module. That approach, rather than testing at specific drift ratios of 0.005, 0.010, etc.,

is specified because, for modules involving prestressed concrete, the likely range of elastic behavior varies with the prestress level.

An example of the test sequence specified in Sections 14.2.4.7.2 through 14.2.4.7.6 is illustrated in Figure C14.2.4.7. The sequence is intended to ensure that displacements are increased gradually in steps that are neither too large nor too small. If steps are too large, the drift capacity of the system may not be determined with sufficient accuracy.

If the steps are too small, the system may be unrealistically softened by loading repetitions, resulting in artificially low maximum lateral resistances and artificially high maximum drifts. Also, when steps are too small, the rate of change of energy stored in the system may be too small compared with the change occurring during a major event. Results, using such small steps, can mask undesirable brittle failure modes that might occur in the inelastic response range during a major event. Because significant diagonal cracking is to be expected in the inelastic range in the web of walls, and in particular in squat walls, the pattern of increasing drifts used in the test sequence can markedly affect diagonal crack response in the post-peak range of behavior.

The drift capacity of a building in a major event is not a single quantity, but depends on how that event shakes the structure. In the forward near field, a single pulse may determine the maximum drift demand, in which case a single large drift demand cycle for the test module would give the best estimation of the drift capacity. More often, however, many small cycles precede the main shock and that is the scenario represented by the specified loading.

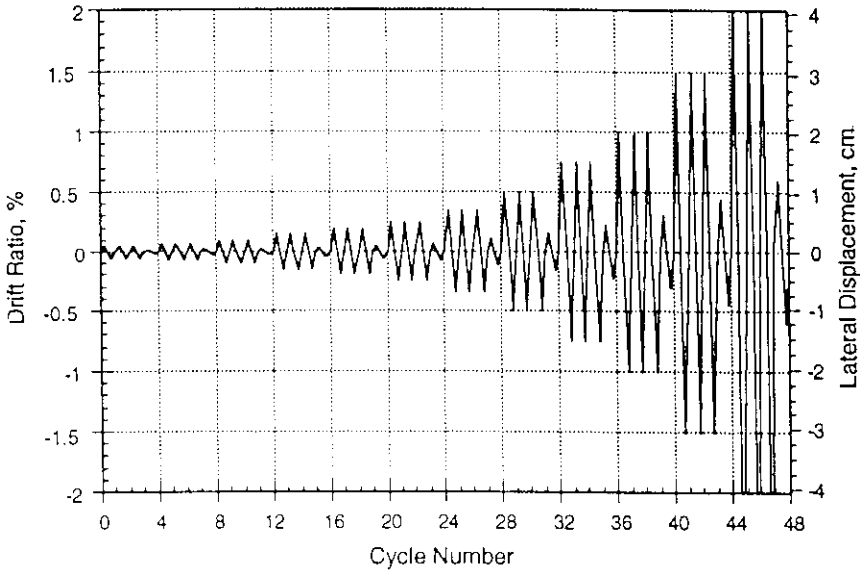

Figure C14.2.4.7 Example of specified test sequence.

There is no requirement for an axial load to be applied to the wall simultaneously with the application of the lateral displacements. In many cases it will be conservative not to apply axial load because, in general, the shear capacity of the wall and the resistance to slip at the base of the wall increase as the axial load on the wall increases. However, as the height of the wall increases and the limiting drift utilized in the design of the wall increases, the likelihood of extreme fiber crushing in compression at maximum drift increases, and the importance of the level of axial load increases. The significance of the level of axial loading should be examined during the development phase.

C14.2.4.7.4 For the response of a structure to the design seismic shear force, building codes (e.g., UBC 97, IBC 2006 or NFPA 5000) or recommended provisions (e.g., ASCE/SEI 7-05 and FEMA 356) specify a maximum allowable drift. However, structures designed to meet that drift limit may experience greater drifts under the design basis earthquake ground motion and are likely to experience greater drifts under the risk-targeted maximum considered earthquake ground motion. In addition to the characteristics of the ground motion, actual drifts will depend on the strength of the structure, its initial elastic stiffness, and the ductility expected for the given lateral load resisting system. Specification of suitable limiting drifts for the test modules requires interpretation and allowance for uncertainties in the assumed ground motions and structural properties.

In IBC 2006, the design seismic shear force applied at the base of a building is related directly to its weight and the design elastic response acceleration, and inversely to a response modification factor, R. That R factor increases with the expected ductility of the lateral force resisting system of the building. Special structural walls satisfying the requirements of Sections 21.1 and 21.9 are assigned an R value of 6 when used in a building frame system and a value of 5 when used in a bearing wall system. They are also assigned allowable story drift ratios that are dependent on the hazard to which the building is exposed. When the design seismic shear force is applied to a building, the building responds inelastically and the resultant computed drifts, (the design story drifts), must be less than a specified allowable drift. Additional guidance is given in FEMA 356 where the deformations for rectangular walls with height to length ratios greater than 2.5, and flanged wall sections with height to length ratios greater than 3.5, are to be assumed to be controlled by flexural actions. When structural walls are part of a building representing a substantial hazard to human life in the event of a failure, the allowable story drift ratio for shear controlled walls is 0.0075 and for flexure controlled walls is a function of the plastic hinge rotation at the base of the wall. For flexure controlled walls values range up to a maximum of about 0.02 for walls with confined boundary elements with low reinforcement ratios and shear stress less than $3\sqrt{f_c'}$.

To compensate for the use of the R value, IBC Section 1617.4.6 requires that the drift determined by an elastic analysis for the code-prescribed seismic forces be multiplied by a deflection amplification factor, C_d, to determine the design story drift and that the design story drift must be less than the allowable story drift. In building frame systems, structural walls satisfying the requirements of Section 21.9 of ACI 318 are assigned a C_d value of 5. However, research has found that design story drift ratios determined in the foregoing manner may be too low. Drift ratios of 6 times IBC-calculated values, (rather than 5), are more representative of the upper bounds to expected drift ratios. The value of 6 is also in agreement with the finding that the drift ratio of an inelastic structure is approximately the same as that of an elastic structure with the same initial period. For flexure controlled walls the value of 6/5 times the present IBC limits on calculated drift ratio, would lead to a limit on real drift ratios of up to 0.024.

Duffy et al. reviewed experimental data for shear walls to define post-peak behavior and limiting drift ratios for walls with height to length ratios between 0.25 and 3.5. Seo et al. re-analyzed the data of Duffy et al. together with data from tests conducted subsequent to the analysis of Duffy et al. Duffy et al. established that for squat walls with web reinforcement satisfying ACI 318-02 requirements and height to length ratios between 0.25 and 1.1, there was a significant range of behavior for which drifts were still reliable in the post-peak response region. Typically the post-peak drift increased by 0.005 for a 20 percent degradation in capacity under cyclic loading. For greater values of degradation, drifts were less reliable. That finding has also been confirmed through tests conducted by Hidalgo et al. (2002) on squat walls with effective height to length ratios ranging between 0.35 and 1.0. Values of the drift ratio of the walls at inclined cracking and at peak capacity varied little with web reinforcement. By contrast, drifts in the post-peak range were reliable to a capacity equal to 80 percent of the peak capacity and were 0.005 greater than the drifts at peak capacity provided the walls contained horizontal and vertical web reinforcement equal to 0.25 percent.

From an analysis of the available test data, and from theoretical considerations for a wall rotating flexurally about a plastic hinge at its base, Seo et al. concluded that the limiting drift at peak capacity increased almost linearly with the height to length ratio of the wall. When the additional post peak drift capacity for walls with adequate web reinforcement was added to the drift at peak capacity, the total available drift capacity in percent was given by $1.0 \le 0.67\,(h_w / l_w) + 0.5 \le 3.0$ where h_w is the height of the wall, and l_w is the length of the wall.

The data from the tests of Hidalgo et al. (2002) suggest that while that formula is correct for squat walls, the lower limit on drift can be decreased to 0.8 as specified in these provisions and that the use of that formula should be limited to walls with height to length ratios equal to or greater than 0.5. For wall height to length ratios less than 0.5, the behavior is controlled principally by shear deformations (Figure C14.2.4.2.2.2c), and Equation 14.2.4-1 should not be used. The upper value of 0.030 for the drift ratio was somewhat optimistic because the data were for walls with height to length ratios equal to or less than 3.5 and subsequent tests have shown that the upper limit of 2.5, as specified in Equation 14.2.4.1, is a more realistic limit.

C14.2.4.7.5 The design capacity for coupled wall systems must be developed by the drift ratio corresponding to that for the wall with the least h_w/l_w value. However, it is desirable that testing be continued to the drift given by Equation 14.2.4-1 for the wall with the greatest h_w/l_w in order to assess the reserve capacity of the coupled wall system.

C14.2.4.7.6 The drift limits of Equation 14.2.4.1 are representative of the maximum that can be achieved by walls designed to ACI 318. The use of smaller drift limits is appropriate if the designer wishes to use performance measures less than the maximum permitted by ACI 318. Examples are the use of reduced shear stresses so that the likelihood of diagonal cracking of the wall is minimized or reduced compressive stresses in the boundary elements of the wall so that the risk of crushing is reduced. Nonlinear time history analyses for the response to a suite of risk-targeted maximum considered earthquakes (MCE_R) ground motions, rather than 1.5 times a suite of the corresponding design basis earthquake (DBE) ground motions, is

required because the drifts for the response to the MCE_R motion can be significantly larger than 1.5 times the drifts for the response to the DBE motions.

C14.2.4.7.10 In many cases, data additional to the minimum specified in Section 14.2.4.7.7 may be useful to confirm both design assumptions and satisfactory response. Such data include relative displacements, rotations, curvatures, and strains.

C14.2.4.8 Test Report. The test report must be sufficiently complete and self-contained for a qualified expert to be satisfied that the tests have been designed and carried out in accordance with these criteria, and that the results satisfy the intent of these provisions. Sections 14.2.4.8.1.1 through 14.2.4.8.1.11 state the minimum evidence to be contained within the test report. The authority having jurisdiction or the registered design professional supervising the testing may require that additional test information be reported.

C14.2.4.9 Test Module Acceptance Criteria.

The requirements of this clause apply to each module of the test program and not to an average of the results of the program. Figure C14.2.4.9.1 illustrates the intent of this clause.

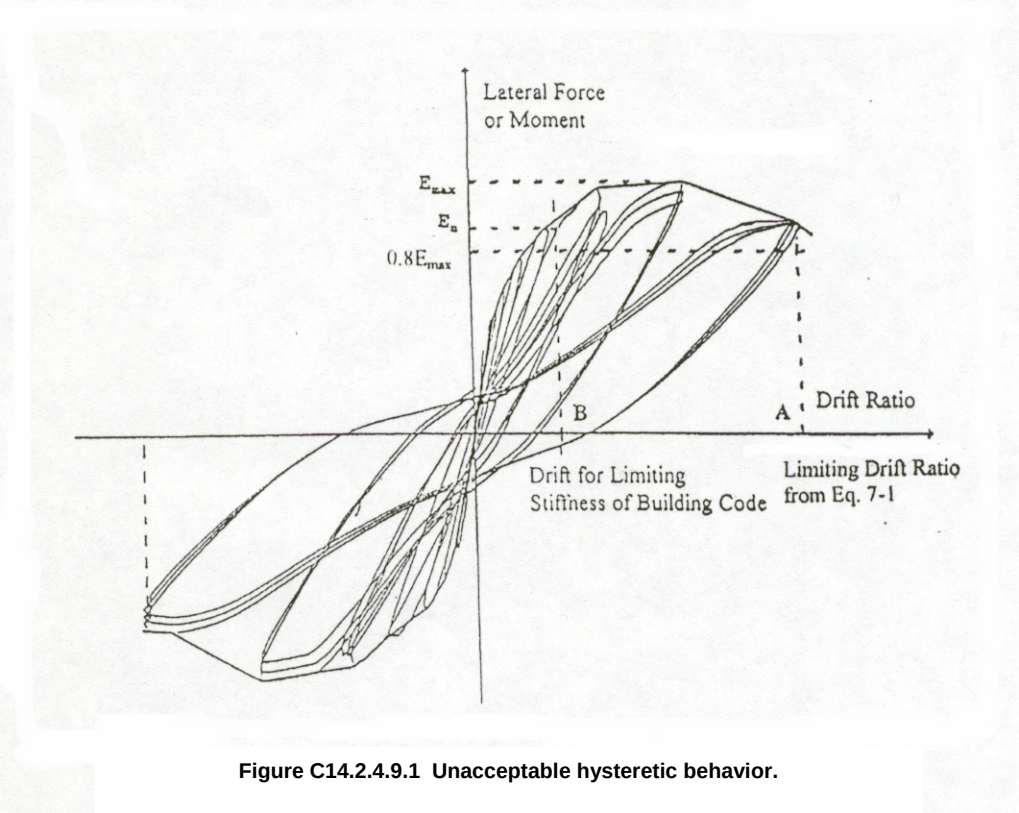

Figure C14.2.4.9.1 Unacceptable hysteretic behavior.

C14.2.4.9.1.1 Where nominal strengths for opposite loading directions differ, as is likely for C-, L- or T- shaped walls, the criterion of Section 14.2.4.9.1.1 applies separately to each direction.

C14.2.4.9.1.2 At high cyclic-drift ratios, strength degradation is inevitable. To limit the level of degradation so that drift ratio demands do not exceed anticipated levels, a maximum strength degradation of $0.20E_{max}$ is specified. Where strengths differ for opposite loading directions, this requirement applies independently to each direction.

C14.2.4.9.1.3. If the relative energy dissipation ratio is less than 1/8, there may be inadequate damping for the building as a whole. Oscillations may continue for some time after an earthquake, producing low-cycle fatigue effects, and displacements may become excessive.

If the stiffness becomes too small around zero drift ratio, the structure will be prone to large displacements for small lateral force changes following a major earthquake. A hysteresis loop for the third cycle between peak drift ratios of 1/10 times the limiting drift ratio given by Equation 14.2.4-1, that has the form shown in Figure C14.2.4.9.1, is acceptable. At zero drift ratio, the stiffnesses for positive and negative loading are about 11 percent of the initial stiffnesses. Those values satisfy

Section 14.2.4.9.1. An unacceptable hysteresis loop form would be that shown in Figure C14.2.4.9.1 where the stiffness around zero drift ratio is unacceptably small for both positive and negative loading.

Seismic Design Requirements for Structures with Damping Systems

SECTION 18.3.1, NONLINEAR RESPONSE HISTORY PROCEDURE

Replace with the following:

18.3.1 Nonlinear Response History Procedure. A nonlinear response history (time history) analysis shall utilize a mathematical model of the structure and the damping system as provided in Chapter 16 and this section. The model shall directly account for the nonlinear hysteretic behavior of elements of the structure and the damping devices to determine its response, through methods of numerical integration, to suites of ground motions compatible with the design response spectrum for the site.

The analysis shall be performed in accordance with Chapter 16 together with the requirements of this section. Inherent damping of the structure shall not be taken greater than 5 percent of critical unless test data consistent with levels of deformation at or just below the effective yield displacement of the seismic-force-resisting system support higher values.

If the calculated force in an element of the seismic force-resisting system does not exceed 1.5 times its nominal strength, that element is permitted to be modeled as linear.

18.3.1.1 Damping Device Modeling. Mathematical models of displacement-dependent damping devices shall include the hysteretic behavior of the devices consistent with test data and accounting for all significant changes in strength, stiffness, and hysteretic loop shape. Mathematical models of velocity-dependent damping devices shall include the velocity coefficient consistent with test data. If this coefficient changes with time and/or temperature, such behavior shall be modeled explicitly. The elements of damping devices connecting damper units to the structure shall be included in the model.

Exception: If the properties of the damping devices are expected to change during the duration of the response history analysis, the dynamic response is permitted to be enveloped by the upper and lower limits of device properties. All these limit cases for variable device properties must satisfy the same conditions as if the time dependent behavior of the devices were explicitly modeled.

18.3.1.2 Response Parameters. For each ground motion analyzed, individual response parameters consisting of the maximum value of the individual member forces, member inelastic deformations and story drifts at each story shall be determined. Moreover, for each ground motion used for response history analysis, individual response parameters consisting of the maximum value of the discrete damping device forces, displacements, and velocities, in the case of velocity-dependent devices, shall be determined.

If at least seven ground motions are used for response history analysis, the design values of the damping device forces, displacements, and velocities are permitted to be taken as the average of the values determined by the analyses. If fewer than seven ground motions are used for response history analysis, the design damping device forces, displacements and velocities shall be taken as the maximum value determined by the analyses. A minimum of three ground motions shall be used.

SECTION 18.3.2, NONLINEAR STATIC PROCEDURE

Replace with the following:

18.3.2 Nonlinear Static Procedure. Nonlinear static procedures may be used to construct the lateral force-displacement curve of the seismic-force-resisting system in lieu of the elastoplastic curve assumed in the response spectrum procedure and in the equivalent lateral force procedure. When nonlinear static procedures is used, the nonlinear modeling described Chapter 16 shall be used. The resulting force-displacement curve shall be used in lieu of the assumed effective yield displacement, D_Y, of Equation 18.6-10 to calculate the effective ductility demand under the design earthquake ground motion, μ_D, and under the risk-targeted maximum considered earthquake ground motion, μ_M, in Equations 18.6-8 and 18.6-9, respectively. The value of (R/C_d) shall be taken as 1.0 in Equations 18.4-4, 18.4-5, 18.4-8, and 18.4-9 for the response spectrum procedure, and in Equations 18.5-6, 18.5-7 and 18.5-15 for the equivalent lateral force procedure.

Chapter 23

VERTICAL GROUND MOTIONS FOR SEISMIC DESIGN

23.1 DESIGN VERTICAL RESPONSE SPECTRUM. Where a design vertical response spectrum is required by these *Provisions* and site-specific procedures are not used, the design vertical response spectral acceleration, S_{av}, (in g – gravity unit) shall be developed as follows:

1. For vertical periods less than or equal to 0.025 second, S_{av} shall be determined in accordance with Equation 23.1-1 as follows:

$$S_{av} = 0.3C_V S_{DS} \qquad (23.1\text{-}1)$$

2. For vertical periods greater than 0.025 second and less than or equal to 0.05 second, S_{av} shall be determined in accordance with Equation 23.1-2 as follows:

$$S_{av} = 20C_V S_{DS}(T_V - 0.025) + 0.3C_V S_{DS} \quad (23.1\text{-}2)$$

3. For vertical periods greater than 0.05 second and less than or equal to 0.15 second, S_{av} shall be determined in accordance with Equation 23.1-3 as follows:

$$S_{av} = 0.8C_V S_{DS} \quad (23.1\text{-}3)$$

4. For vertical periods greater than 0.15 second and less than or equal to 2.0 seconds, S_{av} shall be determined in accordance with Equation 23.1-4 as follows:

$$S_{av} = 0.8C_V S_{DS}\left(\frac{0.15}{T_V}\right)^{0.75} \quad (23.1\text{-}4)$$

where C_V is defined in terms of S_S in Table 23.1-1, S_{DS} = the design spectral response acceleration parameter at short periods, and T_V = the vertical period of vibration.

Table 23.1-1 Values of Vertical Coefficient C_V

MCE_R Spectral Response Parameter at Short Periods [a]	Site Class A, B	Site Class C	Site Class D, E, F
$S_s \geq 2.0$	0.9	1.3	1.5
$S_S = 1.0$	0.9	1.1	1.3
$S_S = 0.6$	0.9	1.0	1.1
$S_S = 0.3$	0.8	0.8	0.9
$S_S \leq 0.2$	0.7	0.7	0.7

[a] Use straight-line interpolation for intermediate values of S_S .

S_{av} shall not be less than one-half (1/2) of the corresponding S_a for horizontal components determined in accordance with the general or site-specific procedures of Section 11.4 or Chapter 21, respectively.

For vertical periods greater than 2.0 seconds, S_{av} shall be developed from a site-specific procedure; however, the resulting ordinate of S_{av} shall not be less than one-half (1/2) of the corresponding S_a for horizontal components determined in accordance with the general or site-specific procedures of Section 11.4 or Chapter 21, respectively.

In lieu of using the above procedure, a site-specific study may be performed to obtain S_{av} at vertical periods less than or equal to 2.0 seconds, but the value so determined shall not be less than 80 percent of the S_{av} value determined from Equations 23.1-1 through 23.1-4.

23.2 MCE_R VERTICAL RESPONSE SPECTRUM. The MCE_R vertical response spectral acceleration shall be 150 percent of the S_{av} determined in Section 23.1.

Commentary to New Chapter 23

Chapter 23 Commentary
VERTICAL GROUND MOTIONS FOR SEISMIC DESIGN

C23.1 DESIGN VERTICAL RESPONSE SPECTRUM

General. ASCE/SEI 7-05 and the earlier editions of the *Provisions* use the term $0.2S_{DS}D$ to reflect the effects of vertical ground motion. Where a more explicit consideration of vertical ground motion effects is advised—as for certain tanks, materials storage facilities, and electric power generation facilities—the requirements of this chapter may be applied. Historically, the amplitude of vertical ground motion has been inferred to be two-thirds (2/3) the amplitude of the horizontal ground motion. However, studies of horizontal and vertical ground motions over the past 25 years have shown that such a simple approach is not valid in many situations (e.g., Bozorgnia and Campbell, 2004, and references therein) for the following main reasons: (a) vertical ground motion has a larger proportion of short-period (high-frequency) spectral content than horizontal ground motion and this difference increases with decreasing soil stiffness and (b) vertical ground motion

attenuates at a higher rate than horizontal ground motion and this difference increases with decreasing distance from the earthquake.

The observed differences in the spectral content and attenuation rate of vertical and horizontal ground motion lead to the following observations regarding the vertical/horizontal (*V/H*) spectral ratio (Bozorgnia and Campbell, 2004):

1. The *V/H* spectral ratio is relatively sensitive to spectral period, distance from the earthquake, local site conditions, and earthquake magnitude (but only for relatively soft sites) and relatively insensitive to earthquake mechanism and sediment depth;
2. The *V/H* spectral ratio has a distinct peak at short periods that generally exceeds 2/3 in the near-source region of an earthquake; and
3. The *V/H* spectral ratio is generally less than 2/3 at mid-to-long periods.

Therefore, depending on the period, the distance to the fault, and the local site conditions of interest, use of the traditional 2/3*V/H* spectral ratio can result in either an underestimation or an overestimation of the expected vertical ground motions.

The procedure for defining the design vertical response spectrum in the *Provisions* is based on the studies of horizontal and vertical ground motions conducted by Campbell and Bozorgnia (2003) and Bozorgnia and Campbell (2004). These procedures are also generally compatible with the general observations of Abrahamson and Silva (1997) and Silva (1997) and the proposed design procedures of Elnashai (1997).

General Design Procedure. In order to be consistent with the shape of the horizontal design response spectrum, the vertical design response spectrum has four regions defined by the vertical period of vibration (T_v). Based on the study of Bozorgnia and Campbell (2004), the periods that define these regions are approximately constant with respect to the magnitude of the earthquake, the distance from the earthquake, and the local site conditions. In this respect, the shape of the vertical response spectrum is simpler than that of the horizontal response spectrum.

The equations that are used to define the design vertical response spectrum are based on three observations made by Bozorgnia and Campbell (2004):

1. The short-period part of the 5 percent damped vertical response spectrum is controlled by the spectral acceleration at T_v = 0.1 second;
2. The mid-period part of the vertical response spectrum is controlled by a spectral acceleration that decays as the inverse of the 0.75 power of the vertical period of vibration ($T_v^{-0.75}$); and
3. The short-period part of the V/H spectral ratio is a function of the local site conditions, the distance from the earthquake (for sites located within about 60 km of the fault), and the earthquake magnitude (for soft sites).

The *Provisions* do not include seismic design maps for the vertical spectral acceleration at T_v = 0.1 second and do not preserve any information on the earthquake magnitudes or the source-to-site distances that contribute to the horizontal spectral accelerations that are mapped. Therefore, the general procedure recommended by Bozorgnia and Campbell (2004) was modified to use only those horizontal spectral accelerations that are available from the seismic design maps, as follows:

1. Estimate the vertical spectral acceleration at T_v = 0.1 second from the ratio of this spectral acceleration to the horizontal spectral acceleration at T = 0.2 second for the Site Class BC boundary (i.e., the boundary between Site Classes B and C ($\bar{v}_s = 760$ m/sec), the reference site condition for the 2008 U.S. Geological Survey National Seismic Hazard Maps). For earthquakes and distances for which the vertical spectrum might be of engineering interest (magnitudes greater than 6.5 and distances less than 60 km), this ratio is approximately 0.8 for all site conditions (Campbell and Bozorgnia, 2003).
2. Estimate the horizontal spectral acceleration at T = 0.2 second from the Next Generation Attenuation (NGA) relationship of Campbell and Bozorgnia (2008) for magnitudes greater than 6.5 and distances ranging between 1 and 60 km for the Site Class BC boundary ($\bar{v}_s = 760$ m/sec). The relationship of Campbell and Bozorgnia (2008), rather than that of Campbell and Bozorgnia (2003), was used for this purpose in order to be consistent with the development of the 2008 U.S. Geological Survey National Seismic Hazard Maps, which use the NGA attenuation relationships to estimate horizontal ground motions in the western United States. Similar results were found for the other two NGA relationships that were used to develop the seismic hazard and design maps (Boore and Atkinson, 2008; Chiou and Youngs, 2008).
3. Use the dependence between the horizontal spectral acceleration at T = 0.2 second and source-site distance estimated in Item 2 and the relationship between the V/H spectral ratio, source-site distance, and local site conditions in Bozorgnia and Campbell (2004) to derive a relationship between the vertical spectral acceleration and the mapped MCE_R spectral response acceleration parameter at short periods, S_S.

4. Use the dependence between the vertical spectral acceleration and the mapped MCE_R spectral response acceleration parameter at short periods, S_S, in Item 3 to derive a vertical coefficient, C_v, that when multiplied by 0.8 and the design horizontal response acceleration at short periods, S_{DS}, results in an estimate of the design vertical spectral acceleration at $T_v = 0.1$ second.

Detailed Design Procedure. The following description of the detailed design procedure listed in Section 23.1 refers to the illustrated design vertical response spectrum in Figure C23.1-1.

Vertical periods less than or equal to 0.025 second. Equation 23.1-1 defines that part of the design vertical response spectrum that is controlled by the vertical peak ground acceleration. The 0.3 factor was approximated by dividing the 0.8 factor that represents the ratio between the vertical spectral acceleration at $T_v = 0.1$ second and the horizontal spectral acceleration at $T = 0.2$ second by 2.5, the factor that represents the ratio between the design horizontal spectral acceleration at $T = 0.2$ second, S_{DS}, and the zero-period acceleration used in the development of the design horizontal response spectrum. The vertical coefficient, C_v, in Table 23.1-1 accounts for the dependence of the vertical spectral acceleration on the amplitude of the horizontal spectral acceleration and the site dependence of the V/H spectral ratio as determined in Items 3 and 4 above. The factors are applied to S_{DS} rather than to S_S because S_{DS} already includes the effects of local site conditions and the 2/3 factor that is required to reduce the horizontal spectral acceleration from its MCE_R value to its design value.

Vertical periods greater than 0.025 second and less than or equal to 0.05 second. Equation 23.1-2 defines that part of the design vertical response spectrum that represents the linear transition from the part of the spectrum that is controlled by the vertical peak ground acceleration and the part of the spectrum that is controlled by the dynamically amplified short-period spectral plateau. The factor of 20 is the factor that is required to make this transition continuous and piecewise linear between these two adjacent parts of the spectrum.

*Vertical periods greater than 0.05 second and less than or equal to 0.15 second***.** Equation 23.1-3 defines that part of the design vertical response spectrum that represents the dynamically amplified short-period spectral plateau.

Vertical periods greater than 0.15 second and less than or equal to 2.0 seconds. Equation 23.1-4 defines that part of the design vertical response spectrum that decays with the inverse of the vertical period of vibration raised to the 0.75 power.

Limits Imposed on S_{av}. Two limits are imposed on the design vertical response spectrum defined by Equations 23.1-1 through 23.1-4 and illustrated in Figure 23.1-1. The first limit restricts the vertical period of vibration to be no larger than 2 seconds. This limit accounts for the fact that such large vertical periods are rare (structures are inherently stiff in the vertical direction) and that the vertical spectrum might decay differently with period at longer periods. There is an allowance for developing a site-specific design vertical response spectrum if this limit is exceeded (see Section 11.4 or Chapter 21 for guidance on applying site-specific methods). The second limit restricts the design vertical response spectrum to be no less than 50 percent of the design horizontal response spectrum. This limit accounts for the fact that a V/H spectral ratio of one-half (1/2) is a reasonable, but somewhat conservative, lower bound over the period range of interest, based on the results of Campbell and Bozorgnia (2003) and Bozorgnia and Campbell (2004).

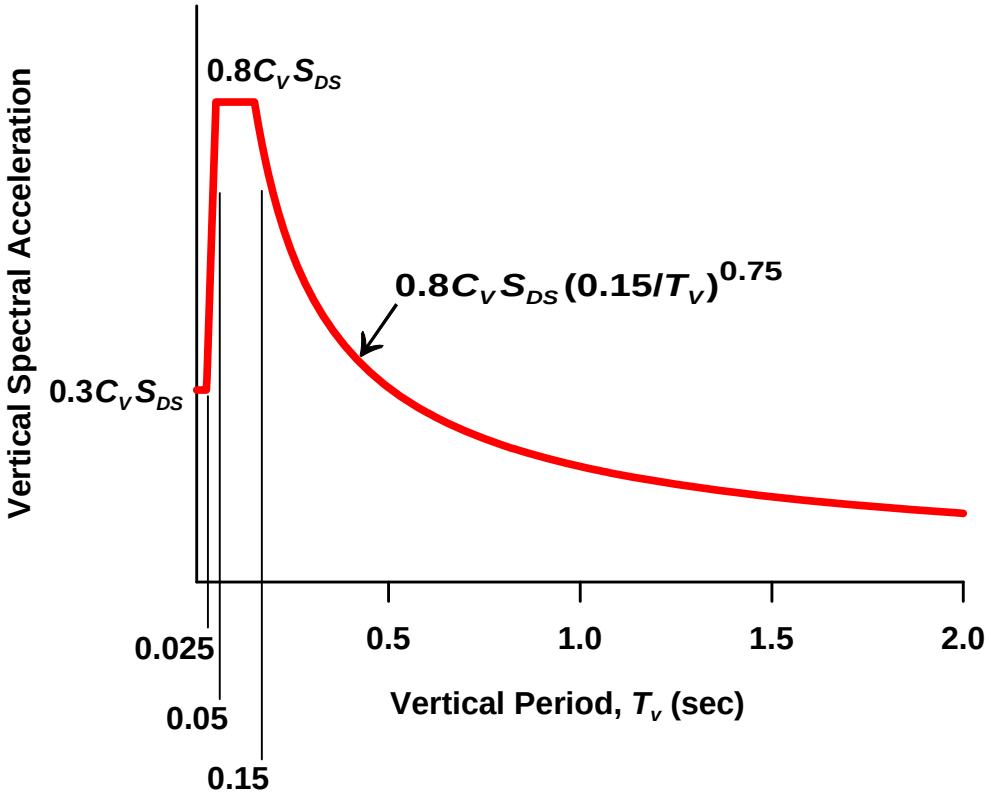

Figure C23.1-1 Illustrative example of the design vertical response spectrum.

An Introduction to the 2015 NEHRP Recommended Seismic Provisions for New Buildings and Other Structures

David R Bonneville[1] and Andrew M Shuck[2]

ABSTRACT

The 2015 *NEHRP Recommended Seismic Provisions for New Buildings and Other Structures* (NEHRP Provisions) serves as the consensus resource document for US seismic codes and standards. The NEHRP Provisions are developed by the Building Seismic Safety Council (BSSC) through a five-year project sponsored by the Federal Emergency Management Agency (FEMA). The Provisions are developed for the BSSC by its Provisions Update Committee (PUC). The PUC is supported by a group of Issue Teams, which develop technical proposals in the form of either seismic provisions with commentary or resource papers. The proposals are in the form changes to ASCE 7-10 and Commentary (ASCE 7-10), which are adopted as the basis for the Provisions. This paper provides a summary the key topics included in the 2015 NEHRP Provisions. The authors served as Chair and Assistant to the Chair of the PUC in the 2015 cycle and present this work as part of FEMA and BSSC's commitment to ongoing outreach to the engineering community.

AN INTRODUCTION TO THE 2015 NEHRP RECOMMENDED SEISMIC PROVISIONS FOR NEW BUILDINGS AND OTHER STRUCTURES

David R Bonneville[1] and Andrew M Shuck[2]

ABSTRACT

The 2015 *NEHRP Recommended Seismic Provisions for New Buildings and Other Structures* (NEHRP Provisions) serves as the consensus resource document for US seismic codes and standards. The NEHRP Provisions are developed by the Building Seismic Safety Council (BSSC) through a five-year project sponsored by the Federal Emergency Management Agency (FEMA). The Provisions are developed for the BSSC by its Provisions Update Committee (PUC). The PUC is supported by a group of Issue Teams, which develop technical proposals in the form of either seismic provisions with commentary or resource papers. The proposals are in the form of changes to ASCE 7-10 and Commentary (ASCE 2010), which are adopted as the basis for the Provisions. This paper provides a summary the key topics included in the 2015 NEHRP Provisions. The authors served as Chair and Assistant to the Chair of the PUC in the 2015 cycle and present this work as part of FEMA and BSSC's commitment to ongoing outreach to the engineering community.

Introduction

The *NEHRP Recommended Provisions for New Buildings and Other Structures* (NEHRP Provisions, the Provisions) serve as a platform for advancing seismic analysis and design concepts that exist in the current edition of ASCE 7 *Minimum Design Loads for Buildings and Other Structures* (ASCE, 2010) based on recent research and experience, and for and introducing new seismic concepts prior to their introduction to ASCE 7. The Provisions are developed through a consensus process involving a Provisions Update Committee (PUC) consisting of a group of experts selected to cover the range of seismic concepts contained in the Provisions. The PUC selects relevant topics it considers most appropriate for development within the five-year update cycle. Topics are then assigned to Issue Teams, which include both PUC members and others with expertise in the issues being considered. The 2015 edition of the NEHRP Provisions is being developed by the Building Seismic Safety Council (BSSC) through a five-year contract sponsored by the Federal Emergency Management Agency (FEMA).

As initiated in the 2009 edition, the NEHRP Provisions are presented in three parts. Part 1 includes consensus-approved modifications to ASCE/SEI 7-10. Part 2 provides commentary, also consistent with ASCE/SEI 7-10, and Part 3 contains resource papers covering material

[1] Senior Principal at Degenkolb Engineers in San Francisco, California and the Chair of the 2015 NEHRP Provisions Update Committee.

[2] Associate III at Wiss, Janney, Elstner Associates in Emeryville, California and Assistant to the Chair of the 2015 NEHRP Provisions Update Committee.

intended to stimulate discussion from the engineering community on new seismic design concepts. BSSC policies and procedures require that material developed for the Provisions, whether by Issue Teams or by the PUC itself, go through balloting by the PUC then, following approval by the BSSC Board of Direction, though balloting by the 50 BSSC member organizations.

Primary Topics Addressed by the PUC and Issue Teams

Evaluation and Quantification of Seismic Performance Objectives

This effort includes a consideration of the *Intent* of the Provisions, in terms of the seismic performance expectations inherent in the current design provisions, and consideration of modifications of the design provisions to achieve enhanced seismic performance in future codes. The Intent language in our current Provisions (Section 1.1) defines life safety in terms of collapse resistance for all occupied buildings and addresses in general terms the loss of function for essential facilities and repair costs for all risk categories. For ordinary (Risk Category II) buildings in areas where the ground motion is probabilistically defined, the targeted performance is a 10% (or lower) collapse probability in the very rare Risk Targeted Maximum Considered Earthquake Ground Motion (MCE_R). In areas close to major active faults, the MCE_R ground motion is deterministically defined using a shaking intensity that is one standard deviation above the mean ground motion resulting from a characteristic earthquake on the fault, and in these locations a higher collapse risk is possible. Lower collapse probabilities are defined for facilities housing essential functions or containing hazardous materials (Risk Category IV) and for those housing large or less mobile populations (Risk III), in which approximately 2.5% and 5% collapse probabilities respectively are targeted in the MCE_R ground motion.

Unlike life safety (addressed through collapse prevention), loss of function and economic loss are not quantitatively defined in the Provisions and this is considered to be a key area of future development for new building performance. In this update cycle a clear consensus did not emerge as to how the Provisions could be modified within Part 1 to address these performance measures. However, Part 3 of the Provisions contains a resource paper that summarizes discussions related to functional loss in terms of a functional level earthquake ground motion that is reduced from the MCE_R ground motion and discusses economic loss without explicitly defining it. Nonstructural damage affecting life safety and functional loss is also discussed.

The Provisions developments related to functional and economic loss were supported substantially by two Applied Technology Council (ATC) projects. Input was provided from the National Institute of Standards and Technology (NIST) funded project, *ACT-84 – Tentative Framework for Development of Advanced Seismic Design Criteria for New Buildings – 100 % Draft* (ATC, 2012), Charles Kircher, Project Director. In addition, the Applied Technology Council (ATC) was awarded a FEMA contract to benchmark building code (structural and nonstructural) performance on various building types using established FEMA methodologies, including *FEMA P-695 – Quantification of Building Seismic Performance Factors* (ATC, 2009), Charles Kircher - Project Technical Director, for collapse prevention and *FEMA P-58 – Seismic Performance Assessment of Buildings – 100% Draft* (ATC, 2012), Ronald Hamburger - Project Technical Director, for all other performance levels. That project, titled *ATC 63-2 -*

Development of Seismic Performance and Methodology Calibration, Ronald Hamburger - Project Technical Director, provided valuable input into the discussions.

Response History Analysis

The 2015 Provisions provide a complete revision to the Seismic Response History Analysis (RHA) requirements given in Chapter 16 of ASCE/SEI 7-10. The PUC judged that the current requirements lack specificity in many areas, leading to inconsistencies in interpretation. In the new provisions, collapse performance goals discussed above under the *Evaluation and Quantification of Seismic Performance Objectives* section are implicitly demonstrated through a prescribed set of analysis rules and acceptance criteria.

The procedure is intended to provide buildings with equivalent or better seismic performance compared to designs using the Chapter 12 procedures. It includes a code-level evaluation of the building using either the Equivalent Lateral Force Procedure or the Modal Response Spectrum Procedure for the purpose of assuring that the structure designed using the RHA provisions will be equivalent in terms of strength (though not necessarily displacement). The nonlinear analysis is then performed to demonstrate that the structure has predictable and stable response under MCE_R level ground shaking and to determine forces for force-controlled components. Service-level evaluation (to address for example Risk Category IV buildings) is not required because ground motion for such analysis is not provided by Chapters 11 and 12.

The level of ground motion is defined by target spectra that may be derived from either the MCE_R spectrum, which conservatively envelopes the results of seismic hazard analysis for each period, or a *Conditional Mean Spectrum*, in which the spectrum is calculated based on a spectral acceleration at an appropriate period and the mean of spectral acceleration values at other periods. The procedure requires eleven ground motions (selected based on judgment) representing near-field (if appropriate) and far field sites. The procedure specifies the lower bound (0.2T) and upper bound (generally 2.0T) period range for ground motions to be scaled to so they are representative of the site specific MCE_R spectrum.

Modeling requirements are given with the intent of reasonably capturing the spatial and temporal distributions of inelasticity. Three-dimensional analysis is required for the final analysis and requirements are specified for realistically addressing gravity loading, P-delta effects and diaphragm modeling to cover the range of expected stiffness. Inherent torsion is addressed through the modeling requirements in a manner similar to that given in Chapter 12 and accidental torsion is not required to be explicitly modeled (a rigorously debated issue), though the commentary provides recommendations for addressing buildings likely to perform in a highly torsional manner.

Acceptance criteria are expressed in terms of global response in which unacceptable performance is defined based on possible collapse, story drift, non-convergence, deformation-controlled response and force-based demands for brittle components; and element-level response, considering both deformation and force-controlled actions.

Design review is required for all structures designed in accordance with the RHA procedure. The review is required to be performed by one or more individuals with experience in ground motion selection and scaling, analytical modeling and structural system behavior.

Diaphragm Issues

The diaphragm provisions in ASCE 7-10 (and previous editions) take an elastic design approach for diaphragm elements, basing the forces on a multiple of the floor force calculated using the Equivalent Lateral Force (ELF) procedure. This has historically resulted in generally acceptable seismic diaphragm performance for most building configurations and diaphragm material types. Recent study has shown that the actual force levels imposed on diaphragms during ground shaking can be significantly higher than those currently in the code, however. The effects of higher modes than the first mode were found to contribute significantly to diaphragm response, and these findings prompted an investigation into the entire process of diaphragm design.

The 2015 Provisions contain new equations for force demands that reflect test and analysis results and that yield larger design forces. Since diaphragms designed with the current procedure are generally well-behaving, though, the capacity side of diaphragm design has also been addressed. Results of component testing show that the observed ductility capacity of diaphragm systems compensates for these proposed higher design forces. In short, demands were previously underestimated but were also assessed against unrealistically limited elastic capacities. The new procedure, despite its higher calculated demands, yields a similar final design because of the additional consideration of diaphragm ductility.

For diaphragms constructed of most materials (wood sheathing, metal deck, etc.), these provisions only mean an improved understanding of seismic diaphragm behavior, but the new procedure is more critical for precast concrete diaphragms. Tests show that, compared to other systems, precast concrete diaphragms have limited ductility; more specifically, the long diaphragm spans that precast diaphragms lend themselves to cause the relatively low performance of the system. The new diaphragm design procedure in the 2015 NEHRP Provisions is an alternative for all materials besides precast concrete. The provisions require the revised design procedure for precast diaphragms to balance the discrepancy between higher design forces and low seismic ductility.

Base Isolation and Energy Dissipation Devices

The chapters of the Provisions regarding base isolation and energy dissipation (based on Chapters 17 and 18 of ASCE 7-10, respectively) were revised to improve the design process for structures using these technologies. The provisions were arranged into a more logical structure based on the most commonly used design techniques for base isolation and energy dissipation. Updated considerations for design value variability, quality control, and quality assurance have been incorporated that take advantage of the knowledge base that has been built up over many years of extensive testing programs for base isolators and dampers.

Base isolation procedures now check force and displacement demands at the MCE_R ground motion level because of the severe consequences of exceeding the limits of an isolation system (pounding as a result of isolator displacements exceeding the isolation moat gap, e.g.). Energy dissipation system design requires use of Design Earthquake and MCE_R forces to achieve similar performance levels to the revised Base Isolation provisions. In addition, the ELF procedure for base-isolated structures has been expanded and adopts the multi-point design spectrum developed by the ground motion mapping team. This allows the demands at the longer periods experienced by isolated structures to be calculated with more confidence, while using the relatively simple and common ELF procedure. The combination of the Provisions structure, quality control requirements, and design procedure simplifications should encourage wider use of these technologies, which have been around for long enough to have gained the confidence of the industry as a whole.

Soil Structure Interaction

The Soil Structure Interaction (SSI) provisions are intended to allow a more complete and accurate analysis of the combined system including structure, foundation and underlying soil/rock, compared to the traditional fixed base assumption assuming free-field ground motions. The 2015 Provisions provide a complete revision to the ASCE 7-10 Chapter 19 SSI requirements, and allow the designer to account for foundation deformations, inertial effects and kinematic effects.

Foundation deformations are addressed through requirements for capturing the translational and rotational movement at the soil-structure interface, either with elastic spring elements in the linear methods or through nonlinear modeling in the case of response history analysis. Inertial effects are addressed through consideration of foundation damping, including radiation damping (damping associated with wave propagation away from the structure) and hysteretic soil damping. Kinematic effects, which were not addressed in previous editions of ASCE 7, include base slab averaging, accounting for the incoherence of ground motions on large area foundations, and embedment effects, accounting for ground motion reductions with depth. Most of the changes to this chapter are based on recommendations from a NIST sponsored project titled *Soil-Structure Interaction for Building Structures* (NIST, 2012).

The provisions impose several limitations on ground motion modifications (reductions) due to SSI effects. First, modifications due to kinematic effects are not permitted in either the ELF or MRS procedures since it was judged that these effects have not been studied sufficiently to determine whether they are valid for an inelastic spectrum, on which the R-factor assumptions are based. Additionally there was concern that reductions due to period lengthening resulting from inelastic yielding may not be accounted for in these analyses, leading to a possible overestimate of the reduction in response parameters. Also for the ELF and MRS procedures the maximum total reduction (from foundation damping) is limited to a percentage of the base shear, reflecting the limited understanding of how SSI effects interact with the R-factor. The reduction varies with R-factor and is permitted only for R=3 of less; the maximum reduction is limited to 30 percent.

All types of SSI reductions are permitted with the RHA. The analysis is required to be based on a site-specific response spectrum because it is judged that the more detailed knowledge of the site associated with this approach (as opposed to the general response spectrum based on mapped acceleration parameters) is needed for proper consideration of SSI effects. The design response accelerations modified for kinematic effects are permitted to be reduced to 80 percent of the site specific values, but not less than 70 percent of the standard (non-site specific) Chapter 11 spectrum. The number is reduced to 60 percent for designs that are peer reviewed. Consideration of foundation damping effects is to be based on direct incorporation of dashpot elements at the soil-foundation interface.

Strength Design of Foundations

The 2015 NEHRP Provisions allow for building foundations and the supporting soils to be designed using the strength design philosophy, or Load and Resistance Factor Design (LRFD). Traditional geotechnical engineering practice provides foundation recommendations based on allowable bearing stresses. It is common practice for allowable soil stresses for gravity loads to be arbitrarily increased by one-third for load combinations that include seismic forces. This practice is overly conservative and not consistent with the design basis of the NEHRP Provisions or ASCE/SEI 7, however, since it is not based on nominal soil strength or the dynamic properties of site soils.

The new Provisions utilize foundation design forces that are modified to incorporate an R-factor-dependent multiplier into the forces. For example, non-light-framed systems need to be designed for horizontal earthquake effects, E_h, of

$$E_h = (0.3R)\rho Q_E \geq Q_E \quad (1)$$

Where ρ is the redundancy factor and Q_E is the effect of horizontal seismic forces. This equation is intended to force nonlinear mechanisms to occur primarily in the supported structure above the foundation, as this is the portion of the structure that dictates the R-factor. Buildings with small R-factors will not see an increase in force and it is anticipated that foundation mechanisms like rocking or sliding may develop for these structures.

LRFD capacity procedures and reduction factors are also provided in the new sections. The Provisions have guidance for strength determination, resistance mechanism combinations, and presumptive capacity that result in nominal strengths consistent with the LRFD philosophy. Reduction factors (φ factors) are 0.45 for vertical resistance, 0.5 for lateral bearing pressure, and 0.85 for sliding.

Soil Site Factors and Liquefaction

The Provisions contain updated values for the F_a and F_v coefficents that scale the mapped spectral values S_s and S_1 to obtain acceleration response parameters for sites with soil classification other than Site Class B. These coefficients were originally developed in the 1990s based primarily on recorded motions from the 1989 Loma Prieta Earthquake. Studies at the Pacific Earthquake Engineering Research Center considered shaking data from more recent earthquakes and combined this information with models of site nonlinearity to derive new coefficients. In general, the values for F_a and F_v are now somewhere between 80% and 120% of

their previously tabulated values. In addition, the new factors show that Site Class D is not necessarily the worst case (and, therefore, default) soil for all levels of seismicity, so an additional table has been added to clarify which amplification factors to use by default for undetermined soil classifications.

Previous editions of the Provisions only included requirements for geotechnical investigations at liquefiable sites and there were no requirements for structures and their foundations on such sites. In an effort to standardize and guide liquefaction design, the Provisions now require that buildings be assessed for the potential consequences of liquefaction and soil strength loss, including but not limited to: estimated total and differential settlement, lateral soil movement, lateral loads on foundations, reduction of foundation soil bearing capacity, reduction of axial and lateral soil reaction on piles, and floatation of buried structures. These criteria are analyzed on the basis of peak ground accelerations, earthquake magnitudes, and source characteristics associated with MCE_G peak ground accelerations, where MCE_G represents the Maximum Considered Earthquake geometric mean ground motion. Evaluating liquefaction for MCE_G ground motions is intended to minimize risk of collapse for the rare MCE ground motion, rather than at the building design level, which assumes a certain level of reserve building structural capacity.

Design Mapping

Similar to previous editions of the NEHRP Provisions, the 2015 Provisions contain updated seismic hazard maps developed by USGS. In 2008 (i.e., for the 2009 Provisions) the design maps were changed significantly, including the use of risk-targeted ground motions, maximum direction ground motions, and near-source 84th percentile ground motions. Mapping changes made by the USGS during this cycle were of a lesser magnitude. The new maps reflect findings from the last five years, driven primarily by regional seismic hazard model projects like UCERF 2. Updated MCE_R spectral values are generally similar to previous values, but some locations do see a significant rise in their mapped accelerations. This is caused by longer assumed rupture lengths for the characteristic event that drives the deterministic hazard level; increasing the deterministic capping accelerations means that the probabilistic earthquake now governs at these locations. The values will be available in the Provisions and on the USGS website.

The team in charge of updating the hazard maps also made a change to the 2015 IBC in order to implement a critical design change ahead of the typical adoption schedule. The hazard maps for Guam and American Samoa had previously been based only on judgment of the regional seismicity and not on rigorous studies. Such studies, when completed recently, showed that the hazard levels were substantially different from the previous values. For example, S_s for Guam was updated to 2.87g from 1.5g, while S_s for Tutuila in American Samoa was updated to 0.42g from 1.0g. These changes to the 2015 IBC mean that designs in Guam and American Samoa will incorporate this improved information much faster than would have otherwise been the case.

The Provisions contain a number of additional ground motion-related updates that were done in support of other PUC efforts. Most importantly, there is now an alternative USGS-

provided design spectrum with substantially more resolution (i.e., more points than the traditional two-point spectrum) available to engineers. This spectrum contains detailed information based on the specific site conditions and defines the hazard at periods much longer than the currently referenced one second acceleration, S_1. Base isolation design will benefit the most from these provisions, as those structures depend heavily on knowledge of long-period accelerations.

Additional Topics

Incorporation of FEMA P695 and P795

FEMA P695 – *Quantification of Building Seismic Performance Factors* (ATC, 2009) is a methodology to quantify the seismic performance factors for code-defined structural systems and to verify the adequacy of proposed new systems. FEMA P795 – *Component Equivalency Method* (ATC, 2011) is a component-based methodology for verifying equivalency of components, connections and sub-assemblies proposed for substitution into an established structural system. Since their publication, P695 and P795 have been generally accepted as the most appropriate approach to assigning seismic design coefficients to new systems and for qualifying new components. The Provisions provide recommendations for adoption of these methodologies or other analytical approaches for justifying seismic design coefficients for alternative systems and for establishment of equivalency of new components.

Simplified Seismic Design Category B Procedure

The Provisions contain a new chapter, Chapter 24, that is a simplified, alternate seismic design procedure for structures in Seismic Design Category (SDC) B. A structure in SDC B designed using Chapter 24 is similar to a design using Chapter 12, but the engineer has the convenience of an abbreviated document to work within. For example, Chapter 24 does not contain the "special" lateral force resisting systems, removes T_L from the calculation for the base shear coefficient, and only contains Chapter 13 requirements for parapet and hazardous materials provisions.

A number of further simplifications arose from the effort to develop Chapter 24 as a standalone document. These include site factors for a subcategory of Site Class F soils, elimination of E_v (vertical earthquake effects) in SDC B design, and exempting SDC B structures from accidental torsion checks unless they have Type 1B horizontal irregularities.

Seismic Anchorage to Concrete

PUC studies have been made in response to general concerns related to the complexity and possibly the conservatism inherent in the application of *ACI 318-11 Building Code Requirements for Structural Concrete* (ACI, 2011) Appendix D. A Part 3 Resource Paper supports the technical basis for the Appendix D provisions, and provides discussion related to the following issues: evaluation of overstrength values for design and evaluation of non-yielding anchorage; consideration of material ductility and post-yield strength; evaluation of interaction

of connection parts; evaluation of stretch length and use of reinforcement as a yielding element; evaluation of pre-load and creep; and evaluation of concrete failure behavior and limit states.

Rigid Wall/Flexible Diaphragm Buildings

Building code provisions have traditionally defined system ductility in terms of the vertical elements of the lateral force resisting system, with more than 80 lateral systems defined in the table of seismic design coefficients. Many large footprint, low-rise buildings have long walls or braced frames at the perimeter with flexible diaphragms spanning between that experience significant mass participation in the diaphragm vibration modes. The behavior of these buildings is not reflected by the current practice of calculating design forces prescribed only on the basis of the vertical lateral force resisting system. Using recent studies as a basis, a Resource Paper in the Provisions outlines a new design procedure for structures dominated by diaphragm behavior.

Modifications to Section 12.14 of ASCE 7

The Provisions contain updates to Section 12.14 of ASCE 7, the Simplified Seismic Design Procedure. The procedure has been streamlined to remove the fifteen percent mass-rigidity check, making the process more straightforward. In addition, all diaphragms, regardless of their actual rigidity, are allowed to be proportioned as if they are flexible diaphragms. This change is a result of extensive analysis that showed that buildings within the scope of section 12.14 that were designed based on a flexible diaphragm assumption performed well.

Modal Response Spectrum Analysis

Engineers have long used Modal Response Spectrum Analysis (MRSA) as a tool to model the dynamic behavior of structures under seismic loading. MRSA can provide a good approximation of more sophisticated tools if structural ductility is limited and it requires only a fraction of the computing power used for nonlinear analyses. In cases where there is a large amount of nonlinearity, systems designed with R=8, e.g., the procedure becomes less accurate. The 2015 NEHRP Provisions address a number of problems with the previous MRSA provisions, including: removing the 15% reduction in base shear relative to the equivalent lateral force procedure, modifying the requirements for mass participation, requiring 3D analysis models, and updating the commentary associated with modal response combination techniques. In addition, a number of items have been targeted for further study during the next Provisions update cycle, including limiting ductility in modes that will behave elastically and the appropriate structural response parameter to use for scaling the analysis results.

Concluding Remarks

The 2015 NEHRP Provisions is intended to serve as a nationally applicable resource document including Part 1 charging language based on and modifying ASCE/SEI 7-10, Part 2 detailed commentary also consistent with ASCE/SEI 7-10, and Part 3 introducing of new technologies. This paper provides an overview of the work that went into the Provisions update project and is intended to contribute to the FEMA goal of outreach to the engineering community. The material in the Provisions represents the state of the art for many topics within

earthquake engineering and was developed by committed volunteers with specialties ranging across the technical spectrum of the practice. The updates to these topics, which were adjudged at the beginning of the 2015 NEHRP Provisions cycle as needing particular attention, represent a net progression towards reducing the earthquake hazard facing the public.

Acknowledgements

The authors wish to acknowledge those who are volunteering their time on the 2015 Provisions update effort, particularly the Provision Update Committee and the Issue Team chairs and members. In addition it is recognized that the Provisions update effort would not be possible without funding and technical support from FEMA and the staff of BSSC.

BUILDING CODE REQUIREMENTS FOR STRUCTURAL CONCRETE (ACI 318-95)* AND COMMENTARY (ACI 318R-95)†

REPORTED BY ACI COMMITTEE 318

The code portion of this document covers the proper design and construction of buildings of structural concrete. The code has been written in such form that it may be adopted by reference in a general building code and earlier editions have been widely used in this manner.

Among the subjects covered are: drawings and specifications; inspection; materials; durability requirements; concrete quality, mixing, and placing; formwork; embedded pipes and construction joints; reinforcement details; analysis and design; strength and serviceability; flexural and axial loads; shear and torsion; development and splices of reinforcement; slab systems; walls; footings; precast concrete; composite flexural members; prestressed concrete; shells and folded plate members; strength evaluation of existing structures; special provisions for seismic design; structural plain concrete; an alternate design method in Appendix A; unified design provisions in Appendix B; and alternative load and strength reduction factors in Appendix C.

The quality and testing of materials used in the construction are covered by reference to the appropriate ASTM standard specifications. Welding of reinforcement is covered by reference to the appropriate ANSI/AWS standard.

Because the ACI Building Code is written as a legal document so that it may be adopted by reference in a general building code, it cannot present background details or suggestions for carrying out its requirements or intent. It is the function of this commentary to fill this need.

The commentary discusses some of the considerations of the committee in developing the code with emphasis given to the explanation of new or revised provisions that may be unfamiliar to code users.

References to much of the research data referred to in preparing the code are cited for the user desiring to study individual questions in greater detail. Other documents that provide suggestions for carrying out the requirements of the code are also cited.

The chapter and section numbering of the code are followed throughout.

Keywords: admixtures; aggregates; anchorage (structural); beam-column frame; beams (supports); **building codes;** cements; cold weather construction; columns (supports); combined stress; composite construction (concrete and steel); composite construction (concrete to concrete); compressive strength; **concrete construction; concretes;** concrete slabs; construction joints; continuity (structural); contraction joints; cover; curing; deep beams; deflections; drawings; earthquake resistant structures; embedded service ducts; flexural strength; floors; folded plates; footings; formwork (construction); frames; hot weather construction; inspection; isolation joints; joints (junctions); joists; lightweight concretes; loads (forces); load tests (structural); materials; mixing; mix proportioning; modulus of elasticity; moments; pipe columns; pipes (tubing); placing; plain concrete; precast concrete; prestressed concrete; prestressing steels; quality control; **reinforced concrete**; reinforcing steels; roofs; serviceability; shear strength; shearwalls; shells (structural forms); spans; specifications; splicing; strength; strength analysis; stresses; **structural analysis; structural concrete; structural design;** structural integrity; T-beams, torsion; walls; water; welded wire fabric.

ACI 318-95 was adopted as a standard of the American Concrete Institute July 1, 1995 to supersede ACI 318-89 (Revised 1992) in accordance with the Institute's standardization procedure.

Vertical lines in the margins indicate the 1995 code changes.

*A complete metric companion to ACI 318/318R has been developed, 318M/318RM; therefore no metric equivalents are included in this document.

†ACI Committee Reports, Guides, Standard Practices, and Commentaries are intended for guidance in designing, planning, executing, or inspecting construction, and in preparing specifications. Reference to these documents shall not be made in the Project Documents. If items found in these documents are desired to be part of the Project Documents they should be phrased in mandatory language and incorporated into the Project Documents.

Copyright © 1995, American Concrete Institute.

All rights reserved including rights of reproduction and use in any form or by any means, including the making of copies by any photo process, or by any electronic or mechanical device, printed or written or oral, or recording for sound or visual reproduction or for use in any knowledge or retrieval system or device, unless permission in writing is obtained from the copyright proprietors.

The 1995 ACI Building Code and Commentary are presented in a side-by-side column format, with code text placed in the left column and the corresponding commentary text aligned in the right column. To further distinguish the Code from the Commentary, the Code has been printed in Helvetica, the same type face in which this paragraph is set. Vertical lines in the margins indicate changes from 318-89 (Revised 1992).

This paragraph is set in Times Roman, all portions of the text exclusive to the Commentary are printed in this type face. Commentary section numbers are preceded by an "R" to further distinguish them from Code section numbers.

INTRODUCTION

This commentary discusses some of the considerations of Committee 318 in developing the provisions contained in "Building Code Requirements for Structural Concrete (ACI 318-95)," hereinafter called the code or the 1995 code. Emphasis is given to the explanation of new or revised provisions that may be unfamiliar to code users. In addition, comments are included for some items contained in previous editions of the code to make the present commentary independent of the commentary for ACI 318-89 (Revised 1992). Comments on specific provisions are made under the corresponding chapter and section numbers of the code.

The commentary is not intended to provide a complete historical background concerning the development of the ACI Building Code,* nor is it intended to provide a detailed résumé of the studies and research data reviewed by the committee in formulating the provisions of the code. However, references to some of the research data are provided for those who wish to study the background material in depth.

As the name implies, "Building Code Requirements for Structural Concrete (ACI 318-95)" is meant to be used as part of a legally adopted building code and as such must differ in form and substance from documents that provide detailed specifications, recommended practice, complete design procedures, or design aids.

The code is intended to cover all buildings of the usual types, both large and small. Requirements more stringent than the code provisions may be desirable for unusual construction. The code and commentary cannot replace sound engineering knowledge, experience, and judgment.

A building code states only the minimum requirements necessary to provide for public health and safety. The ACI Building Code is based on this principle. For any structure, the owner or the structural designer may require the quality of materials and construction to be higher than the minimum requirements necessary to protect the public as stated in the code. However, lower standards are not permitted.

The commentary directs attention to other documents that provide suggestions for carrying out the requirements and intent of the code. However, those documents and the commentary are not intended to be a part of the code.

The code has no legal status unless it is adopted by the government bodies having the police power to regulate building design and construction. Where the code has not been adopted, it may serve as a reference to good practice even though it has no legal status.

The code provides a means of establishing minimum standards for acceptance of designs and construction by a legally appointed building official or his designated representatives. The code and commentary are not intended for use in settling disputes between the owner, engineer, architect, contractor, or their agents, subcontractors, material suppliers, or testing agencies. Therefore, the code cannot define the contract responsibility of each of the parties in usual construction. General references requiring compliance with ACI 318 in the job specifications should be avoided since the contractor is rarely in a position to accept responsibility for design details or construction requirements that depend on a detailed knowledge of the design. Generally, the drawings, specifications and contract documents should contain all of the necessary requirements to insure compliance with the code. In part, this can be accomplished by reference to specific code sections in the job specifications. Other ACI publications, such as "Specifications for Structural Concrete for Buildings" (ACI 301) are written specifically for use as contract documents for construction.

Committee 318 recognizes the desirability of standards of performance for individual parties involved in the contract documents. Available for this purpose are the plant certification programs of the Precast/Prestressed Concrete Institute, the Post-Tensioning Institute, and the National Ready Mixed Concrete Association. In addition, "Recommended Practice for Inspection and Testing Agencies for Concrete, Steel, and Bituminous Materials As Used in Construction" (ASTM E 329-77) recommends performance requirements for inspection and testing agencies.

* For a history of the ACI Building Code see Kerekes, Frank, and Reid, Harold B., Jr., "Fifty Years of Development in Building Code Requirements for Reinforced Concrete," ACI JOURNAL, *Proceedings* V. 50, No. 6, Feb. 1954, p. 441. For a discussion of code philosophy, see Siess, Chester P., "Research, Building Codes, and Engineering Practice," ACI JOURNAL, *Proceedings* V. 56, No. 5, May 1960, p. 1105.

Design reference material illustrating application of the code requirements may be found in the following documents. The design aids listed may be obtained from the sponsoring organization.

Design aids:

"Design Handbook in Accordance with the Strength Design Method of ACI 318-89," Volume 2 — Columns, ACI Committee 340, Publication SP-17A(90), American Concrete Institute, Detroit, 1990, 222 pp. (Provides tables and charts for design of eccentricity loaded columns by the Strength Design Method).

"Design Handbook in Accordance with the Strength Design Method of ACI 318-89," V. 3 — Two-Way Slabs, ACI Committee 340, Publication SP-17(91), American Concrete Institute, Detroit, 1991, 104 pp. (Provides design aids for use in the engineering design and analysis of reinforced concrete slab systems carrying loads by two-way action. Design aids are also provided for the selection of slab thickness and for reinforcement required to control deformation and assure adequate shear and flexural strengths.)

"ACI Detailing Manual—1994," ACI Committee 315, Publication SP-66(94), American Concrete Institute, Detroit, 1994, 244 pp. (Includes the standard, ACI 315-92, and report, ACI 315R-94. Provides recommended methods and standards for preparing design drawings, typical details, and drawings for fabrication and placing of reinforcing steel in reinforced concrete structures. Separate sections define responsibilities of both engineer and reinforcing bar detailer.)

CRSI Handbook, Concrete Reinforcing Steel Institute, Schaumburg, Ill., 7th Edition, 1992, 840 pp. (Provides tabulated designs for structural elements and major concrete slab systems. All designs are based on normal weight concrete and Grade 60 reinforcing bars. Design examples are provided to show the basis of, and use of the load tables. Tabulated designs are given for beams; square, round and rectangular columns; one-way slabs; and one-way joist construction. The design tables for two-way slab systems include flat plates, flat slabs and waffle slabs. The sections on foundations provide design tables for square footings, pile caps, drilled piers (caissons) and cantilever retaining walls. Other design aids are presented for crack control; and development of reinforcement and lap splices.)

"Reinforcement: Anchorages, Lap Splices and Connections," Concrete Reinforcing Steel Institute, Schaumburg, Ill., 3rd Edition, 1990, 37 pp. (Provides accepted practices in splicing reinforcement. The use of lap splices, mechanical connections, and welded splices are described. Simplified design data is presented for development of reinforcement and lap splice lengths.)

"Structural Welded Wire Fabric Manual of Standard Practice," Wire Reinforcement Institute, McLean, Va., 4th Edition, Apr. 1992, 31 pp. (Describes wire fabric material, gives nomenclature and wire size and weight tables. Lists specifications and properties and manufacturing limitations. Book emphasizes ACI 318 Building Code requirements as code affects welded wire fabric. Also gives development length and splice length tables. Manual contains customary units and soft metric units.)

"Structural Welded Wire Fabric Detailing Manual," Wire Reinforcement Institute, McLean Va., 1st Edition, 1983, 76 pp. (Provides information on detailing welded wire fabric reinforcement systems. Includes design aids for welded wire fabric in accordance with ACI 318 Building Code requirements for wire fabric.)

"Strength Design of Reinforced Concrete Columns," Portland Cement Association, Skokie, Ill., EB009D, 1978, 48 pp. (Provides design tables of column strength in terms of load in kips versus moment in ft-kips for concrete strength of 5000 psi and Grade 60 reinforcement. Design examples are included. Note that the PCA design tables do not include the strength reduction factor ϕ in the tabulated values; M_u/ϕ and P_u/ϕ must be used when designing with this aid.

"PCI Design Handbook—Precast and Prestressed Concrete," Precast/Prestressed Concrete Institute, Chicago, 4th Edition, 1992, 580 pp. (Provides load tables for common industry products, and procedures for design and analysis of precast and prestressed elements and structures composed of these elements. Provides design aids and examples.)

"Design and Typical Details of Connections for Precast and Prestressed Concrete," Precast/Prestressed Concrete Institute, Chicago, 2nd Edition, 1988, 270 pp. (Updates available information on design of connections for both structural and architectural products, and presents a full spectrum of typical details. Provides design aids and examples.)

"PTI Post-Tensioning Manual," Post-Tensioning Institute, Phoenix, 5th Edition, 1990, 406 pp. (Provides comprehensive coverage of post-tensioning systems, specifications, and design aid construction concepts.)

"PTI Design of Post-Tensioned Slabs," Post-Tensioning Institute, Phoenix, 2nd Edition, Apr. 1984, 56 pp. (Illustrates application of ACI 318 Building Code requirements for design of one-way and two-way post-tensioned slabs. Detailed design examples are presented.)

6.1—Design of formwork
6.2—Removal of forms, shores, and reshoring
6.3—Conduits and pipes embedded in concrete
6.4—Construction joints

CHAPTER 7—DETAILS OF REINFORCEMENT..... 318-63

7.0—Notation
7.1—Standard hooks
7.2—Minimum bend diameters
7.3—Bending
7.4—Surface conditions of reinforcement
7.5—Placing reinforcement
7.6—Spacing limits for reinforcement
7.7 —Concrete protection for reinforcement
7.8 —Special reinforcement details for columns
7.9 —Connections
7.10—Lateral reinforcement for compression members
7.11—Lateral reinforcement for flexural members
7.12—Shrinkage and temperature reinforcement
7.13—Requirements for structural integrity

PART 4—GENERAL REQUIREMENTS

CHAPTER 8—ANALYSIS AND DESIGN—GENERAL CONSIDERATIONS..... 318-77

8.0—Notation
8.1—Design methods
8.2—Loading
8.3—Methods of analysis
8.4—Redistribution of negative moments in continuous nonprestressed flexural members
8.5—Modulus of elasticity
8.6 —Stiffness
8.7 —Span length
8.8 —Columns
8.9 —Arrangement of live load
8.10—T-beam construction
8.11—Joist construction
8.12—Separate floor finish

CHAPTER 9—STRENGTH AND SERVICEABILITY REQUIREMENTS..... 318-87

9.0—Notation
9.1—General
9.2—Required strength
9.3—Design strength
9.4—Design strength for reinforcement
9.5—Control of deflections

CHAPTER 10—FLEXURE AND AXIAL LOADS.....318-101

10.0—Notation
10.1—Scope
10.2—Design assumptions
10.3—General principles and requirements
10.4—Distance between lateral supports of flexural members
10.5—Minimum reinforcement of flexural members
10.6—Distribution of flexural reinforcement in beams and one-way slabs
10.7—Deep flexural members
10.8—Design dimensions for compression members
10.9 —Limits for reinforcement of compression members
10.10—Slenderness effects in compression members
10.11—Magnified moments—General
10.12—Magnified moments—Non-sway frames
10.13—Magnified moments—Sway frames
10.14—Axially loaded members supporting slab system
10.15—Transmission of column loads through floor system
10.16—Composite compression members
10.17—Bearing strength

CHAPTER 11—SHEAR AND TORSION.....318-131

11.0—Notation
11.1—Shear strength
11.2—Lightweight concrete
11.3—Shear strength provided by concrete for nonprestressed members
11.4—Shear strength provided by concrete for prestressed members
11.5—Shear strength provided by shear reinforcement
11.6 —Design for torsion
11.7 —Shear-friction
11.8 —Special provisions for deep flexural members
11.9 —Special provisions for brackets and corbels
11.10—Special provisions for walls
11.11—Transfer of moments to columns
11.12—Special provisions for slabs and footings

CHAPTER 12—DEVELOPMENT AND SPLICES OF REINFORCEMENT.....318-177

12.0—Notation
12.1—Development of reinforcement—General
12.2—Development of deformed bars and deformed wire in tension
12.3—Development of deformed bars in compression
12.4—Development of bundled bars
12.5—Development of standard hooks in tension
12.6—Mechanical anchorage
12.7—Development of welded deformed wire fabric in tension
12.8—Development of welded plain wire fabric in tension
12.9—Development of prestressing strand
12.10—Development of flexural reinforcement—General
12.11—Development of positive moment reinforcement
12.12—Development of negative moment reinforcement
12.13—Development of web reinforcement
12.14—Splices of reinforcement—General
12.15—Splices of deformed bars and deformed wire in tension
12.16—Splices of deformed bars in compression
12.17—Special splice requirements for columns
12.18—Splices of welded deformed wire fabric in tension
12.19—Splices of welded plain wire fabric in tension

PART 5—STRUCTURAL SYSTEMS OR ELEMENTS

CHAPTER 13—TWO-WAY SLAB SYSTEMS 318-207

PART 1 — GENERAL

CHAPTER 1 — GENERAL REQUIREMENTS

CODE

1.1 — Scope

1.1.1 — This code provides minimum requirements for design and construction of structural concrete elements of any structure erected under requirements of the legally adopted general building code of which this code forms a part. In areas without a legally adopted building code, this code defines minimum acceptable standards of design and construction practice.

1.1.2 — This code supplements the general building code and shall govern in all matters pertaining to

COMMENTARY

R1.1 — Scope

The American Concrete Institute "**Building Code Requirements for Structural Concrete (ACI 318-95)**," hereinafter referred to as the code, provides minimum requirements for any structural concrete design or construction.

The 1995 edition of the ACI 318 Building Code both revised the previous standard **"Building Code Requirements for Reinforced Concrete (ACI 318-89) (Revised 1992)"** and revised and incorporated into the single new standard extensive material from **"Building Code Requirements for Structural Plain Concrete (ACI 318.1-89)(Revised 1992)."** Thus, this new standard includes in one document the rules for all concrete used for structural purposes including both plain and reinforced concrete. Title of the document has been changed in the 1995 edition to **"Building Code Requirements for Structural Concrete (ACI 318-95)."** The term "structural concrete" is used to refer to all plain or reinforced concrete used for structural purposes. This covers the spectrum of structural applications of concrete from nonreinforced concrete to concrete containing nonprestressed reinforcement, pretensioned or post-tensioned tendons, or composite steel shapes, pipe, or tubing.

Prestressed concrete is included under the definition of reinforced concrete. Provisions of the code apply to prestressed concrete except for those that are stated to apply specifically to nonprestressed concrete.

Chapter 21 of the code contains special provisions for design and detailing of earthquake resistant structures. See 1.1.8.

Appendix A of the code contains provisions for an alternate method of design for nonprestressed reinforced concrete members using service loads (without load factors) and permissible service load stresses. The Alternate Design Method is intended to give results that are slightly more conservative than designs by the Strength Design Method of the code.

Appendix B of the code contains new provisions for reinforcement limits, determination of the strength reduction factor ϕ, and moment redistribution. The new provisions are applicable to reinforced and prestressed concrete flexural and compression members. Designs made using the provisions of Appendix B are equally acceptable, provided the provisions of Appendix B are used in their entirety.

R1.1.2 — The American Concrete Institute recommends that the code be adopted in its entirety; however, it is recognized that when the code is made a part of a legally adopted

CODE

design and construction of structural concrete, except wherever this code is in conflict with requirements in the legally adopted general building code.

1.1.3 — This code shall govern in all matters pertaining to design, construction, and material properties wherever this code is in conflict with requirements contained in other standards referenced in this code.

1.1.4 — For special structures, such as arches, tanks, reservoirs, bins and silos, blast-resistant structures, and chimneys, provisions of this code shall govern where applicable.

COMMENTARY

general building code, that general building code may modify some provisions of this code.

R1.1.4 — Some special structures involve unique design and construction problems which are not covered by the code. However, many code provisions, such as the concrete quality and design principles, are applicable for these structures. Detailed recommendations for design and construction of some special structures are given in the following ACI publications:

"Standard Practice for the Design and Construction of Cast-in-Place Reinforced Concrete Chimneys" reported by ACI Committee 307.[1.1] (Gives material, construction, and design requirements for circular cast-in-place reinforced chimneys. It sets forth minimum loadings for the design of reinforced concrete chimneys and contains methods for determining the stresses in the concrete and reinforcement required as a result of these loadings.)

"Standard Practice for Design and Construction of Concrete Silos and Stacking Tubes for Storing Granular Materials" reported by ACI Committee 313.[1.2] (Gives material, design, and construction requirements for reinforced concrete bins, silos, and bunkers and stave silos for storing granular materials. It includes recommended design and construction criteria based on experimental and analytical studies plus worldwide experience in silo design and construction.)

(Bins, silos, and bunkers are special structures, posing special problems not encountered in normal building design. While this standard practice refers to **"Building Code Requirements for Structural Concrete"** (ACI 318) for many applicable requirements, it provides supplemental detail requirements and ways of considering the unique problems of static and dynamic loading of silo structures. Much of the method is empirical, but this standard practice does not preclude the use of more sophisticated methods which give equivalent or better safety and reliability.)

(This standard practice sets forth recommended loadings and methods for determining the stresses in the concrete and reinforcement resulting from these loadings. Methods are recommended for determining the thermal effects resulting from stored material and for determining crack width in concrete walls due to pressure exerted by the stored material. Appendices provide recommended minimum values of overpressure and impact factors.)

CODE

COMMENTARY

"Environmental Engineering Concrete Structures" reported by ACI Committee 350.[1.3] (Gives material, design and construction recommendations for concrete tanks, reservoirs, and other structures commonly used in water and waste treatment works where dense, impermeable concrete with high resistance to chemical attack is required. Special emphasis is placed on a structural design which minimizes the possibility of cracking and accommodates vibrating equipment and other special loads. Proportioning of concrete, placement, curing and protection against chemicals are also described. Design and spacing of joints receive special attention.)

"Code Requirements for Nuclear Safety Related Concrete Structures" reported by ACI Committee 349.[1.4] (Provides minimum requirements for design and construction of concrete structures which form part of a nuclear power plant and which have nuclear safety related functions. The code does not cover concrete reactor vessels and concrete containment structures which are covered by ACI 359.)

"Code for Concrete Reactor Vessels and Containments" reported by ACI-ASME Committee 359.[1.5] (Provides requirements for the design, construction, and use of concrete reactor vessels and concrete containment structures for nuclear power plants.)

1.1.5 — This code does not govern design and installation of portions of concrete piles and drilled piers embedded in ground.

R1.1.5 — The design and installation of piling fully embedded in the ground is regulated by the general building code. For portions of piling in air or water, or in soil not capable of providing adequate lateral restraint throughout the piling length to prevent buckling, the design provisions of this code govern where applicable.

Recommendations for concrete piles are given in detail in **"Recommendations for Design, Manufacture, and Installation of Concrete Piles"** reported by ACI Committee 543.[1.6] (Provides recommendations for the design and use of most types of concrete piles for many kinds of construction.)

Recommendations for drilled piers are given in detail in **"Design and Construction of Drilled Piers"** reported by ACI Committee 336.[1.7] (Provides recommendations for design and construction of foundation piers $2^1/_2$ ft in diameter or larger made by excavating a hole in the soil and then filling it with concrete.)

1.1.6 — This code does not govern design and construction of soil-supported slabs, unless the slab transmits vertical loads from other portions of the structure to the soil.

1.1.7 — Concrete on steel form deck

R1.1.7 — Concrete on steel form deck

In steel framed structures, it is common practice to cast concrete floor slabs on stay-in-place steel form deck. In all cases, the deck serves as the form and may, in some cases, serve an additional structural function.

CODE

1.1.7.1 — Design and construction of structural concrete slabs cast on stay-in-place, noncomposite steel form deck are governed by this code.

1.1.7.2 — This code does not govern the design of structural concrete slabs cast on stay-in-place, composite steel form deck. Concrete used in the construction of such slabs shall be governed by Parts 1, 2, and 3 of this code, where applicable.

1.1.8 — Special provisions for earthquake resistance

1.1.8.1 — In regions of low seismic risk, provisions of Chapter 21 shall not apply.

1.1.8.2 — In regions of moderate or high seismic risk, provisions of Chapter 21 shall be satisfied. See 21.2.1.

COMMENTARY

R1.1.7.1 — In its most basic application, the steel form deck serves as a form, and the concrete serves a structural function and, therefore, must be designed to carry all superimposed loads.

R1.1.7.2 — Another type of steel form deck commonly used develops composite action between the concrete and steel deck. In this type of construction, the steel deck serves as the positive moment reinforcement. The design of composite slabs on steel deck is regulated by **"Standard for the Structural Design of Composite Slabs"** (ANSI/ASCE 3).[1.8] However, ANSI/ASCE 3 references the appropriate portions of ACI 318 for the design and construction of the concrete portion of the composite assembly. Guidelines for the construction of composite steel deck slabs are given in **"Standard Practice for the Construction and Inspection of Composite Slabs"** (ANSI/ASCE 9).[1.9]

R1.1.8 — Special provisions for earthquake resistance

Special provisions for seismic design were first introduced in Appendix A of the 1971 ACI Building Code and were continued without revision in ACI 318-77. These provisions were originally intended to apply only to reinforced concrete structures located in regions of highest seismicity.

The special provisions were extensively revised in the 1983 code edition to include new requirements for certain earthquake-resisting systems located in regions of moderate seismicity. In the 1989 code, the special provisions were moved to Chapter 21.

R1.1.8.1 — For buildings located in regions of low seismic risk, no special design or detailing is required; the general requirements of the main body of the code apply for proportioning and detailing reinforced concrete buildings. It is the intent of Committee 318 that concrete structures proportioned by the main body of the code will provide a level of toughness adequate for low earthquake intensity.

R1.1.8.2 — For buildings in regions of moderate seismic risk, reinforced concrete moment frames proportioned to resist earthquake effects require some special reinforcement details, as specified in 21.8 of Chapter 21. The special details apply only to frames (beams, columns, and slabs) to which the earthquake-induced forces have been assigned in design. The special details are intended principally for unbraced concrete frames, where the frame is required to resist not only normal load effects, but also the lateral load effects of earthquake. The special reinforcement details will serve to provide a suitable level of inelastic behavior if the frame is subjected to an earthquake of such intensity as to require it to perform inelastically. There are no special requirements for structural walls provided to resist lateral effects of wind and earthquake, or nonstructural components of buildings located in regions of moderate seismic risk. Structural walls proportioned by the main body of the code are considered to have sufficient toughness at anticipated drift levels in regions of moderate seismicity.

CODE

1.1.8.3 — Seismic risk level of a region shall be regulated by the legally adopted general building code of which this code forms a part, or determined by local authority.

1.2 — Drawings and specifications

1.2.1 — Copies of design drawings, typical details, and specifications for all structural concrete construction shall bear the seal of a registered engineer or architect. These drawings, details, and specifications shall show:

(a) Name and date of issue of code and supplement to which design conforms

(b) Live load and other loads used in design

(c) Specified compressive strength of concrete at stated ages or stages of construction for which each part of structure is designed

(d) Specified strength or grade of reinforcement

(e) Size and location of all structural elements and reinforcement

(f) Provision for dimensional changes resulting from creep, shrinkage, and temperature

(g) Magnitude and location of prestressing forces

(h) Anchorage length of reinforcement and location and length of lap splices

(i) Type and location of welded splices and mechanical connections of reinforcement

COMMENTARY

For buildings located in regions of high seismic risk, all building components, structural and nonstructural, must satisfy requirements of 21.2 through 21.7 of Chapter 21. The special proportioning and detailing provisions of Chapter 21 are intended to provide a monolithic reinforced concrete structure with adequate "toughness" to respond inelastically under severe earthquake motions. See also R21.2.1

R1.1.8.3 — Definition of low, moderate, and high seismic risk as used by ACI 318 are not precise. Seismic risk level is usually designated by zones or areas of equal probability of risk of damage, related to the intensity of ground shaking, such as Zone 0—no damage; Zone 1—minor damage; Zone 2—moderate damage; and Zones 3 and 4—major damage. The tabulation is provided only as guide in interpreting the requirements of 1.1.8. The correlations implied are neither precise nor inflexible. Seismic risk levels (Seismic Zone Maps) are under the jurisdiction of a general building code rather than ACI 318. In the absence of a general building code that addresses earthquake loads and seismic zoning, it is the intent of Committee 318 that the local authorities (engineers, geologists, and building code officials) should decide on proper need and application of the special provisions for seismic design. Seismic zoning maps, such as recommended in References 1.10 and 1.11, are suitable for correlating seismic risk.

R1.2 — Drawings and specifications

R1.2.1 — The provisions for preparation of design drawings and specifications are, in general, consistent with those of most general building codes and are intended as supplements thereto.

The code lists some of the more important items of information that must be included in the design drawings, details, or specifications. The code does not imply an all inclusive list, and additional items may be required by the building official.

CODE

(j) Details and location of all contraction or isolation joints specified for plain concrete in Chapter 22.

1.2.2 — Calculations pertinent to design shall be filed with the drawings when required by the building official. Analyses and designs using computer programs shall be permitted provided design assumptions, user input, and computer-generated output are submitted. Model analysis shall be permitted to supplement calculations.

1.2.3 — Building official means the officer or other designated authority charged with the administration and enforcement of this code, or his duly authorized representative.

1.3 — Inspection

1.3.1 — As a minimum, concrete construction shall be inspected as required by the legally adopted general building code. In the absence of such requirements, concrete construction shall be inspected throughout the various work stages by an engineer or architect, or by a competent representative responsible to that engineer or architect.

COMMENTARY

R1.2.2 — Documented computer output is acceptable in lieu of manual calculations. The extent of input and output information required will vary, according to the specific requirements of individual building officials. However, when a computer program has been used by the designer, only skeleton data should normally be required. This should consist of sufficient input and output data and other information to allow the building official to perform a detailed review and make comparisons using another program or manual calculations. Input data should be identified as to member designation, applied loads, and span lengths. The related output data should include member designation and the shears, moments, and reactions at key points in the span. For column design, it is desirable to include moment magnification factors in the output where applicable.

The code permits model analysis to be used to supplement structural analysis and design calculations. Documentation of the model analysis should be provided with the related calculations. Model analysis should be performed by an engineer or architect having experience in this technique.

R1.2.3 — "Building official" is the term used by many general building codes to identify the person charged with administration and enforcement of the provisions of the building code. However, such terms as "building commissioner" or "building inspector" are variations of the title, and the term "building official" as used in this code is intended to include those variations as well as others which are used in the same sense.

R1.3 — Inspection

The quality of concrete structures depends largely on workmanship in construction. The best of materials and design practice will not be effective unless the construction is performed well. Inspection is provided to assure satisfactory work in accordance with the design drawings and specifications. Proper performance of the structure depends on construction which accurately represents the design and meets code requirements, within the tolerances allowed. In the public interest, local building ordinances should require the owner to provide inspections.

R1.3.1 — Inspection of construction by or under the supervision of the engineer or architect responsible for the design should be considered because the person in charge of the design is the best qualified to inspect for conformance with the design. When such an arrangement is not feasible, the owner may provide proper inspection of construction through his engineers or architects or through separate inspection organizations with demonstrated capability for performing the inspection.

CODE

COMMENTARY

The building departments having jurisdiction over the construction may have the necessary expertise and capability to inspect structural concrete construction.

When inspection is done independently of the designer, it is recommended that the designer be employed to at least oversee inspection and observe the work to see that his design requirements are properly executed.

In some jurisdictions, legislation has established special registration or licensing procedures for persons performing certain inspection functions. A check should be made in the general building code or with the building official to ascertain if any such requirements exist within a specific jurisdiction.

Inspection responsibility and the degree of inspection required should be set forth in the contracts between the owner, architect, engineer, and contractor. Adequate fees should be provided consistent with the work and equipment necessary to properly perform the inspection.

1.3.2 — The inspector shall require compliance with design drawings and specifications. Unless specified otherwise in the legally adopted general building code, inspection records shall include:

(a) Quality and proportions of concrete materials and strength of concrete

(b) Construction and removal of forms and reshoring

(c) Placing of reinforcement

(d) Mixing, placing, and curing of concrete

(e) Sequence of erection and connection of precast members

(f) Tensioning of prestressing tendons

(g) Any significant construction loadings on completed floors, members, or walls

(h) General progress of work.

R1.3.2 — By "inspection," the code does not mean that the inspector should supervise the construction. Rather it means that the one employed for inspection should visit the project with the frequency necessary to observe the various stages of work and ascertain that it is being done in compliance with contract documents and code requirements. The frequency should be at least enough to provide general knowledge of each operation, whether this be several times a day or once in several days.

Inspection in no way relieves the contractor from his obligation to follow the plans and specifications implicitly and to provide the designated quality and quantity of materials and workmanship for all job stages. The inspector should be present as frequently as he/she deems necessary to judge whether the quality and quantity of the work complies with the contract documents; to counsel on possible ways of obtaining the desired results; to see that the general system proposed for formwork appears proper (though it remains the contractor's responsibility to design and build adequate forms and to leave them in place until it is safe to remove them); to see that reinforcement is properly installed; to see that concrete is of the correct quality, properly placed, and cured; and to see that tests for quality control are being made as specified.

The code prescribes minimum requirements for inspection of all structures within its scope. It is not a construction specification and any user of the code may require higher standards of inspection than cited in the legal code if additional requirements are necessary.

Recommended procedures for organization and conduct of concrete inspection are given in detail in **"Guide for Concrete Inspection."**[1.12] (Sets forth procedures relating to concrete construction to serve as a guide to owners, architects, and engineers in planning an inspection program.)

CODE

COMMENTARY

Detailed methods of inspecting concrete construction are given in **"ACI Manual of Concrete Inspection"** (SP-2) reported by ACI Committee 311.[1.13] (Describes methods of inspecting concrete construction which are generally accepted as good practice. Intended as a supplement to specifications and as a guide in matters not covered by specifications.)

1.3.3 — When the ambient temperature falls below 40 F or rises above 95 F, a record shall be kept of concrete temperatures and of protection given to concrete during placement and curing.

R1.3.3 — The term "ambient temperature" means the temperature of the environment to which the concrete is directly exposed. Concrete temperature as used in this section may be taken as the air temperature near the surface of the concrete; however, during mixing and placing it is practical to measure the temperature of the mixture.

1.3.4 — Records of inspection required in 1.3.2 and 1.3.3 shall be preserved by the inspecting engineer or architect for 2 years after completion of the project.

R1.3.4 — A record of inspection in the form of a job diary is required in case questions subsequently arise concerning the performance or safety of the structure or members. Photographs documenting job progress may also be desirable.

Records of inspection must be preserved for at least 2 years after the completion of the project. The completion of the project is the date at which the owner accepts the project, or when a certificate of occupancy is issued, whichever date is later. The general building code or other legal requirements may require a longer preservation of such records.

1.3.5 — For moment frames resisting seismic loads in structures designed in conformance with Chapter 21 and located in regions of high seismic risk, a specially qualified inspector under the supervision of the person responsible for the structural design shall provide continuous inspection for the placement of the reinforcement and concrete.

R1.3.5 — The purpose of this section is to assure that the special detailing required in concrete ductile frames is properly executed through inspection by personnel who are qualified to do this work. Qualifications of inspectors should be determined by the jurisdiction enforcing the general building code.

1.4 — Approval of special systems of design or construction

R1.4 — Approval of special systems of design or construction

Sponsors of any system of design or construction within the scope of this code, the adequacy of which has been shown by successful use or by analysis or test, but which does not conform to or is not covered by this code, shall have the right to present the data on which their design is based to the building official or to a board of examiners appointed by the building official. This board shall be composed of competent engineers and shall have authority to investigate the data so submitted, to require tests, and to formulate rules governing design and construction of such systems to meet the intent of this code. These rules when approved by the building official and promulgated shall be of the same force and effect as the provisions of this code.

New methods of design, new materials, and new uses of materials must undergo a period of development before being specifically covered in a code. Hence, good systems or components might be excluded from use by implication if means were not available to obtain acceptance.

For special systems considered under this section, specific tests, load factors, deflection limits, and other pertinent requirements should be set by the board of examiners, and should be consistent with the intent of the code.

The provisions of this section do not apply to model tests used to supplement calculations under 1.2.2 or to strength evaluation of existing structures under Chapter 20.

CHAPTER 2 — DEFINITIONS

CODE

2.1 — The following terms are defined for general use in this code. Specialized definitions appear in individual chapters.

Admixture — Material other than water, aggregate, or hydraulic cement, used as an ingredient of concrete and added to concrete before or during its mixing to modify its properties.

Aggregate — Granular material, such as sand, gravel, crushed stone, and iron blast-furnace slag, used with a cementing medium to form a hydraulic cement concrete or mortar.

Aggregate, lightweight — Aggregate with a dry, loose weight of 70 lb/ft^3 or less.

Anchorage — In post-tensioning, a device used to anchor tendon to concrete member; in pretensioning, a device used to anchor tendon during hardening of concrete.

Bonded tendon — Prestressing tendon that is bonded to concrete either directly or through grouting.

Building official — See 1.2.3.

Cementitious materials — Materials as specified in Chapter 3, which have cementing value when used in concrete either by themselves, such as portland cement, blended hydraulic cements, and expansive cement, or such materials in combination with fly ash, other raw or calcined natural pozzolans, silica fume, and/or ground granulated blast-furnace slag.

Column — Member with a ratio of height-to-least lateral dimension exceeding 3 used primarily to support axial compressive load.

Composite concrete flexural members — Concrete flexural members of precast and/or cast-in-place concrete elements constructed in separate placements but so interconnected that all elements respond to loads as a unit.

Compression-controlled section — A cross section in which the net tensile strain in the extreme tension steel at nominal strength is less than or equal to the compression-controlled strain limit.

Compression-controlled strain limit — The net tensile strain at balanced strain conditions. See B10.3.2.

Concrete — Mixture of portland cement or any other

COMMENTARY

R2.1 — For consistent application of the code, it is necessary that terms be defined where they have particular meanings in the code. The definitions given are for use in application of this code only and do not always correspond to ordinary usage. A glossary of most used terms relating to cement manufacturing, concrete design and construction, and research in concrete is contained in **"Cement and Concrete Terminology"** reported by ACI Committee 116.[2.1]

By code definition, "sand-lightweight concrete" is structural lightweight concrete with *all* of the fine aggregate replaced by sand. This definition may not be in agreement with usage by some material suppliers or contractors where the majority, but not all, of the lightweight fines are replaced by sand. For proper application of the code provisions, the replacement limits must be stated, with interpolation when partial sand replacement is used.

Deformed reinforcement is defined as that meeting the deformed bar specifications of 3.5.3.1, or the specifications of 3.5.3.3, 3.5.3.4, 3.5.3.5, or 3.5.3.6. No other bar or fabric qualifies. This definition permits accurate statement of anchorage lengths. Bars or wire not meeting the deformation requirements or fabric not meeting the spacing requirements are "plain reinforcement," for code purposes, and may be used only for spirals.

A number of definitions for loads are given as the code contains requirements that must be met at various load levels. The terms "dead load" and "live load" refer to the unfactored loads (service loads) specified or defined by the general building code. Service loads (loads without load factors) are to be used where specified in the code to proportion or investigate members for adequate serviceability as in 9.5, Control of Deflections. Loads used to proportion a member for adequate strength are defined as "factored loads." Factored loads are service loads multiplied by the appropriate load factors specified in 9.2 for required strength. The term "design loads," as used in the 1971 code edition to refer to loads multiplied by appropriate load factors, was discontinued in the 1977 code to avoid confusion with the design load terminology used in general building codes to denote service loads, or posted loads in buildings. The factored load terminology, first adopted in the 1977 code, clarifies when the load factors are applied to a particular load, moment, or shear value as used in the code provisions.

Reinforced concrete is defined to include prestressed concrete. Although the behavior of a prestressed member with unbonded tendons may vary from that of members with

CODE

hydraulic cement, fine aggregate, coarse aggregate, and water, with or without admixtures.

Concrete, specified compressive strength of, (f_c') — Compressive strength of concrete used in design and evaluated in accordance with provisions of Chapter 5, expressed in pounds per square inch (psi). Whenever the quantity f_c' is under a radical sign, square root of numerical value only is intended, and result has units of pounds per square inch (psi).

Concrete, structural lightweight — Concrete containing lightweight aggregate that conforms to 3.3 and has an air-dry unit weight as determined by "Test Method for Unit Weight of Structural Lightweight Concrete" (ASTM C 567), not exceeding 115 lb/ft^3. In this code, a lightweight concrete without natural sand is termed "all-lightweight concrete" and lightweight concrete in which all of the fine aggregate consists of normal weight sand is termed "sand-lightweight concrete."

Contraction joint — Formed, sawed, or tooled groove in a concrete structure to create a weakened plane and regulate the location of cracking resulting from the dimensional change of different parts of the structure.

Curvature friction — Friction resulting from bends or curves in the specified prestressing tendon profile.

Deformed reinforcement — Deformed reinforcing bars, bar mats, deformed wire, welded plain wire fabric, and welded deformed wire fabric conforming to 3.5.3.

Development length — Length of embedded reinforcement required to develop the design strength of reinforcement at a critical section. See 9.3.3.

Effective depth of section (d) — Distance measured from extreme compression fiber to centroid of tension reinforcement.

Effective prestress — Stress remaining in prestressing tendons after all losses have occurred, excluding effects of dead load and superimposed load.

Embedment length — Length of embedded reinforcement provided beyond a critical section.

Extreme tension steel — The reinforcement (prestressed or nonprestressed) that is the farthest from the extreme compression fiber.

Isolation joint — A separation between adjoining parts of a concrete structure, usually a vertical plane, at a designed location such as to interfere least with performance of the structure, yet such as to allow rela-

COMMENTARY

continuously bonded tendons, bonded and unbonded prestressed concrete are combined with conventionally reinforced concrete under the generic term "reinforced concrete." Provisions common to both prestressed and conventionally reinforced concrete are integrated to avoid overlapping and conflicting provisions.

Strength of a member or cross section calculated using standard assumptions and strength equations, and nominal (specified) values of material strengths and dimensions is referred to as "nominal strength." The subscript n is used to denote the nominal strengths; nominal axial load strength P_n, nominal moment strength M_n, and nominal shear strength V_n. "Design strength" or usable strength of a member or cross section is the nominal strength reduced by the strength reduction factor ϕ.

The required axial load, moment, and shear strengths used to proportion members are referred to either as factored axial loads, factored moments, and factored shears, or required axial loads, moments, and shears. The factored load effects are calculated from the applied factored loads and forces in such load combinations as are stipulated in the code (see 9.2).

The subscript u is used only to denote the required strengths; required axial load strength P_u, required moment strength M_u, and required shear strength V_u, calculated from the applied factored loads and forces.

The basic requirement for strength design may be expressed as follows:

$$\text{Design strength} \geq \text{Required strength}$$

$$\phi P_n \geq P_u$$

$$\phi M_n \geq M_u$$

$$\phi V_n \geq V_u$$

For additional discussion on the concepts and nomenclature for strength design see commentary Chapter 9.

The term "compression member" is used in the code to define any member in which the primary stress is longitudinal compression. Such a member need not be vertical but may have any orientation in space. Bearing walls, columns, and pedestals qualify as compression members under this definition.

The differentiation between columns and walls in the code is based on the principal use rather than on arbitrary relationships of height and cross-sectional dimensions. The code, however, permits walls to be designed using the prin-

CODE

tive movement in three directions and avoid formation of cracks elsewhere in the concrete and through which all or part of the bonded reinforcement is interrupted.

Jacking force — In prestressed concrete, temporary force exerted by device that introduces tension into prestressing tendons.

Load, dead — Dead weight supported by a member, as defined by general building code of which this code forms a part (without load factors).

Load, factored — Load, multiplied by appropriate load factors, used to proportion members by the strength design method of this code. See 8.1.1 and 9.2.

Load, live — Live load specified by general building code of which this code forms a part (without load factors).

Load, service — Load specified by general building code of which this code forms a part (without load factors).

Modulus of elasticity — Ratio of normal stress to corresponding strain for tensile or compressive stresses below proportional limit of material. See 8.5.

Net tensile strain — The tensile strain at nominal strength exclusive of strains due to effective prestress, creep, shrinkage, and temperature.

Pedestal — Upright compression member with a ratio of unsupported height to average least lateral dimension of less than 3.

Plain concrete — Structural concrete with no reinforcement or with less reinforcement than the minimum amount specified for reinforced concrete.

Plain reinforcement — Reinforcement that does not conform to definition of deformed reinforcement. See 3.5.4.

Post-tensioning — Method of prestressing in which tendons are tensioned after concrete has hardened.

Precast concrete — Structural concrete element cast elsewhere than its final position in the structure.

Prestressed concrete — Structural concrete in which internal stresses have been introduced to reduce potential tensile stresses in concrete resulting from loads.

Pretensioning — Method of prestressing in which tendons are tensioned before concrete is placed.

Reinforced concrete — Structural concrete reinforced with no less than the minimum amounts of pre-

COMMENTARY

ciples stated for column design (see 14.4), as well as by the empirical method (see 14.5).

While a wall always encloses or separates spaces, it may also be used to resist horizontal or vertical forces or bending. For example, a retaining wall or a basement wall also supports various combinations of loads.

A column is normally used as a main vertical member carrying axial loads combined with bending and shear. It may, however, form a small part of an enclosure or separation.

CODE

stressing tendons or nonprestressed reinforcement specified in Chapters 1 through 21 and Appendices A through C.

Reinforcement — Material that conforms to 3.5, excluding prestressing tendons unless specifically included.

Reshores — Shores placed snugly under a concrete slab or other structural member after the original forms and shores have been removed from a larger area, thus requiring the new slab or structural member to deflect and support its own weight and existing construction loads applied prior to the installation of the reshores.

Shores — Vertical or inclined support members designed to carry the weight of the formwork, concrete, and construction loads above.

Span length — See 8.7.

Spiral reinforcement — Continuously wound reinforcement in the form of a cylindrical helix.

Splitting tensile strength (f_{ct}) — Tensile strength of concrete determined in accordance with ASTM C 496 as described in "Specification for Lightweight Aggregates for Structural Concrete" (ASTM C 330). See 5.1.4.

Stirrup — Reinforcement used to resist shear and torsion stresses in a structural member; typically bars, wires, or welded wire fabric (plain or deformed) either single leg or bent into L, U, or rectangular shapes and located perpendicular to or at an angle to longitudinal reinforcement. (The term "stirrups" is usually applied to lateral reinforcement in flexural members and the term "ties" to those in compression members.) See also *Tie.*

Strength, design — Nominal strength multiplied by a strength reduction factor ϕ. See 9.3.

Strength, nominal — Strength of a member or cross section calculated in accordance with provisions and assumptions of the strength design method of this code before application of any strength reduction factors. See 9.3.1.

Strength, required — Strength of a member or cross section required to resist factored loads or related internal moments and forces in such combinations as are stipulated in this code. See 9.1.1.

Stress — Intensity of force per unit area.

COMMENTARY

CODE

COMMENTARY

Structural concrete — All concrete used for structural purposes including plain and reinforced concrete.

Tendon — Steel element such as wire, cable, bar, rod, or strand, or a bundle of such elements, used to impart prestress to concrete.

Tension-controlled section — A cross section in which the net tensile strain in the extreme tension steel at nominal strength is greater than or equal to 0.005.

Tie — Loop of reinforcing bar or wire enclosing longitudinal reinforcement. A continuously wound bar or wire in the form of a circle, rectangle, or other polygon shape without re-entrant corners is acceptable. See also *Stirrup*.

Transfer — Act of transferring stress in prestressing tendons from jacks or pretensioning bed to concrete member.

Wall — Member, usually vertical, used to enclose or separate spaces.

Wobble friction — In prestressed concrete, friction caused by unintended deviation of prestressing sheath or duct from its specified profile.

Yield strength — Specified minimum yield strength or yield point of reinforcement in pounds per square inch. Yield strength or yield point shall be determined in tension according to applicable ASTM standards as modified by 3.5 of this code.

CODE COMMENTARY

Notes

PART 2 — STANDARDS FOR TESTS AND MATERIALS

CHAPTER 3 — MATERIALS

CODE

COMMENTARY

3.0 — Notation

f_y = specified yield strength of nonprestressed reinforcement, psi

3.1 — Tests of materials

3.1.1 — Building official shall have the right to order testing of any materials used in concrete construction to determine if materials are of quality specified.

3.1.2 — Tests of materials and of concrete shall be made in accordance with standards listed in 3.8.

3.1.3 — A complete record of tests of materials and of concrete shall be available for inspection during progress of work and for 2 years after completion of the project, and shall be preserved by inspecting engineer or architect for that purpose.

R3.1 — Tests of materials

R3.1.3 — The record of tests of materials and of concrete must be preserved for at least 2 years after completion of the project. Completion of the project is the date at which the owner accepts the project or when the certificate of occupancy is issued, whichever date is later. Local legal requirements may require longer preservation of such records.

3.2 — Cements

3.2.1 — Cement shall conform to one of the following specifications:

(a) "Specification for Portland Cement" (ASTM C 150).

(b) "Specification for Blended Hydraulic Cements" (ASTM C 595), excluding Types S and SA which are not intended as principal cementing constituents of structural concrete.

(c) "Specification for Expansive Hydraulic Cement" (ASTM C 845).

3.2.2 — Cement used in the work shall correspond to that on which selection of concrete proportions was based. See 5.2.

R3.2 — Cements

R3.2.2 — Depending on the circumstances, the provision of 3.2.2 may require only the same type of cement or may require cement from the identical source. The latter would be the case if the standard deviation[3.1] of strength tests used in establishing the required strength margin was based on a cement from a particular source. If the standard deviation was based on tests involving a given type of cement obtained from several sources, the former interpretation would apply.

CODE	COMMENTARY
3.3 — Aggregates	**R3.3 — Aggregates**
3.3.1 — Concrete aggregates shall conform to one of the following specifications: (a) "Specification for Concrete Aggregates" (ASTM C 33). (b) "Specification for Lightweight Aggregates for Structural Concrete" (ASTM C 330). Exception: Aggregates which have been shown by special test or actual service to produce concrete of adequate strength and durability and approved by the building official.	**R3.3.1** — It is recognized that aggregates conforming to the ASTM specifications are not always economically available and that, in some instances, noncomplying materials have a long history of satisfactory performance. Such nonconforming materials are permitted with special approval when acceptable evidence of satisfactory performance is provided. It should be noted, however, that satisfactory performance in the past does not guarantee good performance under other conditions and in other localities. Whenever possible, aggregates conforming to the designated specifications should be used.
3.3.2 — Nominal maximum size of coarse aggregate shall be not larger than: (a) $^1/_5$ the narrowest dimension between sides of forms, nor (b) $^1/_3$ the depth of slabs, nor (c) $^3/_4$ the minimum clear spacing between individual reinforcing bars or wires, bundles of bars, or prestressing tendons or ducts. These limitations shall not apply if, in the judgment of the engineer, workability and methods of consolidation are such that concrete can be placed without honeycomb or voids.	**R3.3.2** — The size limitations on aggregates are provided to ensure proper encasement of reinforcement and to minimize honeycomb. Note that the limitations on maximum size of the aggregate may be waived if, in the judgment of the engineer, the workability and methods of consolidation of the concrete are such that the concrete can be placed without honeycomb or voids. In this instance, the engineer must decide whether or not the limitations on maximum size of aggregate may be waived.
3.4 — Water	**R3.4 — Water**
3.4.1 — Water used in mixing concrete shall be clean and free from injurious amounts of oils, acids, alkalis, salts, organic materials, or other substances deleterious to concrete or reinforcement.	**R3.4.1** — Almost any natural water that is drinkable (potable) and has no pronounced taste or odor is satisfactory as mixing water for making concrete. Impurities in mixing water, when excessive, may affect not only setting time, concrete strength, and volume stability (length change), but may also cause efflorescence or corrosion of reinforcement. Where possible, water with high concentrations of dissolved solids should be avoided. Salts, or other deleterious substances contributed from the aggregate or admixtures are additive to the amount which might be contained in the mixing water. These additional amounts must be considered in evaluating the acceptability of the total impurities that may be deleterious to concrete or steel.

CODE

3.4.2 — Mixing water for prestressed concrete or for concrete that will contain aluminum embedments, including that portion of mixing water contributed in the form of free moisture on aggregates, shall not contain deleterious amounts of chloride ion. See 4.4.1.

3.4.3 — Nonpotable water shall not be used in concrete unless the following are satisfied:

3.4.3.1 — Selection of concrete proportions shall be based on concrete mixes using water from the same source.

3.4.3.2 — Mortar test cubes made with nonpotable mixing water shall have 7-day and 28-day strengths equal to at least 90 percent of strengths of similar specimens made with potable water. Strength test comparison shall be made on mortars, identical except for the mixing water, prepared and tested in accordance with "Test Method for Compressive Strength of Hydraulic Cement Mortars (Using 2-in. or 50-mm Cube Specimens)" (ASTM C 109).

3.5 — Steel reinforcement

3.5.1 — Reinforcement shall be deformed reinforcement, except that plain reinforcement shall be permitted for spirals or tendons; and reinforcement consisting of structural steel, steel pipe, or steel tubing shall be permitted as specified in this code.

3.5.2 — Welding of reinforcing bars shall conform to "Structural Welding Code — Reinforcing Steel," ANSI/AWS D1.4 of the American Welding Society. Type and location of welded splices and other required welding of reinforcing bars shall be indicated on the design drawings or in the project specifications. ASTM reinforcing bar specifications, except for ASTM A 706, shall be supplemented to require a report of material properties necessary to conform to the requirements in ANSI/AWS D1.4.

AWS D1.4-92 new code

COMMENTARY

R3.5 — Steel reinforcement

R3.5.1 — Materials permitted for use as reinforcement are specified. Other metal elements, such as inserts, anchor bolts, or plain bars for dowels at isolation or contraction joints, are not normally considered to be reinforcement under the provisions of this code.

R3.5.2 — When welding of reinforcing bars is required, the weldability of the steel and compatible welding procedures need to be considered. The provisions in ANSI/AWS D1.4 Welding Code cover aspects of welding reinforcing bars, including criteria to qualify welding procedures.

Weldability of the steel is based on its chemical composition or carbon equivalent (CE). The Welding Code establishes preheat and interpass temperatures for a range of carbon equivalents and reinforcing bar sizes. Carbon equivalent is calculated from the chemical composition of the reinforcing bars. The Welding Code has two expressions for calculating carbon equivalent. A relatively short expression, considering only the elements carbon and manganese, is to be used for bars other than ASTM A 706 material. A more comprehensive expression is given for ASTM A 706 bars. The CE formula in the Welding Code for A 706 bars is identical to the CE formula in the ASTM A 706 specification.

The engineer should realize that the chemical analysis, for bars other than A 706, required to calculate the carbon equivalent is not routinely provided by the producer of the

CODE

COMMENTARY

reinforcing bars. Hence, for welding reinforcing bars other than A 706 bars, the design drawings or project specifications should specifically require results of the chemical analysis to be furnished.

The ASTM A 706 specification covers low-alloy steel reinforcing bars intended for applications requiring controlled tensile properties or welding. Weldability is accomplished in the A 706 specification by limits or controls on chemical composition and on carbon equivalent.[3.2] The producer is required by the A 706 specification to report the chemical composition and carbon equivalent.

The ANSI/AWS D1.4 Welding Code requires the contractor to prepare written welding procedure specifications conforming to the requirements of the Welding Code. Appendix A of the Welding Code contains a suggested form which shows the information required for such a specification for each joint welding procedure.

Often it is necessary to weld to existing reinforcing bars in a structure when no mill test report of the existing reinforcement is available. This condition is particularly common in alterations or building expansions. ANSI/AWS D1.4 states for such bars that a chemical analysis may be performed on representative bars. If the chemical composition is not known or obtained, the Welding Code requires a minimum preheat. For bars other than A 706 material, the minimum preheat required is 300 F for bars No. 6 or smaller, and 400 F for No. 7 bars or larger. The required preheat for all sizes of A 706 is to be the temperature given in the Welding Code's table for minimum preheat corresponding to the range of CE "over 45 percent to 55 percent." Welding of the particular bars must then be performed in accordance with ANSI/AWS D 1.4. It should also be determined if additional precautions are in order, based on other considerations such as stress level in the bars, consequences of failure, and heat damage to existing concrete due to welding operations.

Welding of wire to wire, and of wire or welded wire fabric to reinforcing bars or structural steel elements is not covered by ANSI/AWS D1.4. If welding of this type is required on a project, the engineer should specify requirements or performance criteria for this welding. If cold drawn wires are to be welded, the welding procedures should address the potential loss of yield strength and ductility, achieved by the cold working process (during manufacture), when such wires are heated by welding. Machine and resistance welding as used in the manufacture of welded wire fabrics is covered by ASTM A 185 and A 497 and is not part of this concern.

3.5.3 — Deformed reinforcement

3.5.3.1 — Deformed reinforcing bars shall conform to one of the following specifications:

R3.5.3 — Deformed reinforcement

R3.5.3.1 — ASTM A 615 covers specifications for deformed billet-steel reinforcing bars which are normally

CODE

(a) "Specification for Deformed and Plain Billet-Steel Bars for Concrete Reinforcement" (ASTM A 615).

(b) "Specification for Rail-Steel Deformed and Plain Bars for Concrete Reinforcement" including Supplementary Requirement S1 (ASTM A 616 including S1).

(c) "Specification for Axle-Steel Deformed and Plain Bars for Concrete Reinforcement" (ASTM A 617).

(d) "Specification for Low-Alloy Steel Deformed Bars for Concrete Reinforcement" (ASTM A 706).

3.5.3.2 — Deformed reinforcing bars with a specified yield strength f_y exceeding 60,000 psi shall be permitted, provided f_y shall be the stress corresponding to a strain of 0.35 percent and the bars otherwise conform to one of the ASTM specifications listed in 3.5.3.1. See 9.4.

3.5.3.3 — Bar mats for concrete reinforcement shall conform to "Specification for Fabricated Deformed Steel Bar Mats for Concrete Reinforcement" (ASTM A 184). Reinforcing bars used in bar mats shall conform to one of the specifications listed in 3.5.3.1.

3.5.3.4 — Deformed wire for concrete reinforcement shall conform to "Specification for Steel Wire, Deformed, for Concrete Reinforcement" (ASTM A 496), except that wire shall not be smaller than size D4 and for wire with a specified yield strength f_y exceeding 60,000 psi, f_y shall be the stress corresponding to a strain of 0.35 percent if the yield strength specified in the design exceeds 60,000 psi.

COMMENTARY

used in reinforced concrete construction in the United States. The specification also requires that all billet-steel reinforcing bars be marked with the letter S.

Rail-steel reinforcing bars used with this code must conform to ASTM A 616 including Supplementary Requirement S1, marked with the letter R, in addition to the rail symbol. S1 prescribes more restrictive requirements for bend tests.

ASTM A 706 covers low-alloy steel deformed bars intended for special applications where welding or bending, or both, are of importance. The specification requires that the bars be marked with the letter W for type of steel.

R3.5.3.2 — ASTM A 615 includes provisions for Grade 75 bars in sizes No. 6 through 18.

The 0.35 percent strain limit is necessary to ensure that the assumption of an elasto-plastic stress-strain curve in 10.2.4 will not lead to unconservative values of the member strength.

The 0.35 strain requirement is not applied to reinforcing bars having yield strengths of 60,000 psi or less. For steels, having strengths of 40,000 psi, as were once used extensively, the assumption of an elasto-plastic stress-strain curve is well justified by extensive test data. For higher strength steels, up to 60,000 psi, the stress-strain curve may or may not be elasto-plastic as assumed in 10.2.4, depending on the properties of the steel and the manufacturing process. However, when the stress-strain curve is not elasto-plastic, there is limited experimental evidence to suggest that the actual steel stress at ultimate strength may not be enough less than the specified yield strength to warrant the additional effort of testing to the more restrictive criterion applicable to steels having f_y greater than 60,000 psi. In such cases, the ϕ-factor can be expected to account for the strength deficiency.

CODE

3.5.3.5 — Welded plain wire fabric for concrete reinforcement shall conform to "Specification for Steel Welded Wire Fabric, Plain, for Concrete Reinforcement" (ASTM A 185), except that for wire with a specified yield strength f_y exceeding 60,000 psi, f_y shall be the stress corresponding to a strain of 0.35 percent if the yield strength specified in the design exceeds 60,000 psi. Welded intersections shall not be spaced farther apart than 12 in. in direction of calculated stress, except for wire fabric used as stirrups in accordance with 12.13.2.

3.5.3.6 — Welded deformed wire fabric for concrete reinforcement shall conform to "Specification for Steel Welded Wire Fabric, Deformed, for Concrete Reinforcement" (ASTM A 497), except that for wire with a specified yield strength f_y exceeding 60,000 psi, f_y shall be the stress corresponding to a strain of 0.35 percent if the yield strength specified in the design exceeds 60,000 psi. Welded intersections shall not be spaced farther apart than 16 in. in direction of calculated stress, except for wire fabric used as stirrups in accordance with 12.13.2.

3.5.3.7 — Galvanized reinforcing bars shall comply with "Specification for Zinc-Coated (Galvanized) Steel Bars for Concrete Reinforcement" (ASTM A 767). Epoxy-coated reinforcing bars shall comply with "Specification for Epoxy-Coated Reinforcing Steel Bars" (ASTM A 775) or with "Specification for Epoxy-Coated Prefabricated Steel Reinforcing Bars" (ASTM A 934). Galvanized or epoxy-coated reinforcement shall conform to one of the specifications listed in 3.5.3.1.

3.5.3.8 — Epoxy-coated wires and welded wire fabric shall comply with "Specification for Epoxy-Coated Steel Wire and Welded Wire Fabric for Reinforcement" (ASTM A 884). Epoxy-coated wires shall conform to 3.5.3.4 and epoxy-coated welded wire fabric shall conform to 3.5.3.5 or 3.5.3.6.

3.5.4 — Plain reinforcement

3.5.4.1 — Plain bars for spiral reinforcement shall conform to the specification listed in 3.5.3.1(a), (b), or (c).

3.5.4.2 — Plain wire for spiral reinforcement shall conform to "Specification for Steel Wire, Plain, for Concrete Reinforcement" (ASTM A 82), except that for wire with a specified yield strength f_y exceeding 60,000 psi, f_y shall be the stress corresponding to a strain of 0.35 percent if the yield strength specified in the design exceeds 60,000 psi.

COMMENTARY

R3.5.3.5 — Welded plain wire fabric must be made of wire conforming to "Specification for Steel Wire, Plain, for Concrete Reinforcement" (ASTM A 82). ASTM A 82 has a minimum yield strength of 70,000 psi. The code has assigned a yield strength value of 60,000 psi, but makes provision for the use of higher yield strengths provided the stress corresponds to a strain of 0.35 percent.

R3.5.3.6 — Welded deformed wire fabric must be made of wire conforming to "Specification for Steel Wire, Deformed, for Concrete Reinforcement" (ASTM A 496). ASTM A 496 has a minimum yield strength of 70,000 psi. The code has assigned a yield strength value of 60,000 psi, but makes provision for the use of higher yield strengths provided the stress corresponds to a strain of 0.35 percent.

R3.5.3.7 — Galvanized reinforcing bars (A 767) and epoxy-coated reinforcing bars (A 775) were added to the 1983 code, and epoxy-coated prefabricated reinforcing bars (A 934) were added to the 1995 code recognizing their usage, especially for conditions where corrosion resistance of reinforcement is of particular concern. They have typically been used in parking decks, bridge decks, and other highly corrosive environments.

R3.5.4 — Plain reinforcement

Plain bars and plain wire are permitted only for spiral reinforcement (either as lateral reinforcement for compression members, for torsion members, or for confining reinforcement for splices).

CODE

3.5.5 — Prestressing tendons

3.5.5.1 — Tendons for prestressed reinforcement shall conform to one of the following specifications:

(a) Wire conforming to "Specification for Uncoated Stress-Relieved Steel Wire for Prestressed Concrete" (ASTM A 421).

(b) Low-relaxation wire conforming to "Specification for Uncoated Stress-Relieved Steel Wire for Prestressed Concrete" including Supplement "Low-Relaxation Wire" (ASTM A 421).

(c) Strand conforming to "Specification for Steel Strand, Uncoated Seven-Wire for Prestressed Concrete" (ASTM A 416).

(d) Bar conforming to "Specification for Uncoated High-Strength Steel Bar for Prestressed Concrete" (ASTM A 722).

3.5.5.2 — Wire, strands, and bars not specifically listed in ASTM A 421, A 416, or A 722 are allowed provided they conform to minimum requirements of these specifications and do not have properties that make them less satisfactory than those listed in ASTM A 421, A 416, or A 722.

3.5.6 — Structural steel, steel pipe, or tubing

3.5.6.1 — Structural steel used with reinforcing bars in composite compression members meeting requirements of 10.16.7 or 10.16.8 shall conform to one of the following specifications:

(a) "Specification for Structural Steel" (ASTM A 36).

(b) "Specification for High-Strength Low-Alloy Structural Steel" (ASTM A 242).

(c) "Specification for High-Strength Low-Alloy Columbium-Vanadium Steels of Structural Quality" (ASTM A 572).

(d) "Specification for High-Strength Low-Alloy Structural Steel with 50 ksi (345 MPa) Minimum Yield Point to 4 in. (100 mm) Thick" (ASTM A 588).

3.5.6.2 — Steel pipe or tubing for composite compression members composed of a steel encased concrete core meeting requirements of 10.16.6 shall conform to one of the following specifications:

(a) Grade B of "Specification for Pipe, Steel, Black and Hot-Dipped, Zinc-Coated Welded and Seamless" (ASTM A 53).

COMMENTARY

R3.5.5 — Prestressing tendons

R3.5.5.1 — Since low-relaxation tendons are addressed in a supplement to ASTM A 421 which applies only when low-relaxation material is specified, the appropriate ASTM reference is listed as a separate entity.

CODE

COMMENTARY

(b) "Specification for Cold-Formed Welded and Seamless Carbon Steel Structural Tubing in Rounds and Shapes" (ASTM A 500).

(c) "Specification for Hot-Formed Welded and Seamless Carbon Steel Structural Tubing" (ASTM A 501).

3.6 — Admixtures

R3.6 — Admixtures

3.6.1 — Admixtures to be used in concrete shall be subject to prior approval by the engineer.

3.6.2 — An admixture shall be shown capable of maintaining essentially the same composition and performance throughout the work as the product used in establishing concrete proportions in accordance with 5.2.

3.6.3 — Calcium chloride or admixtures containing chloride from other than impurities from admixture ingredients shall not be used in prestressed concrete, in concrete containing embedded aluminum, or in concrete cast against stay-in-place galvanized steel forms. See 4.3.2 and 4.4.1.

R3.6.3 — Admixtures containing any chloride, other than impurities from admixture ingredients, must not be used in prestressed concrete or in concrete with aluminum embedments. Concentrations of chloride ion may produce corrosion of embedded aluminum (e.g., conduit), especially if the aluminum is in contact with embedded steel and the concrete is in a humid environment. Serious corrosion of galvanized steel sheet and galvanized steel stay-in-place forms occurs, especially in humid environments or where drying is inhibited by the thickness of the concrete or coatings or impermeable coverings. See 4.4.1 for specific limits on chloride ion concentration in concrete.

3.6.4 — Air-entraining admixtures shall conform to "Specification for Air-Entraining Admixtures for Concrete" (ASTM C 260).

3.6.5 — Water-reducing admixtures, retarding admixtures, accelerating admixtures, water-reducing and retarding admixtures, and water-reducing and accelerating admixtures shall conform to "Specification for Chemical Admixtures for Concrete" (ASTM C 494) or "Specification for Chemical Admixtures for Use in Producing Flowing Concrete" (ASTM C 1017).

3.6.6 — Fly ash or other pozzolans used as admixtures shall conform to "Specification for Fly Ash and Raw or Calcined Natural Pozzolan for Use as a Mineral Admixture in Portland Cement Concrete" (ASTM C 618).

3.6.7 — Ground granulated blast-furnace slag used as an admixture shall conform to "Specification for Ground Granulated Blast-Furnace Slag for Use in Concrete and Mortars" (ASTM C 989).

R3.6.7 — Ground granulated blast-furnace slag conforming to ASTM C 989 is used as an admixture in concrete in much the same way as fly ash. Generally, it should be used with portland cements conforming to ASTM C 150 and only

CODE

COMMENTARY

rarely would it be appropriate to use ASTM C 989 slag with an ASTM C 595 blended cement which already contains a pozzolan or slag. Such use with ASTM C 595 cements might be considered for massive concrete placements where slow strength gain can be tolerated and where low heat of hydration is of particular importance. ASTM C 989 includes appendices which discuss effects of ground granulated blast-furnace slag on concrete strength, sulfate resistance, and alkali-aggregate reaction.

3.6.8 — Admixtures used in concrete containing C 845 expansive cements shall be compatible with the cement and produce no deleterious effects.

R3.6.8 — The use of admixtures in concrete containing C 845 expansive cements has reduced levels of expansion or increased shrinkage values. See ACI 223.[3.3]

3.6.9 — Silica fume used as an admixture shall conform to "Specification for Silica Fume for Use in Hydraulic-Cement Concrete and Mortar" (ASTM C 1240).

3.7 — Storage of materials

3.7.1 — Cementitious materials and aggregates shall be stored in such manner as to prevent deterioration or intrusion of foreign matter.

3.7.2 — Any material that has deteriorated or has been contaminated shall not be used for concrete.

3.8 — Standards cited in this code

R3.8 — Standards cited in this code

3.8.1 — Standards of the American Society for Testing and Materials referred to in this code are listed below with their serial designations, including year of adoption or revision, and are declared to be part of this code as if fully set forth herein:

A 36-94	Standard Specification for Structural Steel
A 53-93a	Standard Specification for Pipe, Steel, Black and Hot-Dipped, Zinc-Coated Welded and Seamless
A 82-94	Standard Specification for Steel Wire, Plain, for Concrete Reinforcement
A 184-90	Standard Specification for Fabricated Deformed Steel Bar Mats for Concrete Reinforcement
A 185-94	Standard Specification for Steel Welded Wire Fabric, Plain, for Concrete Reinforcement

The ASTM standard specifications listed are the latest editions at the time these code provisions were adopted. Since these specifications are revised frequently, generally in minor details only, the user of the code should check directly with the sponsoring organization if it is desired to reference the latest edition. However, such a procedure obligates the user of the specification to evaluate if any changes in the later edition are significant in the use of the specification.

Standard specifications or other material to be legally adopted by reference into a building code must refer to a specific document. This can be done by simply using the complete serial designation since the first part indicates the subject and the second part the year of adoption. All standard documents referenced in this code are listed in 3.8, with the title and complete serial designation. In other sections of the code, the designations do not include the date so that all may be kept up-to-date by simply revising 3.8.

PART 3 — CONSTRUCTION REQUIREMENTS

CHAPTER 4 — DURABILITY REQUIREMENTS

CODE

4.0 — Notation

f_c' = specified compressive strength of concrete, psi

4.1 — Water-cementitious materials ratio

4.1.1 — The water-cementitious materials ratios specified in Tables 4.2.2 and 4.3.1 shall be calculated using the weight of cement meeting ASTM C 150, C 595, or C 845 plus the weight of fly ash and other pozzolans meeting ASTM C 618, slag meeting ASTM C 989, and silica fume meeting ASTM C 1240, if any, except that when concrete is exposed to deicing chemicals, 4.2.3 further limits the amount of fly ash, pozzolans, silica fume, slag or the combination of these materials.

COMMENTARY

Chapters 4 and 5 of earlier editions of the code were reformatted in 1989 to emphasize the importance of considering durability requirements before the designer selects f_c' and cover over the reinforcing steel.

Maximum water-cementitious materials ratios of 0.40 to 0.50 that may be required for concretes exposed to freezing and thawing, sulfate soils or waters, or for preventing corrosion of reinforcement will typically be equivalent to requiring an f_c' of 5000 to 4000 psi, respectively. Generally, the required average concrete strengths, f_{cr}', will be 500 to 700 psi higher than the specified compressive strength, f_c'. Since it is difficult to accurately determine the water-cementitious materials ratio of concrete during production, the f_c' specified should be reasonably consistent with the water-cementitious materials ratio required for durability. Selection of an f_c' which is consistent with the water-cementitious materials ratio selected for durability will help ensure that the required water-cementitious materials ratio is actually obtained in the field. Because the usual emphasis on inspection is for strength, test results substantially higher than the specified strength may lead to a lack of concern for quality and production of concrete which exceeds the maximum water-cementitious materials ratio. Thus an f_c' of 3000 psi and a maximum water-cementitious materials ratio of 0.45 should not be specified for a parking structure, if the structure will be exposed to deicing salts.

The code does not include provisions for especially severe exposures, such as acids or high temperatures, and is not concerned with aesthetic considerations such as surface finishes. These items are beyond the scope of the code and must be covered specifically in the project specifications. Concrete ingredients and proportions must be selected to meet the minimum requirements stated in the code and the additional requirements of the contract documents.

R4.1 — Water-cementitious materials ratio

R4.1.1 — For concrete exposed to deicing chemicals the quantity of fly ash, other pozzolans, silica fume, slag, or blended cements used in the concrete is subject to the percentage limits in 4.2.3. Further, in 4.3 for sulfate exposures, the pozzolan should be Class F by ASTM C 618,[4.1] or have been tested by ASTM C 1012[4.2] or determined by service record to improve sulfate resistance.

CODE

4.2 — Freezing and thawing exposures

4.2.1 — Normal weight and lightweight concrete exposed to freezing and thawing or deicing chemicals shall be air-entrained with air content indicated in Table 4.2.1. Tolerance on air content as delivered shall be ± 1.5 percent. For specified compressive strength f_c' greater than 5000 psi, reduction of air content indicated in Table 4.2.1 by 1.0 percent shall be permitted.

TABLE 4.2.1—TOTAL AIR CONTENT FOR FROST-RESISTANT CONCRETE

Nominal maximum aggregate size, in.*	Air content, percent	
	Severe exposure	Moderate exposure
3/8	7 1/2	6
1/2	7	5 1/2
3/4	6	5
1	6	4 1/2
1 1/2	5 1/2	4 1/2
2†	5	4
3†	4 1/2	3 1/2

* See ASTM C 33 for tolerance on oversize for various nominal maximum size designations.

† These air contents apply to total mix, as for the preceding aggregate sizes. When testing these concretes, however, aggregate larger than 1 1/2 in. is removed by handpicking or sieving and air content is determined on the minus 1 1/2 in. fraction of mix (tolerance on air content as delivered applies to this value.). Air content of total mix is computed from value determined on the minus 1 1/2 in. fraction.

4.2.2 — Concrete that will be subject to the exposures given in Table 4.2.2 shall conform to the corresponding maximum water-cementitious materials ratios and minimum specified concrete compressive strength requirements of that table. In addition, concrete that will be exposed to deicing chemicals shall conform to the limitations of 4.2.3.

Table 4.2.2—REQUIREMENTS FOR SPECIAL EXPOSURE CONDITIONS

Exposure condition	Maximum water-cementitious materials ratio, by weight, normal weight aggregate concrete	Minimum f_c', normal weight and lightweight aggregate concrete, psi
Concrete intended to have low permeability when exposed to water	0.50	4000
Concrete exposed to freezing and thawing in a moist condition or to deicing chemicals	0.45	4500
For corrosion protection of reinforcement in concrete exposed to chlorides from deicing chemicals, salt, salt water, brackish water, seawater, or spray from these sources.	0.40	5000

COMMENTARY

R4.2 — Freezing and thawing exposures

R4.2.1—A table of required air contents for frost-resistant concrete is included in the code, based on **"Standard Practice for Selecting Proportions for Normal, Heavyweight, and Mass Concrete"** (ACI 211.1).[4.3] Values are provided for both severe and moderate exposures depending on the exposure to moisture or deicing salts. Entrained air will not protect concrete containing coarse aggregates that undergo disruptive volume changes when frozen in a saturated condition. In Table 4.2.1, a severe exposure is where the concrete in a cold climate may be in almost continuous contact with moisture prior to freezing, or where deicing salts are used. Examples are pavements, bridge decks, sidewalks, parking garages, and water tanks. A moderate exposure is where the concrete in a cold climate will be only occasionally exposed to moisture prior to freezinrg, and where no deicing salts are used. Examples are certain exterior walls, beams, girders, and slabs not in direct contact with soil. Section 4.2.1 permits 1 percent lower air content for concrete with f_c' greater than 5000 psi. Such high-strength concretes will have lower water-cementitious materials ratios and porosity and, therefore, improved frost resistance.

R4.2.2 — Maximum water-cementitious materials ratios are not specified for lightweight aggregate concrete because determination of the absorption of these aggregates is uncertain, making calculation of water-cementitious materials ratio uncertain. The use of a minimum specified strength will ensure the use of a high-quality cement paste. For normal weight aggregate concrete use of both minimum strength and maximum water-cementitious materials ratio provide additional assurance that this objective is met.

CODE

4.2.3 — For concrete exposed to deicing chemicals, the maximum weight of fly ash, other pozzolans, silica fume, or slag that is included in the concrete shall not exceed the percentages of the total weight of cementitious materials given in Table 4.2.3.

TABLE 4.2.3—REQUIREMENTS FOR CONCRETE EXPOSED TO DEICING CHEMICALS

Cementitious materials	Maximum percent of total cementitious materials by weight*
Fly ash or other pozzolans conforming to ASTM C 618	25
Slag conforming to ASTM C 989	50
Silica fume conforming to ASTM C 1240	10
Total of fly ash or other pozzolans, slag, and silica fume	50†
Total of fly ash or other pozzolans and silica fume	35†

* The total cementitious material also includes ASTM C 150, C 595, and C 845 cement.
The maximum percentages above shall include:
(a) Fly ash or other pozzolans present in Type IP or I(PM) blended cement, ASTM C 595
(b) Slag used in the manufacture of a IS or I(SM) blended cement, ASTM C 595
(c) Silica fume, ASTM C 1240, present in a blended cement
† Fly ash or other pozzolans and silica fume shall constitute no more than 25 and 10 percent, respectively, of the total weight of the cementitious materials.

COMMENTARY

R4.2.3 — Section 4.2.3 and Table 4.2.3 establish limitations on the amount of fly ash, other pozzolans, silica fume, and slag that can be included in concrete exposed to deicing chemicals.[4.4-4.6] Recent research has demonstrated that the use of fly ash, slag, and silica fume produce concrete with a finer pore structure and, therefore, lower permeability.[4.7-4.9]

4.3 — Sulfate exposures

4.3.1 — Concrete to be exposed to sulfate-containing solutions or soils shall conform to requirements of Table 4.3.1 or shall be concrete made with a cement that provides sulfate resistance and that has a maximum water-cementitious materials ratio and minimum compressive strength from Table 4.3.1.

R4.3 — Sulfate exposures

R4.3.1 — Concrete exposed to injurious concentrations of sulfates from soil and water should be made with a sulfate-resisting cement. Table 4.3.1 lists the appropriate types of cement and the maximum water-cementitious materials ratios and minimum strengths for various exposure conditions. In selecting a cement for sulfate resistance, the principal consideration is its C_3A content. For moderate exposures, Type II cement is limited to a maximum C_3A content of 8.0 percent under ASTM C 150. The blended cements under ASTM C 595 made with portland cement clinker with less than 8 percent C_3A qualify for the MS designation, and therefore, are appropriate for use in moderate sulfate exposures. The appropriate types under ASTM C 595 are IP(MS), IS(MS), I(PM)(MS), and I(SM)(MS). For severe exposures, Type V cement with a maximum C_3A

TABLE 4.3.1—REQUIREMENTS FOR CONCRETE EXPOSED TO SULFATE-CONTAINING SOLUTIONS

Sulfate exposure	Water soluble sulfate (SO_4) in soil, percent by weight	Sulfate (SO_4) in water, ppm	Cement type	Maximum water-cementitious materials ratio, by weight, normal weight aggregate concrete*	Minimum f'_c, normal weight and lightweight aggregate concrete, psi*
Negligible	0.00-0.10	0-150	—	—	—
Moderate†	0.10-0.20	150-1500	II, IP(MS), IS(MS), P(MS), I(PM)(MS), I(SM)(MS)	0.50	4000
Severe	0.20-2.00	1500-10,000	V	0.45	4500
Very severe	Over 2.00	Over 10,000	V plus pozzolan‡	0.45	4500

* A lower water-cementitious materials ratio or higher strength may be required for low permeability or for protection against corrosion of embedded items or freezing and thawing (Table 4.2.2).
† Seawater.
‡ Pozzolan that has been determined by test or service record to improve sulfate resistance when used in concrete containing Type V cement.

CODE

COMMENTARY

content of 5 percent is specified. In certain areas, the C_3A content of other available types such as Type III or Type I may be less than 8 or 5 percent and are usable in moderate or severe sulfate exposures. Note that sulfate-resisting cement will not increase resistance to some chemically aggressive solutions, for example ammonium nitrate. The project specifications should cover all special cases.

The judicious employment of a good quality fly ash (ASTM C 618, Class F) also has been shown to improve the sulfate resistance of concrete.[4.9] Certain Type IP cements made by blending Class F pozzolan with portland cement having a tricalcium aluminate (C_3A) content greater than 8 percent can provide sulfate resistance for moderate exposures.

A note to Table 4.3.1 lists seawater as "moderate exposure," even though it generally contains more than 1500 ppm SO_4. In seawater exposures, other types of cement with C_3A up to 10 percent may be used if the maximum water-cementitious materials ratio is reduced to 0.40.

ASTM test method C 1012[4.2] can be used to evaluate the sulfate resistance of mixtures using combinations of cementitious materials.

In addition to the proper selection of cement, other requirements for durable concrete exposed to concentrations of sulfate such as: low water-cementitious materials ratio, strength, adequate air entrainment, low slump, adequate consolidation, uniformity, adequate cover of reinforcement, and sufficient moist curing to develop the potential properties of the concrete, are essential.

4.3.2 — Calcium chloride as an admixture shall not be used in concrete to be exposed to severe or very severe sulfate-containing solutions, as defined in Table 4.3.1.

4.4 — Corrosion protection of reinforcement

R4.4 — Corrosion protection of reinforcement

4.4.1 — For corrosion protection of reinforcement in concrete, maximum water soluble chloride ion concentrations in hardened concrete at ages from 28 to 42 days contributed from the ingredients including water, aggregates, cementitious materials, and admixtures shall not exceed the limits of Table 4.4.1. When testing is performed to determine water soluble chloride ion content, test procedures shall conform to ASTM C 1218.

R4.4.1 — Additional information on the effects of chlorides on the corrosion of reinforcing steel is given in **"Guide to Durable Concrete"** reported by ACI Committee 201[4.10] and **"Corrosion of Metals in Concrete"** reported by ACI Committee 222.[4.11] Test procedures must conform to those given in ASTM C 1218. An initial evaluation may be obtained by testing individual concrete ingredients for total chloride ion content. If total chloride ion content, calculated on the basis of concrete proportions, exceeds those permitted in Table 4.4.1, it may be necessary to test samples of the hardened concrete for water soluble chloride ion content described in the guide. Some of the total chloride ions present in the ingredients will either be insoluble or will react with the cement during hydration and become insoluble under the test procedures described.

CODE

TABLE 4.4.1—MAXIMUM CHLORIDE ION CONTENT FOR CORROSION PROTECTION OF REINFORCEMENT

Type of member	Maximum water soluble chloride ion (Cl^-) in concrete, percent by weight of cement
Prestressed concrete	0.06
Reinforced concrete exposed to chloride in service	0.15
Reinforced concrete that will be dry or protected from moisture in service	1.00
Other reinforced concrete construction	0.30

4.4.2 — If concrete with reinforcement will be exposed to chlorides from deicing chemicals, salt, salt water, brackish water, seawater, or spray from these sources, requirements of Table 4.2.2 for water-cementitious materials ratio and concrete strength, and the minimum concrete cover requirements of 7.7 shall be satisfied. See 18.14 for unbonded prestressing tendons.

COMMENTARY

When concretes are tested for soluble chloride ion content the tests should be made at an age of 28 to 42 days. The limits in Table 4.4.1 are to be applied to chlorides contributed from the concrete ingredients, not those from the environment surrounding the concrete.

The chloride ion limits in Table 4.4.1 differ from those recommended in ACI 201.2R and ACI 222R. For reinforced concrete that will be dry in service, a limit of one percent has been included to control total soluble chlorides. Table 4.4.1 includes limits of 0.15 and 0.30 percent for reinforced concrete that will be exposed to chlorides or will be damp in service, respectively. These limits compare to 0.10 and 0.15 recommended in ACI 201.2R. ACI 222R recommends limits of 0.08 and 0.20 percent by weight of cement for chlorides in prestressed and reinforced concrete, respectively, based on tests for acid soluble chlorides, not the test for water soluble chlorides required here.

When epoxy- or zinc-coated bars are used, the limits in Table 4.4.1 may be more restrictive than necessary.

R4.4.2 — When concretes are exposed to external sources of chlorides the water-cementitious materials ratio and specified compressive strength f_c' of 4.2.2 are the minimum requirements that must be considered. The designer should evaluate conditions in structures where chlorides may be applied, in parking structures where chlorides may be tracked in by vehicles or in structures near seawater. Epoxy- or zinc-coated bars or cover greater than the minimum required in 7.7 may be desirable. Use of slag meeting ASTM C 989 or fly ash meeting ASTM C 618 and increased levels of specified strength provide increased protection. Use of silica fume meeting ASTM C 1240 with an appropriate high-range water reducer, ASTM C 494, Types F and G, or ASTM C 1017 can also provide additional protection.[4.12] Performance tests for chloride permeability by AASHTO T 277[4.13] of concrete mixtures prior to use will also provide additional assurance.

CODE COMMENTARY

Notes

CHAPTER 5 — CONCRETE QUALITY, MIXING, AND PLACING

CODE

5.0 — Notation

f_c' = specified compressive strength of concrete, psi
f_{cr}' = required average compressive strength of concrete used as the basis for selection of concrete proportions, psi
f_{ct} = average splitting tensile strength of lightweight aggregate concrete, psi
s = standard deviation, psi

5.1 — General

5.1.1 — Concrete shall be proportioned to provide an average compressive strength as prescribed in 5.3.2 as well as satisfy the durability criteria of Chapter 4. Concrete shall be produced to minimize frequency of strengths below f_c' as prescribed in 5.6.2.3.

5.1.2 — Requirements for f_c' shall be based on tests of cylinders made and tested as prescribed in 5.6.2.

5.1.3 — Unless otherwise specified, f_c' shall be based on 28-day tests. If other than 28 days, test age for f_c' shall be as indicated in design drawings or specifications.

5.1.4 — Where design criteria in 9.5.2.3, 11.2, and 12.2.4 provide for use of a splitting tensile strength value of concrete, laboratory tests shall be made in accordance with "Specification for Lightweight Aggregates for Structural Concrete" (ASTM C 330) to establish value of f_{ct} corresponding to specified value of f_c'.

COMMENTARY

The requirements for proportioning of concrete mixtures are based on the philosophy that concrete should provide both adequate durability (Chapter 4) and strength. The criteria for acceptance of concrete are based on the philosophy that the code is intended primarily to protect the safety of the public. Chapter 5 describes procedures by which concrete of adequate strength can be obtained, and provides procedures for checking the quality of the concrete during and after its placement in the work.

Chapter 5 also prescribes minimum criteria for mixing and placing concrete.

The purpose of 5.3, together with Chapter 4, is to establish the required mixture proportions, and not to constitute a basis for confirming the adequacy of concrete strength, which is covered in 5.6 (evaluation and acceptance of concrete).

R5.1 — General

R5.1.1 — The basic premises governing the designation and evaluation of concrete strength are presented. It is emphasized that the average strength of concrete produced must always exceed the specified value of f_c' used in the structural design calculations. This is based on probabilistic concepts, and is intended to ensure that adequate concrete strength will be developed in the structure. The durability requirements prescribed in Chapter 4 must be satisfied in addition to attaining the average concrete strength in accordance with 5.3.2.

R5.1.4 — Code Sections 9.5.2.3 (modulus of rupture), 11.2 (concrete shear strength) and 12.2.4 (development of reinforcement) require modification in the design criteria for the use of lightweight aggregate concrete. Two alternate modification procedures are provided. One alternate is based on laboratory tests to determine the relationship between splitting tensile strength f_{ct} and specified compressive strength f_c' for the lightweight concrete. For a lightweight aggregate from a given source, it is intended that appropriate values of f_{ct} be obtained in advance of design.

CODE

5.1.5 — Splitting tensile strength tests shall not be used as a basis for field acceptance of concrete.

COMMENTARY

R5.1.5 — Tests for splitting tensile strength of concrete (as required by 5.1.4) are not intended for control of, or acceptance of, the strength of concrete in the field. Indirect control will be maintained through the normal compressive strength test requirements provided by 5.6 (evaluation and acceptance of concrete).

5.2 — Selection of concrete proportions

R5.2 — Selection of concrete proportions

Recommendations for selecting proportions for concrete are given in detail in **"Standard Practice for Selecting Proportions for Normal, Heavyweight, and Mass Concrete"** (ACI 211.1).[5.1] (Provides two methods for selecting and adjusting proportions for normal weight concrete: the estimated weight and absolute volume methods. Example calculations are shown for both methods. Proportioning of heavyweight concrete by the absolute volume method is presented in an appendix.)

Recommendations for lightweight concrete are given in **"Standard Practice for Selecting Proportions for Structural Lightweight Concrete"** (ACI 211.2).[5.2] (Provides a method of proportioning and adjusting structural grade concrete containing lightweight aggregates.)

5.2.1 — Proportions of materials for concrete shall be established to provide:

(a) Workability and consistency to permit concrete to be worked readily into forms and around reinforcement under conditions of placement to be employed, without segregation or excessive bleeding.

(b) Resistance to special exposures as required by Chapter 4.

(c) Conformance with strength test requirements of 5.6.

R5.2.1 — The selected water-cementitious materials ratio must be low enough, or the compressive strength high enough (for lightweight concrete) to satisfy both the strength criteria (see 5.3 or 5.4) and the special exposure requirements (Chapter 4). The code does not include provisions for especially severe exposures, such as acids or high temperatures, and is not concerned with aesthetic considerations such as surface finishes. These items are beyond the scope of the code and must be covered specifically in the project specifications. Concrete ingredients and proportions must be selected to meet the minimum requirements stated in the code and the additional requirements of the contract documents.

5.2.2 — Where different materials are to be used for different portions of proposed work, each combination shall be evaluated.

5.2.3 — Concrete proportions, including water-cementitious materials ratio, shall be established on the basis of field experience and/or trial mixtures with materials to be employed (see 5.3), except as permitted in 5.4 or required by Chapter 4.

R5.2.3 — The code emphasizes the use of field experience or laboratory trial mixtures (see 5.3) as the preferred method for selecting concrete mixture proportions. When no prior experience or trial mixture data is available, estimation of the water-cementitious materials ratio as prescribed in 5.4 is permitted, but only when special permission is given.

5.3 — Proportioning on the basis of field experience and/or trial mixtures

R5.3 — Proportioning on the basis of field experience and/or trial mixtures

In selecting a suitable concrete mixture there are three basic steps. The first is the determination of the standard deviation, and the second, the determination of the required aver-

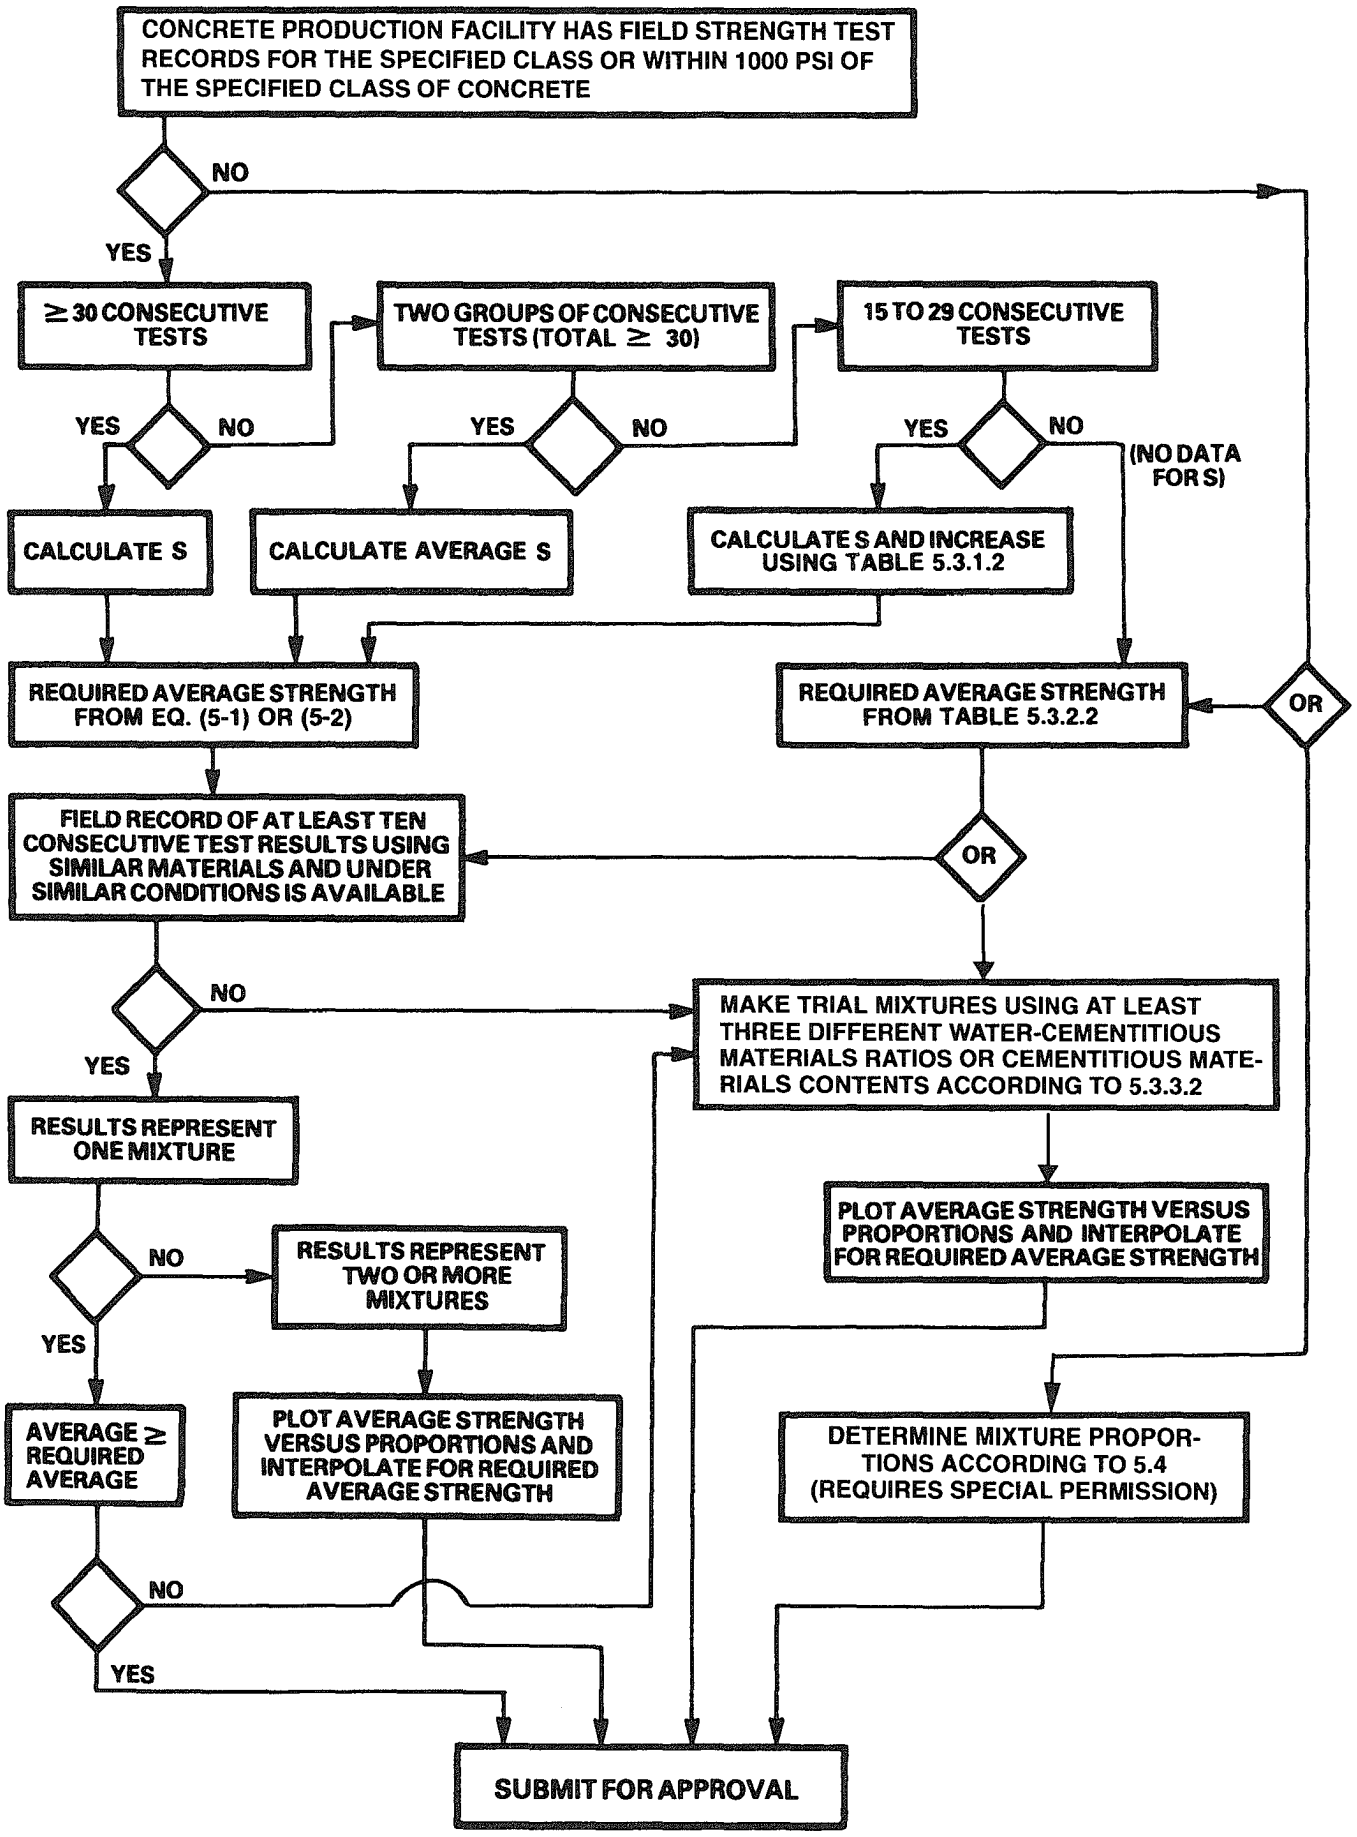

Fig. R5.3—Flow chart for selection and documentation of concrete proportions

CODE

5.3.1 — Standard deviation

5.3.1.1 — Where a concrete production facility has test records, a standard deviation shall be established. Test records from which a standard deviation is calculated:

(a) Shall represent materials, quality control procedures, and conditions similar to those expected and changes in materials and proportions within the test records shall not have been more restricted than those for proposed work.

(b) Shall represent concrete produced to meet a specified strength or strengths f_c' within 1000 psi of that specified for proposed work.

(c) Shall consist of at least 30 consecutive tests or two groups of consecutive tests totaling at least 30 tests as defined in 5.6.1.4, except as provided in 5.3.1.2.

5.3.1.2 — Where a concrete production facility does not have test records meeting requirements of 5.3.1.1, but does have a record based on 15 to 29 consecutive tests, a standard deviation shall be established as the product of the calculated standard deviation and modification factor of Table 5.3.1.2. To be acceptable, test record shall meet requirements (a) and (b) of 5.3.1.1, and represent only a single record of consecutive tests that span a period of not less than 45 calendar days.

TABLE 5.3.1.2—MODIFICATION FACTOR FOR STANDARD DEVIATION WHEN LESS THAN 30 TESTS ARE AVAILABLE

No. of tests*	Modification factor for standard deviation†
Less than 15	Use table 5.3.2.2
15	1.16
20	1.08
25	1.03
30 or more	1.00

* Interpolate for intermediate numbers of tests.

† Modified standard deviation to be used to determine required average strength f_{cr}' from 5.3.2.1.

COMMENTARY

age strength. The third step is the selection of mixture proportions required to produce that average strength, either by conventional trial mixture procedures or by a suitable experience record. Fig. R5.3 is a flow chart outlining the mix selection and documentation procedure.

The mixture selected must yield an average strength appreciably higher than the specified strength f_c'. The degree of mixture overdesign depends on the variability of the test results.

R5.3.1 — Standard deviation

When a concrete production facility has a suitable record of 30 consecutive tests of similar materials and conditions expected, the standard deviation is calculated from those results in accordance with the following formula:

$$s = \left[\frac{\Sigma (X_i - \bar{X})^2}{(n-1)}\right]^{1/2}$$

where:

s = standard deviation, psi
X_i = individual strength tests as defined in 5.6.1.4
$\bar{X}$ = average of n strength test results
n = number of consecutive strength tests

The standard deviation is used to determine the average strength required in 5.3.2.1.

If two test records are used to obtain at least 30 tests, the standard deviation used shall be the statistical average of the values calculated from each test record in accordance with the following formula:

$$\bar{s} = \left[\frac{(n_1 - 1)(s_1)^2 + (n_2 - 1)(s_2)^2}{(n_1 + n_2 - 2)}\right]^{1/2}$$

where

$\bar{s}$ = statistical average standard deviation where two test records are used to estimate the standard deviation
s_1, s_2 = standard deviations calculated from two test records, 1 and 2, respectively
n_1, n_2 = number of tests in each test record, respectively

If less than 30, but at least 15 tests are available, the calculated standard deviation is increased by the factor given in Table 5.3.1.2. This procedure results in a more conservative (increased) required average strength. The factors in Table 5.3.1.2 are based on the sampling distribution of the standard deviation and provide protection (equivalent to that

CODE

COMMENTARY

from a record of 30 tests) against the possibility that the smaller sample underestimates the true or universe population standard deviation.

The standard deviation used in the calculation of required average strength must be developed under conditions "similar to those expected" [see 5.3.1.1(a)]. This requirement is important to ensure acceptable concrete.

Concrete for background tests to determine standard deviation is considered to be "similar" to that required if made with the same general types of ingredients under no more restrictive conditions of control over material quality and production methods than on the proposed work, and if its specified strength does not deviate more than 1000 psi from the f_c' required [see 5.3.1.1(b)]. A change in the type of concrete or a major increase in the strength level may increase the standard deviation. Such a situation might occur with a change in type of aggregate (i.e., from natural aggregate to lightweight aggregate or vice versa) or a change from non-air-entrained concrete to air-entrained concrete. Also, there may be an increase in standard deviation when the average strength level is raised by a significant amount, although the increment of increase in standard deviation should be somewhat less than directly proportional to the strength increase. When there is reasonable doubt, any estimated standard deviation used to calculate the required average strength should always be on the conservative (high) side.

Note that the code uses the standard deviation in pounds per square inch instead of the coefficient of variation in percent. The latter is equal to the former expressed as a percent of the average strength.

When a suitable record of test results is not available, the average strength must exceed the design strength by an amount that ranges from 1000 to 1400 psi, depending on the design strength. See Table 5.3.2.2.

Even when the average strength and standard deviation are of the levels assumed, there will be occasional tests that fail to meet the acceptance criteria prescribed in 5.6.2.3 (perhaps 1 test in 100).

5.3.2 — Required average strength

5.3.2.1 — Required average compressive strength f_{cr}' used as the basis for selection of concrete proportions shall be the larger of Eq. (5-1) or (5-2) using a standard deviation calculated in accordance with 5.3.1.1 or 5.3.1.2.

$$f_{cr}' = f_c' + 1.34s \quad (5\text{-}1)$$

or

R5.3.2 — Required average strength

R5.3.2.1 — Once the standard deviation has been determined, the required average strength is obtained from the larger of Eq. (5-1) or (5-2). Eq. (5-1) provides a probability of 1-in-100 that averages of three consecutive tests will be below the specified strength f_c'. Eq. (5-2) provides a similar probability of individual tests more than 500 psi below the specified strength f_c'. These equations assume that the standard deviation used is equal to the population value appropriate for an infinite or very large number of tests. For this

CODE

$$f'_{cr} = f'_c + 2.33s - 500 \quad (5\text{-}2)$$

5.3.2.2 — When a concrete production facility does not have field strength test records for calculation of standard deviation meeting requirements of 5.3.1.1 or 5.3.1.2, required average strength f'_{cr} shall be determined from Table 5.3.2.2 and documentation of average strength shall be in accordance with requirements of 5.3.3.

TABLE 5.3.2.2—REQUIRED AVERAGE COMPRESSIVE STRENGTH WHEN DATA ARE NOT AVAILABLE TO ESTABLISH A STANDARD DEVIATION

Specified compressive strength, f'_c, psi	Required average compressive strength, f'_{cr}, psi
Less than 3000 psi	f'_c + 1000
3000 to 5000	f'_c + 1200
Over 5000	f'_c + 1400

5.3.3 — Documentation of average strength

Documentation that proposed concrete proportions will produce an average compressive strength equal to or greater than required average compressive strength (see 5.3.2) shall consist of a field strength test record, several strength test records, or trial mixtures.

5.3.3.1 — When test records are used to demonstrate that proposed concrete proportions will produce the required average strength f'_{cr} (see 5.3.2), such records shall represent materials and conditions similar to those expected. Changes in materials, condi-

COMMENTARY

reason, use of standard deviations estimated from records of 100 or more tests is desirable. When 30 tests are available, the probability of failure will likely be somewhat greater than 1-in-100. The additional refinements required to achieve the 1-in-100 probability are not considered necessary, because of the uncertainty inherent in assuming that conditions operating when the test record was accumulated will be similar to conditions when the concrete will be produced.

Additionally, the change adopted in ACI 318-77 (requiring action to increase the average strength whenever either of the acceptance criteria of 5.6.2.3 is not met) is considered to provide significant additional protection against subsequent low tests.

R.5.3.3 — Documentation of average strength

Once the required average strength f'_{cr} is known, the next step is to select mixture proportions that will produce an average strength at least as great as the required average strength, and also meet special exposure requirements of Chapter 4. The documentation may consist of a strength test record, several strength test records, or suitable laboratory trial mixtures. Generally, if a test record is used, it will be the same one that was used for computation of the standard deviation. However, if this test record shows either lower or higher average strength than the required average strength, different proportions may be necessary or desirable. In such instances, the average from a record of as few as 10 tests may be used, or the proportions may be established by interpolation between the strengths and proportions of two such records of consecutive tests. All test records for establishing proportions necessary to produce the average strength must meet the requirements of 5.3.3.1 for "similar materials and conditions."

The 1971 code required trial mixtures to be mixed at the maximum permitted slump and air content. Since 1977, the code has provided tolerances at the maximum permissible slump and air content. The code text makes it clear that these tolerances on slump and air content apply only to the trial mixtures and not to records of field tests or to later production of the concrete in the field.

CODE

COMMENTARY

tions, and proportions within the test records shall not have been more restricted than those for proposed work. For the purpose of documenting average strength potential, test records consisting of less than 30 but not less than 10 consecutive tests are acceptable provided test records encompass a period of time not less than 45 days. Required concrete proportions shall be permitted to be established by interpolation between the strengths and proportions of two or more test records each of which meets other requirements of this section.

5.3.3.2 — When an acceptable record of field test results is not available, concrete proportions established from trial mixtures meeting the following restrictions shall be permitted:

(a) Combination of materials shall be those for proposed work.

(b) Trial mixtures having proportions and consistencies required for proposed work shall be made using at least three different water-cementitious materials ratios or cementitious materials contents that will produce a range of strengths encompassing the required average strength f'_{cr}.

(c) Trial mixtures shall be designed to produce a slump within ± 0.75 in. of maximum permitted, and for air-entrained concrete, within ± 0.5 percent of maximum allowable air content.

(d) For each water-cementitious materials ratio or cementitious materials content, at least three test cylinders for each test age shall be made and cured in accordance with "Method of Making and Curing Concrete Test Specimens in the Laboratory" (ASTM C 192). Cylinders shall be tested at 28 days or at test age designated for determination of f'_c.

(e) From results of cylinder tests a curve shall be plotted showing relationship between water-cementitious materials ratio or cementitious materials content and compressive strength at designated test age.

(f) Maximum water-cementitious materials ratio or minimum cementitious materials content for concrete to be used in proposed work shall be that shown by the curve to produce the average strength required by 5.3.2, unless a lower water-cementitious materials ratio or higher strength is required by Chapter 4.

CODE

5.4 — Proportioning without field experience or trial mixtures

5.4.1 — If data required by 5.3 are not available, concrete proportions shall be based upon other experience or information, if approved by the engineer/architect. The required average compressive strength f'_{cr} of concrete produced with materials similar to those proposed for use shall be at least 1200 psi greater than the specified compressive strength f'_c. This alternative shall not be used for specified compressive strength greater than 4000 psi.

5.4.2 — Concrete proportioned by this section shall conform to the durability requirements of Chapter 4 and to compressive strength test criteria of 5.6.

5.5 — Average strength reduction

As data become available during construction, it shall be permitted to reduce the amount by which f'_{cr} must exceed the specified value of f'_c, provided:

(a) 30 or more test results are available and average of test results exceeds that required by 5.3.2.1, using a standard deviation calculated in accordance with 5.3.1.1, or

(b) 15 to 29 test results are available and average of test results exceeds that required by 5.3.2.1 using a standard deviation calculated in accordance with 5.3.1.2, and

(c) special exposure requirements of Chapter 4 are met.

5.6 — Evaluation and acceptance of concrete

5.6.1 — Frequency of testing

5.6.1.1 — Samples for strength tests of each class of concrete placed each day shall be taken not less than once a day, nor less than once for each 150 yd^3 of concrete, nor less than once for each 5000 ft^2 of surface area for slabs or walls.

COMMENTARY

R5.4 — Proportioning without field experience or trial mixtures

R5.4.1 — When no prior experience (5.3.3.1) or trial mixture data (5.3.3.2) meeting the requirements of these sections is available, other experience may be used only when special permission is given. Because combinations of different ingredients may vary considerably in strength level, this procedure is not permitted for f'_c greater than 4000 psi and the required average strength should exceed f'_c by 1200 psi. The purpose of this provision is to allow work to continue when there is an unexpected interruption in concrete supply and there is not sufficient time for tests and evaluation or in small structures where the cost of trial mixture data is not justified.

R5.6 — Evaluation and acceptance of concrete

Once the mixture proportions have been selected and the job started, the criteria for evaluation and acceptance of the concrete can be obtained from 5.6.

An effort has been made in the code to provide a clear-cut basis for judging the acceptability of the concrete, as well as to indicate a course of action to be followed when the results of strength tests are not satisfactory.

R5.6.1 — Frequency of testing

R5.6.1.1 — The following three criteria establish the required minimum sampling frequency for each class of concrete:

(a) Once each day a given class is placed, nor less than

CODE

COMMENTARY

(b) Once for each 150 yd^3 of each class placed each day, nor less than

(c) Once for each 5000 ft^2 of slab or wall surface area placed each day.

In calculating surface area, only one side of the slab or wall should be considered. If the average wall or slab thickness is less than $9^3/_4$ in. Criteria (c) will require more frequent sampling than once for each 150 yd^3 placed.

5.6.1.2 — On a given project, if total volume of concrete is such that frequency of testing required by 5.6.1.1 would provide less than five strength tests for a given class of concrete, tests shall be made from at least five randomly selected batches or from each batch if fewer than five batches are used.

R5.6.1.2 — Samples for strength tests must be taken on a strictly random basis if they are to measure properly the acceptability of the concrete. To be representative, the choice of times of sampling, or the batches of concrete to be sampled, must be made on the basis of chance alone, within the period of placement. If batches to be sampled are selected on the basis of appearance, convenience, or other possibly biased criteria, the statistical concepts lose their validity. Obviously, not more than one test (average of two cylinders made from a sample, 5.6.1.4) should be taken from a single batch, and water may not be added to the concrete after the sample is taken.

ASTM D 3665 describes procedures for random selection of the batches to be tested.

5.6.1.3 — When total quantity of a given class of concrete is less than 50 yd^3, strength tests are not required when evidence of satisfactory strength is submitted to and approved by the building official.

5.6.1.4 — A strength test shall be the average of the strengths of two cylinders made from the same sample of concrete and tested at 28 days or at test age designated for determination of f_c'.

5.6.2 — Laboratory-cured specimens

R5.6.2 — Laboratory-cured specimens

5.6.2.1 — Samples for strength tests shall be taken in accordance with "Method of Sampling Freshly Mixed Concrete" (ASTM C 172).

5.6.2.2 — Cylinders for strength tests shall be molded and laboratory-cured in accordance with "Practice for Making and Curing Concrete Test Specimens in the Field" (ASTM C 31) and tested in accordance with "Test Method for Compressive Strength of Cylindrical Concrete Specimens" (ASTM C 39).

5.6.2.3 — Strength level of an individual class of concrete shall be considered satisfactory if both of the following requirements are met:

(a) Every arithmetic average of any three consecutive strength tests equals or exceeds f_c'.

R5.6.2.3 — A single set of criteria is given for acceptability of strength and is applicable to all concrete used in structures designed in accordance with the code, regardless of design method used. The concrete strength is considered to be satisfactory as long as averages of any three consecutive strength tests remain above the specified f_c' and no individ-

CODE

(b) No individual strength test (average of two cylinders) falls below f_c' by more than 500 psi.

5.6.2.4 — If either of the requirements of 5.6.2.3 are not met, steps shall be taken to increase the average of subsequent strength test results. Requirements of 5.6.4 shall be observed if requirement of 5.6.2.3(b) is not met.

COMMENTARY

ual strength test falls below the specified f_c' by more than 500 psi. Evaluation and acceptance of the concrete can be judged immediately as test results are received during the course of the work. Strength tests failing to meet these criteria will occur occasionally (probably about once in 100 tests) even though concrete strength and uniformity are satisfactory. Allowance should be made for such statistically expected variations in deciding whether the strength level being produced is adequate. In terms of the probability of failure, the criterion of minimum individual strength test result of 500 psi less than f_c' adapts itself readily to small numbers of tests. For example, if only five strength tests are made on a small job, it is apparent that, if any of the strength test results (average of two cylinders) is more than 500 psi below f_c', the criterion is not met.

R5.6.2.4 — When concrete fails to meet either of the strength requirements of 5.6.2.3, steps must be taken to increase the average of the concrete test results. If sufficient concrete has been produced to accumulate at least 15 tests, these should be used to establish a new target average strength as described in 5.3.

If fewer than 15 tests have been made on the class of concrete in question, the new target level should be at least as great as the average level used in the initial selection of proportions. If the average of the available tests made on the project equals or exceeds the level used in the initial selection of proportions, a further increase in average level is required.

The steps taken to increase the average level of test results will depend on the particular circumstances, but could include one or more of the following:

(a) an increase in cementitious materials content,

(b) changes in mixture proportions,

(c) reductions in or better control of levels of slump supplied,

(d) a reduction in delivery time,

(e) closer control of air content, or

(f) an improvement in the quality of the testing, including strict compliance with standard test procedures.

Such changes in operating and testing procedures, or changes in cementitious materials content, or slump should not require a formal resubmission under the procedures of 5.3; however, important changes in sources of cement, aggregates, or admixtures, should be accompanied by evidence that the average strength level will be improved.

CODE

COMMENTARY

Laboratories testing cylinders or cores to determine compliance with these requirements should be accredited or inspected for conformance to the requirement of ASTM C 1077[5.3] by a recognized agency such as the American Association for Laboratory Accreditation (A2LA), AASHTO Materials Reference Laboratory (AMRL), National Voluntary Laboratory Accreditation Program (NVLAP), Cement and Concrete Reference Laboratory (CCRL), or their equivalent.

5.6.3 — Field-cured specimens

5.6.3.1 — If required by the building official, results of strength tests of cylinders cured under field conditions shall be provided.

5.6.3.2 — Field-cured cylinders shall be cured under field conditions in accordance with "Practice for Making and Curing Concrete Test Specimens in the Field" (ASTM C 31).

5.6.3.3 — Field-cured test cylinders shall be molded at the same time and from the same samples as laboratory-cured test cylinders.

5.6.3.4 — Procedures for protecting and curing concrete shall be improved when strength of field-cured cylinders at test age designated for determination of f_c' is less than 85 percent of that of companion laboratory-cured cylinders. The 85 percent limitation shall not apply if field-cured strength exceeds f_c' by more than 500 psi.

R5.6.3 — Field-cured specimens

R5.6.3.1 — Strength tests of cylinders cured under field conditions may be required to check the adequacy of curing and protection of concrete in the structure.

R5.6.3.4 — Positive guidance is provided in the code concerning the interpretation of tests of field-cured cylinders. Research has shown that cylinders protected and cured to simulate good field practice should test not less than about 85 percent of standard laboratory moist-cured cylinders. This percentage has been set merely as a rational basis for judging the adequacy of field curing. The comparison is made between the actual measured strengths of companion job-cured and laboratory-cured cylinders, not between job-cured cylinders and the specified value of f_c'. However, results for the job-cured cylinders are considered satisfactory if the job-cured cylinders exceed the specified f_c' by more than 500 psi, even though they fail to reach 85 percent of the strength of companion laboratory-cured cylinders.

5.6.4 — Investigation of low-strength test results

5.6.4.1 — If any strength test (see 5.6.1.4) of laboratory-cured cylinders falls below specified value of f_c' by more than 500 psi [see 5.6.2.3(b)] or if tests of field-cured cylinders indicate deficiencies in protection and curing (see 5.6.3.4), steps shall be taken to assure that load-carrying capacity of the structure is not jeopardized.

5.6.4.2 — If the likelihood of low-strength concrete is confirmed and calculations indicate that load-carrying capacity is significantly reduced, tests of cores drilled from the area in question in accordance with "Method of Obtaining and Testing Drilled Cores and Sawed

R5.6.4 — Investigation of low-strength test results

Instructions are provided concerning the procedure to be followed when strength tests have failed to meet the specified acceptance criteria. For obvious reasons, these instructions cannot be dogmatic. The building official must apply judgment as to the true significance of low test results and whether they indicate need for concern. If further investigation is deemed necessary, such investigation may include nondestructive tests, or in extreme cases, strength tests of cores taken from the structure.

Nondestructive tests of the concrete in place, such as by probe penetration, impact hammer, ultrasonic pulse velocity or pull out may be useful in determining whether or not a

CODE

Beams of Concrete" (ASTM C 42) shall be permitted. In such cases, three cores shall be taken for each strength test more than 500 psi below the specified value of f_c'.

5.6.4.3 — If concrete in the structure will be dry under service conditions, cores shall be air dried (temperature 60 to 80 F, relative humidity less than 60 percent) for 7 days before test and shall be tested dry. If concrete in the structure will be more than superficially wet under service conditions, cores shall be immersed in water for at least 40 hr and be tested wet.

5.6.4.4 — Concrete in an area represented by core tests shall be considered structurally adequate if the average of three cores is equal to at least 85 percent of f_c' and if no single core is less than 75 percent of f_c'. Additional testing of cores extracted from locations represented by erratic core strength results shall be permitted.

5.6.4.5 — If criteria of 5.6.4.4 are not met and if the structural adequacy remains in doubt, the responsible authority shall be permitted to order a strength evaluation in accordance with Chapter 20 for the questionable portion of the structure, or take other appropriate action.

COMMENTARY

portion of the structure actually contains low-strength concrete. Such tests are of value primarily for comparisons within the same job rather than as quantitative measures of strength. For cores, if required, conservatively safe acceptance criteria are provided which should assure structural adequacy for virtually any type of construction.[5.4-5.7] Lower strength may, of course, be tolerated under many circumstances, but this again becomes a matter of judgment on the part of the building official and design engineer. When the core tests fail to provide assurance of structural adequacy, it may be practical, particularly in the case of floor or roof systems, for the building official to require a load test (Chapter 20). Short of load tests, if time and conditions permit, an effort may be made to improve the strength of the concrete in place by supplemental wet curing. Effectiveness of such a treatment must be verified by further strength evaluation using procedures previously discussed.

It should be noted that core tests having an average of 85 percent of the specified strength are entirely realistic. To expect core tests to be equal to f_c' is not realistic, since differences in the size of specimens, conditions of obtaining samples, and procedures for curing, do not permit equal values to be obtained.

The code, as stated, concerns itself with assuring structural safety, and the instructions in 5.6 are aimed at that objective. It is not the function of the code to assign responsibility for strength deficiencies, whether or not they are such as to require corrective measures.

Under the requirements of this section, cores taken to confirm structural adequacy will usually be taken at ages later than those specified for determination of f_c'.

5.7 — Preparation of equipment and place of deposit

5.7.1 — Preparation before concrete placement shall include the following:

(a) All equipment for mixing and transporting concrete shall be clean.

(b) All debris and ice shall be removed from spaces to be occupied by concrete.

(c) Forms shall be properly coated.

(d) Masonry filler units that will be in contact with concrete shall be well drenched.

(e) Reinforcement shall be thoroughly clean of ice or other deleterious coatings.

(f) Water shall be removed from place of deposit

R5.7 — Preparation of equipment and place of deposit

Recommendations for mixing, handling and transporting, and placing concrete are given in detail in **"Guide for Measuring, Mixing, Transporting, and Placing Concrete"** reported by ACI Committee 304.[5.8] (Presents methods and procedures for control, handling and storage of materials, measurement, batching tolerances, mixing, methods of placing, transporting, and forms.)

Attention is directed to the need for using clean equipment and for cleaning forms and reinforcement thoroughly before beginning to deposit concrete. In particular, sawdust, nails, wood pieces, and other debris that may collect inside the forms must be removed. Reinforcement must be thoroughly cleaned of ice, dirt, loose rust, mill scale, or other coatings. Water should be removed from the forms.

CODE

COMMENTARY

before concrete is placed unless a tremie is to be used or unless otherwise permitted by the building official.

(g) All laitance and other unsound material shall be removed before additional concrete is placed against hardened concrete.

5.8 — Mixing

5.8.1 — All concrete shall be mixed until there is a uniform distribution of materials and shall be discharged completely before mixer is recharged.

5.8.2 — Ready-mixed concrete shall be mixed and delivered in accordance with requirements of "Specification for Ready-Mixed Concrete" (ASTM C 94) or "Specification for Concrete Made by Volumetric Batching and Continuous Mixing" (ASTM C 685).

5.8.3 — Job-mixed concrete shall be mixed in accordance with the following:

(a) Mixing shall be done in a batch mixer of approved type.

(b) Mixer shall be rotated at a speed recommended by the manufacturer.

(c) Mixing shall be continued for at least 1½ minutes after all materials are in the drum, unless a shorter time is shown to be satisfactory by the mixing uniformity tests of "Specification for Ready-Mixed Concrete" (ASTM C 94).

(d) Materials handling, batching, and mixing shall conform to applicable provisions of "Specification for Ready-Mixed Concrete" (ASTM C 94).

(e) A detailed record shall be kept to identify:

(1) number of batches produced;

(2) proportions of materials used;

(3) approximate location of final deposit in structure;

(4) time and date of mixing and placing.

R5.8 — Mixing

Concrete of uniform and satisfactory quality requires the materials to be thoroughly mixed until uniform in appearance and all ingredients are distributed. Samples taken from different portions of a batch should have essentially the same unit weight, air content, slump, and coarse aggregate content. Test methods for uniformity of mixing are given in ASTM C 94. The necessary time of mixing will depend on many factors including batch size, stiffness of the batch, size and grading of the aggregate, and the efficiency of the mixer. Excessively long mixing times should be avoided to guard against grinding of the aggregates.

5.9 — Conveying

5.9.1 — Concrete shall be conveyed from mixer to place of final deposit by methods that will prevent separation or loss of materials.

R5.9 — Conveying

Each step in the handling and transporting of concrete needs to be carefully controlled to maintain uniformity within a batch and from batch to batch. It is essential to avoid segre-

CODE

5.9.2 — Conveying equipment shall be capable of providing a supply of concrete at site of placement without separation of ingredients and without interruptions sufficient to permit loss of plasticity between successive increments.

COMMENTARY

gation of the coarse aggregate from the mortar or of water from the other ingredients.

The code requires the equipment for handling and transporting concrete to be capable of supplying concrete to the place of deposit continuously and reliably under all conditions and for all methods of placement. The provisions of 5.9 apply to all placement methods, including pumps, belt conveyors, pneumatic systems, wheelbarrows, buggies, crane buckets, and tremies.

Serious loss in strength can result when concrete is pumped through pipe made of aluminum or aluminum alloy.[5.9] Hydrogen gas generated by the reaction between the cement alkalies and the aluminum eroded from the interior of the pipe surface has been shown to cause strength reduction as much as 50 percent. Hence, equipment made of aluminum or aluminum alloys should not be used for pump lines, tremies, or chutes other than short chutes such as those used to convey concrete from a truck mixer.

5.10 — Depositing

5.10.1 — Concrete shall be deposited as nearly as practical in its final position to avoid segregation due to rehandling or flowing.

5.10.2 — Concreting shall be carried on at such a rate that concrete is at all times plastic and flows readily into spaces between reinforcement.

5.10.3 — Concrete that has partially hardened or been contaminated by foreign materials shall not be deposited in the structure.

5.10.4 — Retempered concrete or concrete that has been remixed after initial set shall not be used unless approved by the engineer.

5.10.5 — After concreting is started, it shall be carried on as a continuous operation until placing of a panel or section, as defined by its boundaries or predetermined joints, is completed except as permitted or prohibited by 6.4.

5.10.6 — Top surfaces of vertically formed lifts shall be generally level.

5.10.7 — When construction joints are required, joints shall be made in accordance with 6.4.

5.10.8 — All concrete shall be thoroughly consolidated by suitable means during placement and shall be thoroughly worked around reinforcement and embedded fixtures and into corners of forms.

R5.10 — Depositing

Rehandling concrete can cause segregation of the materials. Hence the code cautions against this practice. Retempering of partially set concrete with the addition of water should not be permitted, unless authorized. This does not preclude the practice (recognized in ASTM C 94) of adding water to mixed concrete to bring it up to the specified slump range so long as prescribed limits on the maximum mixing time and water-cementitious materials ratio are not violated.

Section 5.10.4 of the 1971 ACI Building Code contained a requirement that "where conditions make consolidation difficult or where reinforcement is congested, batches of mortar containing the same proportions of cement, sand, and water as used in the concrete, shall first be deposited in the forms to a depth of at least 1 in." That requirement was deleted from the 1977 code since the conditions for which it was applicable could not be defined precisely enough to justify its inclusion as a code requirement. The practice, however, has merit and should be incorporated in job specifications where appropriate, with the specific enforcement the responsibility of the job inspector rather than the building official. The use of mortar batches aids in preventing honeycomb and poor bonding of the concrete with the reinforcement. The mortar should be placed immediately before depositing the concrete and must be plastic (neither stiff nor fluid) when the concrete is placed.

Recommendations for consolidation of concrete are given in detail in **"Guide for Consolidation of Concrete"** reported by ACI Committee 309.[5.10] (Presents current information on the mechanism of consolidation and gives recommendations on equipment characteristics and procedures for various classes of concrete.)

CODE

5.11 — Curing

5.11.1 — Concrete (other than high-early-strength) shall be maintained above 50 F and in a moist condition for at least the first 7 days after placement, except when cured in accordance with 5.11.3.

5.11.2 — High-early-strength concrete shall be maintained above 50 F and in a moist condition for at least the first 3 days, except when cured in accordance with 5.11.3.

5.11.3 — Accelerated curing

5.11.3.1 — Curing by high pressure steam, steam at atmospheric pressure, heat and moisture, or other accepted processes, shall be permitted to accelerate strength gain and reduce time of curing.

5.11.3.2 — Accelerated curing shall provide a compressive strength of the concrete at the load stage considered at least equal to required design strength at that load stage.

5.11.3.3 — Curing process shall be such as to produce concrete with a durability at least equivalent to the curing method of 5.11.1 or 5.11.2.

5.11.4 — When required by the engineer or architect, supplementary strength tests in accordance with 5.6.3 shall be performed to assure that curing is satisfactory.

COMMENTARY

R5.11 — Curing

Recommendations for curing concrete are given in detail in **"Standard Practice for Curing Concrete"** reported by ACI Committee 308.[5.11] (Presents basic principles of proper curing and describes the various methods, procedures, and materials for curing of concrete.)

R5.11.3 — Accelerated curing

The provisions of this section apply whenever an accelerated curing method is used, whether for precast or cast-in-place elements. The compressive strength of steam-cured concrete is not as high as that of similar concrete continuously cured under moist conditions at moderate temperatures. Also the elastic modulus E_c of steam-cured specimens may vary from that of specimens moist-cured at normal temperatures. When steam curing is to be used, it is advisable to base the concrete mix proportions on steam-cured test cylinders.

Accelerated curing procedures require careful attention to obtain uniform and satisfactory results. It is essential that moisture loss during the curing process be prevented.

R5.11.4 — In addition to requiring a minimum curing temperature and time for normal- and high-early-strength concrete, the code provides a specific criterion in 5.6.3 for judging the adequacy of field curing. At the test age for which the strength is specified (usually 28 days), field-cured cylinders should produce strength not less than 85 percent of that of the standard, laboratory-cured cylinders. For a reasonably valid comparison to be made, field-cured cylinders and companion laboratory-cured cylinders must come from the same sample. Field-cured cylinders must be cured under conditions identical to those of the structure. If the structure is protected from the elements, the cylinder should be protected similarly.

That is, cylinders related to members not directly exposed to weather should be cured adjacent to those members and provided with the same degree of protection and method of curing.

Obviously, the field cylinders should not be treated more favorably than the elements they represent. (See code and commentary, 5.6.3 for additional information.)

If the field-cured cylinders do not provide satisfactory strength by this comparison, measures should be taken to improve the curing of the structure. If the tests indicate a possible serious deficiency in strength of concrete in the

CODE

5.12 — Cold weather requirements

5.12.1 — Adequate equipment shall be provided for heating concrete materials and protecting concrete during freezing or near-freezing weather.

5.12.2 — All concrete materials and all reinforcement, forms, fillers, and ground with which concrete is to come in contact shall be free from frost.

5.12.3 — Frozen materials or materials containing ice shall not be used.

5.13 — Hot weather requirements

During hot weather, proper attention shall be given to ingredients, production methods, handling, placing, protection, and curing to prevent excessive concrete temperatures or water evaporation that could impair required strength or serviceability of the member or structure.

COMMENTARY

structure, core tests may be required, with or without supplemental wet curing, to check the structural adequacy, as provided in 5.6.4.

R5.12 — Cold weather requirements

Recommendations for cold weather concreting are given in detail in **"Cold Weather Concreting"** reported by ACI Committee 306.[5.12] (Presents requirements and methods for producing satisfactory concrete during cold weather.)

R5.13 — Hot weather requirements

Recommendations for hot weather concreting are given in detail in **"Hot Weather Concreting"** reported by ACI Committee 305.[5.13] (Defines the hot weather factors that affect concrete properties and construction practices and recommends measures to eliminate or minimize the undesirable effects.)

CHAPTER 6 — FORMWORK, EMBEDDED PIPES, AND CONSTRUCTION JOINTS

CODE

6.1 — Design of formwork

6.1.1 — Forms shall result in a final structure that conforms to shapes, lines, and dimensions of the members as required by the design drawings and specifications.

6.1.2 — Forms shall be substantial and sufficiently tight to prevent leakage of mortar.

6.1.3 — Forms shall be properly braced or tied together to maintain position and shape.

6.1.4 — Forms and their supports shall be designed so as not to damage previously placed structure.

6.1.5 — Design of formwork shall include consideration of the following factors:

(a) Rate and method of placing concrete

(b) Construction loads, including vertical, horizontal, and impact loads

(c) Special form requirements for construction of shells, folded plates, domes, architectural concrete, or similar types of elements.

6.1.6 — Forms for prestressed concrete members shall be designed and constructed to permit movement of the member without damage during application of prestressing force.

6.2 — Removal of forms, shores, and reshoring

6.2.1 — Removal of forms

Forms shall be removed in such a manner as not to impair safety and serviceability of the structure. Concrete to be exposed by form removal shall have sufficient strength not to be damaged by removal operation.

6.2.2 — Removal of shores and reshoring

The provisions of 6.2.2.1 through 6.2.2.3 shall apply to slabs and beams except where cast on the ground.

6.2.2.1 — Before starting construction, the contractor shall develop a procedure and schedule for

COMMENTARY

R6.1 — Design of formwork

Only minimum performance requirements for formwork, necessary to provide for public health and safety, are prescribed in Chapter 6. Formwork for concrete, including proper design, construction, and removal, demands sound judgment and planning to achieve adequate forms that are both economical and safe. Detailed information on formwork for concrete is given in: **"Guide to Formwork for Concrete."**[6.1] (Provides recommendations for design, construction, and materials for formwork, forms for special structures, and formwork for special methods of construction. Directed primarily to contractors, the suggested criteria will aid engineers and architects in preparing job specifications for the contractors.)

Formwork for Concrete[6.2] reported by ACI Committee 347. (A how-to-do-it handbook for contractors, engineers, and architects following the guidelines established in ACI 347R-88. Planning, building, and using formwork are discussed, including tables, diagrams, and formulas for form design loads.)

R6.2 — Removal of forms, shores, and reshoring

In determining the time for removal of forms, consideration should be given to the construction loads and to the possibilities of deflections.[6.3] The construction loads are frequently at least as great as the specified live loads. At early ages, a structure may be adequate to support the applied loads but may deflect sufficiently to cause permanent damage.

Evaluation of concrete strength during construction may be demonstrated by field-cured test cylinders or other procedures approved by the building official such as:

(a) Tests of cast-in-place cylinders in accordance with "Standard Test Method for Compressive Strength of Con-

CODE

removal of shores and installation of reshores and for calculating the loads transferred to the structure during the process.

(a) The structural analysis and concrete strength data used in planning and implementing form removal and shoring shall be furnished by the contractor to the building official when so requested.

(b) No construction loads shall be supported on, nor any shoring removed from, any part of the structure under construction except when that portion of the structure in combination with remaining forming and shoring system has sufficient strength to support safely its weight and loads placed thereon.

(c) Sufficient strength shall be demonstrated by structural analysis considering proposed loads, strength of forming and shoring system, and concrete strength data. Concrete strength data shall be based on tests of field-cured cylinders or, when approved by the building official, on other procedures to evaluate concrete strength.

6.2.2.2 — No construction loads exceeding the combination of superimposed dead load plus specified live load shall be supported on any unshored portion of the structure under construction, unless analysis indicates adequate strength to support such additional loads.

6.2.2.3 — Form supports for prestressed concrete members shall not be removed until sufficient prestressing has been applied to enable prestressed members to carry their dead load and anticipated construction loads.

COMMENTARY

crete Cylinders Cast-in-Place in Cylindrical Molds" (ASTM C 873). (This method is limited to use in slabs where the depth of concrete is from 5 to 12 in.)

(b) Penetration resistance in accordance with "Standard Test Method for Penetration Resistance of Hardened Concrete" (ASTM C 803).

(c) Pullout strength in accordance with "Standard Test Method for Pullout Strength of Hardened Concrete" (ASTM C 900).

(d) Maturity factor measurements and correlation in accordance with ASTM C 1074.[6.4]

Procedures (b), (c), and (d) require sufficient data, using job materials, to demonstrate correlation of measurements on the structure with compressive strength of molded cylinders or drilled cores.

Where the structure is adequately supported on shores, the side forms of beams, girders, columns, walls, and similar vertical forms, may generally be removed after 12 hr of cumulative curing time, provided the side forms support no loads other than the lateral pressure of the plastic concrete. "Cumulative curing time" represents the sum of time intervals, not necessarily consecutive, during which the temperature of the air surrounding the concrete is above 50 F. The 12-hr cumulative curing time is based on regular cements and ordinary conditions; the use of special cements or unusual conditions may require adjustment of the given limits. For example, concrete made with Type II or V (ASTM C 150) or ASTM C 595 cements, concrete containing retarding admixtures, and concrete to which ice was added during mixing (to lower the temperature of fresh concrete) may not have sufficient strength in 12 hr and should be investigated before removal of formwork.

The removal of formwork for multistory construction should be a part of a planned procedure considering the temporary support of the whole structure as well as that of each individual member. Such a procedure should be worked out prior to construction and should be based on a structural analysis taking into account the following items, as a minimum:

(a) The structural system that exists at the various stages of construction and the construction loads corresponding to those stages;

(b) The strength of the concrete at the various ages during construction;

(c) The influence of deformations of the structure and shoring system on the distribution of dead loads and construction loads during the various stages of construction;

CODE

COMMENTARY

(d) The strength and spacing of shores or shoring systems used, as well as the method of shoring, bracing, shore removal, and reshoring including the minimum time intervals between the various operations;

(e) Any other loading or condition that affects the safety or serviceability of the structure during construction.

For multistory construction, the strength of the concrete during the various stages of construction should be substantiated by field-cured test specimens or other approved methods.

6.3 — Conduits and pipes embedded in concrete

6.3.1 — Conduits, pipes, and sleeves of any material not harmful to concrete and within limitations of 6.3 shall be permitted to be embedded in concrete with approval of the engineer, provided they are not considered to replace structurally the displaced concrete.

R6.3 — Conduits and pipes embedded in concrete

R6.3.1 — Conduits, pipes, and sleeves not harmful to concrete can be embedded within the concrete, but the work must be done in such a manner that the structure will not be endangered. Empirical rules are given in 6.3 for safe installations under common conditions; for other than common conditions, special designs must be made. Many general building codes have adopted ANSI/ASME piping codes B 31.1 for power piping[6.5] and B 31.3 for chemical and petroleum piping.[6.6] The specifier should be sure that the appropriate piping codes are used in the design and testing of the system. The contractor should not be permitted to install conduits, pipes, ducts, or sleeves that are not shown on the plans or not approved by the engineer or architect.

For the integrity of the structure, it is important that all conduit and pipe fittings within the concrete be carefully assembled as shown on the plans or called for in the job specifications.

6.3.2 — Conduits and pipes of aluminum shall not be embedded in structural concrete unless effectively coated or covered to prevent aluminum-concrete reaction or electrolytic action between aluminum and steel.

R6.3.2 — The code prohibits the use of aluminum in structural concrete unless it is effectively coated or covered. Aluminum reacts with concrete and, in the presence of chloride ions, may also react electrolytically with steel, causing cracking and/or spalling of the concrete. Aluminum electrical conduits present a special problem since stray electric current accelerates the adverse reaction.

6.3.3 — Conduits, pipes, and sleeves passing through a slab, wall, or beam shall not impair significantly the strength of the construction.

6.3.4 — Conduits and pipes, with their fittings, embedded within a column shall not displace more than 4 percent of the area of cross section on which strength is calculated or which is required for fire protection.

6.3.5 — Except when drawings for conduits and pipes are approved by the structural engineer, conduits and pipes embedded within a slab, wall, or beam (other than those merely passing through) shall satisfy the following:

6.3.5.1 — They shall not be larger in outside dimension than $1/3$ the overall thickness of slab, wall, or beam in which they are embedded.

CODE

6.3.5.2 — They shall not be spaced closer than 3 diameters or widths on center.

6.3.5.3 — They shall not impair significantly the strength of the construction.

6.3.6 — Conduits, pipes, and sleeves shall be permitted to be considered as replacing structurally in compression the displaced concrete provided:

6.3.6.1 — They are not exposed to rusting or other deterioration.

6.3.6.2 — They are of uncoated or galvanized iron or steel not thinner than standard Schedule 40 steel pipe.

6.3.6.3 — They have a nominal inside diameter not over 2 in. and are spaced not less than 3 diameters on centers.

6.3.7 — Pipes and fittings shall be designed to resist effects of the material, pressure, and temperature to which they will be subjected.

6.3.8 — No liquid, gas, or vapor, except water not exceeding 90 F nor 50 psi pressure, shall be placed in the pipes until the concrete has attained its design strength.

6.3.9 — In solid slabs, piping, unless it is for radiant heating or snow melting, shall be placed between top and bottom reinforcement.

6.3.10 — Concrete cover for pipes, conduits, and fittings shall not be less than $1\frac{1}{2}$ in. for concrete exposed to earth or weather, nor $\frac{3}{4}$ in. for concrete not exposed to weather or in contact with ground.

6.3.11 — Reinforcement with an area not less than 0.002 times area of concrete section shall be provided normal to piping.

6.3.12 — Piping and conduit shall be so fabricated and installed that cutting, bending, or displacement of reinforcement from its proper location will not be required.

6.4 — Construction joints

6.4.1 — Surface of concrete construction joints shall be cleaned and laitance removed.

COMMENTARY

R6.3.7 — The 1983 code limited the maximum pressure in embedded pipe to 200 psi, which was considered too restrictive. Nevertheless, the effects of such pressures and the expansion of embedded pipe should be considered in the design of the concrete member.

R6.4 — Construction joints

For the integrity of the structure, it is important that all construction joints be carefully defined in construction documents and constructed as required. Any deviations therefrom should be approved by the engineer or architect.

CODE

6.4.2 — Immediately before new concrete is placed, all construction joints shall be wetted and standing water removed.

6.4.3 — Construction joints shall be so made and located as not to impair the strength of the structure. Provision shall be made for transfer of shear and other forces through construction joints. See 11.7.9.

6.4.4 — Construction joints in floors shall be located within the middle third of spans of slabs, beams, and girders. Joints in girders shall be offset a minimum distance of two times the width of intersecting beams.

6.4.5 — Beams, girders, or slabs supported by columns or walls shall not be cast or erected until concrete in the vertical support members is no longer plastic.

6.4.6 — Beams, girders, haunches, drop panels, and capitals shall be placed monolithically as part of a slab system, unless otherwise shown in design drawings or specifications.

COMMENTARY

R6.4.2 — The requirements of the 1977 code for the use of neat cement on vertical joints have been removed, since it is rarely practical and can be detrimental where deep forms and steel congestion prevent proper access. Often wet blasting and other procedures are more appropriate. Since the code sets only minimum standards the engineer may have to specify special procedures if conditions warrant. The degree to which mortar batches are needed at the start of concrete placement depend on concrete proportions, congestion of steel, vibrator access, and other factors.

R6.4.3 — Construction joints should be located where they will cause the least weakness in the structure. When shear due to gravity load is not significant, as is usually the case in the middle of the span of flexural members, a simple vertical joint may be adequate. Lateral force design may require special design treatment of construction joints. Shear keys, intermittent shear keys, diagonal dowels, or the shear transfer method of 11.7 may be used whenever a force transfer is required.

R6.4.5 — Delay in placing concrete in members supported by columns and walls is necessary to prevent cracking at the interface of the slab and supporting member, caused by bleeding and settlement of plastic concrete in the supporting member.

R6.4.6 — Separate placement of slabs and beams, haunches, and similar elements is permitted when shown on the drawings and where provision has been made to transfer forces as required in 6.4.3.

CODE COMMENTARY

Notes

CHAPTER 7 — DETAILS OF REINFORCEMENT

CODE

7.0 — Notation

d = distance from extreme compression fiber to centroid of tension reinforcement, in.
d_b = nominal diameter of bar, wire, or prestressing strand, in.
f_y = specified yield strength of nonprestressed reinforcement, psi
ℓ_d = development length, in. See Chapter 12

7.1 — Standard hooks

The term "standard hook" as used in this code shall mean one of the following:

7.1.1 — 180-deg bend plus $4d_b$ extension, but not less than $2^1/_2$ in. at free end of bar.

7.1.2 — 90-deg bend plus $12d_b$ extension at free end of bar.

7.1.3 — For stirrup and tie hooks*

(a) No. 5 bar and smaller, 90-deg bend plus $6d_b$ extension at free end of bar, or

(b) No. 6, No. 7, and No. 8 bar, 90-deg bend plus $12d_b$ extension at free end of bar, or

(c) No. 8 bar and smaller, 135-deg bend plus $6d_b$ extension at free end of bar.

7.2 — Minimum bend diameters

7.2.1 — Diameter of bend measured on the inside of the bar, other than for stirrups and ties in sizes No. 3 through No. 5, shall not be less than the values in Table 7.2.

7.2.2 — Inside diameter of bend for stirrups and ties

*For closed ties and continuously wound ties defined as hoops in Chapter 21, a 135-deg bend plus an extension of at least $6d_b$, but not less than 3 in. (See definition of "hoop" in 21.1.)

COMMENTARY

Recommended methods and standards for preparing design drawings, typical details, and drawings for the fabrication and placing of reinforcing steel in reinforced concrete structures are given in ***ACI Detailing Manual — 1994***, reported by ACI Committee 315.[7.1]

All provisions in this code relating to bar, wire, or strand diameter (and area) are based on the nominal dimensions of the reinforcement as given in the appropriate ASTM specification. Nominal dimensions are equivalent to those of a circular area having the same weight per foot as the ASTM designated bar, wire, or strand sizes. Cross-sectional area of reinforcement is based on nominal dimensions.

R7.1 — Standard hooks

R7.1.3 — Standard stirrup and tie hooks are limited to No. 8 bars and smaller, and the 90-deg hook with $6d_b$ extension is further limited to No. 5 bars and smaller, in both cases as the result of research showing that larger bar sizes with 90-deg hooks and $6d_b$ extensions tend to "pop out" under high load.

R7.2 — Minimum bend diameters

Standard bends in reinforcing bars are described in terms of the inside diameter of bend since this is easier to measure than the radius of bend. The primary factors affecting the minimum bend diameter are feasibility of bending without breakage and avoidance of crushing the concrete inside the bend.

R7.2.2 — The minimum $4d_b$ bend for the bar sizes commonly used for stirrups and ties is based on accepted industry practice in the United States. Use of a stirrup bar size not greater than No. 5 for either the 90-deg or 135-deg standard

CODE

shall not be less than $4d_b$ for No. 5 bar and smaller. For bars larger than No. 5, diameter of bend shall be in accordance with Table 7.2.

7.2.3 — Inside diameter of bend in welded wire fabric (plain or deformed) for stirrups and ties shall not be less than $4d_b$ for deformed wire larger than D6 and $2d_b$ for all other wires. Bends with inside diameter of less than $8d_b$ shall not be less than $4d_b$ from nearest welded intersection.

TABLE 7.2—MINIMUM DIAMETERS OF BEND

Bar size	Minimum diameter
No. 3 through No. 8	$6d_b$
No. 9, No. 10, and No. 11	$8d_b$
No. 14 and No. 18	$10d_b$

7.3 — Bending

7.3.1 — All reinforcement shall be bent cold, unless otherwise permitted by the engineer.

7.3.2 — Reinforcement partially embedded in concrete shall not be field bent, except as shown on the design drawings or permitted by the engineer.

7.4 — Surface conditions of reinforcement

7.4.1—At time concrete is placed, reinforcement shall be free from mud, oil, or other nonmetallic coatings that decrease bond. Epoxy coatings of bars in accord

COMMENTARY

stirrup hook will permit multiple bending on standard stirrup bending equipment.

R7.2.3 — Welded wire fabric, of plain or deformed wire, can be used for stirrups and ties. The wire at welded intersections does not have the same uniform ductility and bendability as in areas which were not heated. These effects of the welding temperature are usually dissipated in a distance of approximately four wire diameters. Minimum bend diameters permitted are in most cases the same as those required in the ASTM bend tests for wire material.

R7.3 — Bending

R7.3.1—The engineer may be the design engineer or architect or the engineer or architect employed by the owner to perform inspection. For unusual bends with inside diameters less than ASTM bend test requirements, special fabrication may be required.

R7.3.2 — Construction conditions may make it necessary to bend bars that have been embedded in concrete. Such field bending should not be done without authorization of the engineer. The engineer must determine whether the bars should be bent cold or if heating should be used. Bends should be gradual and must be straightened as required.

Tests[7.2,7.3] have shown that A 615 Grade 40 and Grade 60 reinforcing bars can be cold bent and straightened up to 90 deg at or near the minimum diameter specified in 7.2. If cracking or breakage is encountered, heating to a maximum temperature of 1500 F should be beneficial for avoiding this condition for the remainder of the bars. Bars that fracture during bending or straightening can be spliced outside the bend region.

Heating must be performed in a manner that will avoid damage to the concrete. If the bend area is within approximately 6 in. of the concrete, some protective insulation may need to be applied. Heating of the bar should be controlled by temperature-indicating crayons or other suitable means. The heated bars should not be artificially cooled (with water or forced air) until after cooling to at least 600 F.

R7.4 — Surface conditions of reinforcement

Specific limits on rust are based on tests,[7.4] plus a review of earlier tests and recommendations. Reference 7.4 provides guidance with regard to the effects of rust and mill scale on

CODE

with standards in this code shall be permitted.

7.4.2 — Reinforcement, except prestressing tendons, with rust, mill scale, or a combination of both shall be considered satisfactory, provided the minimum dimensions (including height of deformations) and weight of a hand-wire-brushed test specimen are not less than applicable ASTM specification requirements.

7.4.3 — Prestressing tendons shall be clean and free of oil, dirt, scale, pitting and excessive rust. A light oxide shall be permitted.

7.5 — Placing reinforcement

7.5.1 — Reinforcement, prestressing tendons, and ducts shall be accurately placed and adequately supported before concrete is placed, and shall be secured against displacement within tolerances permitted in 7.5.2.

7.5.2 — Unless otherwise specified by the engineer, reinforcement, prestressing tendons, and prestressing ducts shall be placed within the following tolerances:

7.5.2.1 — Tolerance for depth ***d***, and minimum concrete cover in flexural members, walls and compression members shall be as follows:

COMMENTARY

bond characteristics of deformed reinforcing bars. Research has shown that a normal amount of rust increases bond. Normal rough handling generally removes rust which is loose enough to injure the bond between the concrete and reinforcement.

R7.5 — Placing reinforcement

R7.5.1 — Reinforcement including prestressing tendons must be adequately supported in the forms to prevent displacement by concrete placement or workers. Beam stirrups should be supported on the bottom form of the beam by positive supports such as continuous longitudinal beam bolsters. If only the longitudinal beam bottom reinforcement is supported, construction traffic can dislodge the stirrups as well as any prestressing tendons tied to the stirrups.

R7.5.2 — Generally accepted practice, as reflected in **"Standard Tolerances for Concrete Construction and Materials"** (ACI 117)[7.5] has established tolerances on total depth (formwork or finish) and fabrication of truss bent reinforcing bars and closed ties, stirrups, and spirals. The engineer should specify more restrictive tolerances than those permitted by the code when it is necessary to minimize the accumulation of tolerances resulting in excessive reduction in effective depth or cover.

More restrictive tolerances have been placed on minimum clear distance to formed soffits because of its importance for durability and fire protection, and because bars are usually supported in such a manner that the specified tolerance is practical.

More restrictive tolerances than those required by the code may be desirable for prestressed concrete to achieve camber control within limits acceptable to the designer or owner. In such cases, the engineer should specify the necessary tolerances. Recommendations are given in Reference 7.6.

R7.5.2.1 — The code specifies a tolerance on depth ***d***, an essential component of strength of the member. Because reinforcing steel is placed with respect to edges of members and formwork surfaces, the depth ***d*** is not always conveniently measured in the field. Engineers should spec-

CODE

	Tolerance on d	Tolerance on minimum concrete cover
$d \leq 8$ in.	$\pm 3/8$ in.	$-3/8$ in.
$d > 8$ in.	$\pm 1/2$ in.	$-1/2$ in.

except that tolerance for the clear distance to formed soffits shall be minus 1/4 in. and tolerance for cover shall not exceed minus 1/3 the minimum concrete cover required in the design drawings or specifications.

7.5.2.2 — Tolerance for longitudinal location of bends and ends of reinforcement shall be ± 2 in. except at discontinuous ends of members where tolerance shall be ± 1/2 in.

7.5.3 — Welded wire fabric (with wire size not greater than W5 or D5) used in slabs not exceeding 10 ft in span shall be permitted to be curved from a point near the top of slab over the support to a point near the bottom of slab at midspan, provided such reinforcement is either continuous over, or securely anchored at support.

7.5.4 — Welding of crossing bars shall not be permitted for assembly of reinforcement unless authorized by the engineer.

7.6 — Spacing limits for reinforcement

7.6.1 — The minimum clear spacing between parallel bars in a layer shall be d_b, but not less than 1 in. See also 3.3.2.

7.6.2 — Where parallel reinforcement is placed in two or more layers, bars in the upper layers shall be placed directly above bars in the bottom layer with clear distance between layers not less than 1 in.

7.6.3 — In spirally reinforced or tied reinforced compression members, clear distance between longitudinal bars shall be not less than $1.5d_b$ nor 1 1/2 in. See also 3.3.2.

7.6.4 — Clear distance limitation between bars shall apply also to the clear distance between a contact lap splice and adjacent splices or bars.

7.6.5 — In walls and slabs other than concrete joist construction, primary flexural reinforcement shall be spaced not farther apart than three times the wall or slab thickness, nor 18 in.

COMMENTARY

ify tolerances for bar placement, cover, and member size. See ACI 117.[7.5]

R7.5.4 — "Tack" welding (welding crossing bars) can seriously weaken a bar at the point welded by creating a metallurgical notch effect. This operation can be performed safely only when the material welded and welding operations are under continuous competent control, as in the manufacture of welded wire fabric.

R7.6 — Spacing limits for reinforcement

Although the minimum bar spacings are unchanged in this code, the development lengths given in Chapter 12 became a function of the bar spacings since the 1989 code. As a result, it may be desirable to use larger than minimum bar spacings in some cases. The minimum limits were originally established to permit concrete to flow readily into spaces between bars and between bars and forms without honeycomb, and to ensure against concentration of bars on a line that may cause shear or shrinkage cracking. Use of "nominal" bar diameter to define minimum spacing permits a uniform criteria for all bar sizes.

CODE

7.6.6 — Bundled bars

7.6.6.1 — Groups of parallel reinforcing bars bundled in contact to act as a unit shall be limited to four in any one bundle.

7.6.6.2 — Bundled bars shall be enclosed within stirrups or ties.

7.6.6.3 — Bars larger than No. 11 shall not be bundled in beams.

7.6.6.4 — Individual bars within a bundle terminated within the span of flexural members shall terminate at different points with at least $40d_b$ stagger.

7.6.6.5 — Where spacing limitations and minimum concrete cover are based on bar diameter d_b, a unit of bundled bars shall be treated as a single bar of a diameter derived from the equivalent total area.

7.6.7 — Prestressing tendons and ducts

7.6.7.1 — Clear distance between pretensioning tendons at each end of a member shall be not less than $4d_b$ for wire, nor $3d_b$ for strands. See also 3.3.2. Closer vertical spacing and bundling of tendons shall be permitted in the middle portion of a span.

7.6.7.2 — Bundling of post-tensioning ducts shall be permitted if shown that concrete can be satisfactorily placed and if provision is made to prevent the tendons, when tensioned, from breaking through the duct.

7.7 — Concrete protection for reinforcement

7.7.1 — Cast-in-place concrete (nonprestressed)

The following minimum concrete cover shall be provided for reinforcement:

	Minimum cover, in.
(a) Concrete cast against and permanently exposed to earth	3
(b) Concrete exposed to earth or weather:	

COMMENTARY

R7.6.6 — Bundled bars

Bond research[7.7] showed that bar cutoffs within bundles should be staggered. Bundled bars should be tied, wired, or otherwise fastened together to ensure remaining in position whether vertical or horizontal.

A limitation that bars larger than No. 11 not be bundled in beams or girders is a practical limit for application to building size members. (The "**Standard Specifications for Highway Bridges**"[7.8] permits two-bar bundles for No. 14 and No. 18 bars in bridge girders.) Conformance to the crack control requirements of 10.6 will effectively preclude bundling of bars larger than No. 11 as tensile reinforcement. The code phrasing "bundled in contact to act as a unit," is intended to preclude bundling more than two bars in the same plane. Typical bundle shapes are triangular, square, or L-shaped patterns for three- or four-bar bundles. As a practical caution, bundles more than one bar deep in the plane of bending may not be hooked or bent as a unit. Where end hooks are required, it is preferable to stagger the individual bar hooks within a bundle.

R7.6.7 — Prestressing tendons and ducts

R7.6.7.2 — When ducts for post-tensioning tendons in a beam are arranged closely together vertically, provision must be made to prevent the tendons, when tensioned, from breaking through the duct. Horizontal disposition of ducts must allow proper placement of concrete. Generally a clear spacing of one and one-third times the size of the coarse aggregate, but not less than 1 in., has proven satisfactory. Where concentration of tendons or ducts tends to create a weakened plane in the concrete cover, reinforcement should be provided to control cracking.

R7.7 — Concrete protection for reinforcement

Concrete cover as protection of reinforcement against weather and other effects is measured from the concrete surface to the outermost surface of the steel to which the cover requirement applies. Where minimum cover is prescribed for a class of structural member, it is measured to the outer edge of stirrups, ties, or spirals if transverse reinforcement encloses main bars; to the outermost layer of bars if more than one layer is used without stirrups or ties; to the metal end fitting or duct on post-tensioned prestressing steel.

The condition "concrete surfaces exposed to the weather" refers to direct exposure to moisture changes and not just to

CODE

Minimum cover, in.

No. 6 through No. 18 bars 2
No. 5 bar, W31 or D31 wire, and smaller 1 1/2

(c) Concrete not exposed to weather or in contact with ground:
Slabs, walls, joists:
No. 14 and No. 18 bars 1 1/2
No. 11 bar and smaller 3/4

Beams, columns:
Primary reinforcement, ties, stirrups, spirals 1 1/2

Shells, folded plate members:
No. 6 bar and larger 3/4
No. 5 bar, W31 or D31 wire, and smaller 1/2

7.7.2 — Precast concrete (manufactured under plant control conditions)

The following minimum concrete cover shall be provided for reinforcement:

(a) Concrete exposed to earth or weather:
Wall panels:
No. 14 and No. 18 bars 1 1/2
No. 11 bar and smaller 3/4

Other members:
No. 14 and No. 18 bars 2
No. 6 through No. 11 bars 1 1/2
No. 5 bar, W31 or D31 wire, and smaller 1 1/4

(b) Concrete not exposed to weather or in contact with ground:
Slabs, walls, joists:
No. 14 and No. 18 bars 1 1/4
No. 11 bar and smaller 5/8

Beams, columns:
Primary reinforcement ..... d_b but not less than 5/8 and need not exceed 1 1/2
Ties, stirrups, spirals 3/8

Shells, folded plate members:
No. 6 bar and larger 5/8
No. 5 bar, W31 or D31 wire, and smaller 3/8

7.7.3 — Prestressed concrete

7.7.3.1 — The following minimum concrete cover shall be provided for prestressed and nonprestressed reinforcement, ducts, and end fittings, except as provided in 7.7.3.2 and 7.7.3.3:

COMMENTARY

temperature changes. Slab or thin shell soffits are not usually considered directly "exposed" unless subject to alternate wetting and drying, including that due to condensation conditions or direct leakage from exposed top surface, run off, or similar effects.

Alternative methods of protecting the reinforcement from weather may be provided if they are equivalent to the additional concrete cover required by the code. When approved by the building official under the provisions of 1.4, reinforcement with alternative protection from the weather may have concrete cover not less than the cover required for reinforcement not exposed to weather.

The development lengths given in Chapter 12 are now a function of the bar cover. As a result, it may be desirable to use larger than minimum cover in some cases.

R7.7.2 — Precast concrete (manufactured under plant control conditions)

The lesser thicknesses for precast construction reflect the greater convenience of control for proportioning, placing, and curing inherent in precasting. The term "manufactured under plant controlled conditions" does not specifically imply that precast members must be manufactured in a plant. Structural elements precast at the job site will also qualify under this section if the control of form dimensions, placing of reinforcement, quality control of concrete, and curing procedure are equal to that normally expected in a plant.

CODE

	Minimum cover, in.
(a) Concrete cast against and permanently exposed to earth	3
(b) Concrete exposed to earth or weather:	
Wall panels, slabs, joists	1
Other members	$1^1/_2$
(c) Concrete not exposed to weather or in contact with ground:	
Slabs, walls, joists	$^3/_4$
Beams, columns:	
Primary reinforcement	$1^1/_2$
Ties, stirrups, spirals	1
Shells, folded plate members:	
No. 5 bar, W31 or D31 wire, and smaller	$^3/_8$
Other reinforcement	d_b but not less than $^3/_4$

7.7.3.2 — For prestressed concrete members exposed to earth, weather, or corrosive environments, and in which permissible tensile stress of 18.4.2(c) is exceeded, minimum cover shall be increased 50 percent.

7.7.3.3 — For prestressed concrete members manufactured under plant control conditions, minimum concrete cover for nonprestressed reinforcement shall be as required in 7.7.2.

7.7.4 — Bundled bars

For bundled bars, minimum concrete cover shall be equal to the equivalent diameter of the bundle, but need not be greater than 2 in.; except for concrete cast against and permanently exposed to earth, minimum cover shall be 3 in.

7.7.5 — Corrosive environments

In corrosive environments or other severe exposure conditions, amount of concrete protection shall be suitably increased, and denseness and nonporosity of protecting concrete shall be considered, or other protection shall be provided.

COMMENTARY

R7.7.5 — Corrosive environments

When concrete will be exposed to external sources of chlorides in service, such as deicing salts, brackish water, seawater, or spray from these sources, concrete must be proportioned to satisfy the special exposure requirements of Chapter 4. These include minimum air content, maximum water-cementitious materials ratio, minimum strength for normal weight and lightweight concrete, maximum chloride ion in concrete, and cement type. Additionally, for corrosion protection, a minimum concrete cover for reinforcement of 2 in. for walls and slabs and $2^1/_2$ in. for other members is recommended. For precast concrete manufactured under plant control conditions, a minimum cover of $1^1/_2$ and 2 in., respectively, is recommended.

CODE

7.7.6 — Future extensions

Exposed reinforcement, inserts, and plates intended for bonding with future extensions shall be protected from corrosion.

7.7.7 — Fire protection

When the general building code (of which this code forms a part) requires a thickness of cover for fire protection greater than the minimum concrete cover specified in 7.7, such greater thicknesses shall be used.

7.8 — Special reinforcement details for columns

7.8.1 — Offset bars

Offset bent longitudinal bars shall conform to the following:

7.8.1.1 — Slope of inclined portion of an offset bar with axis of column shall not exceed 1 in 6.

7.8.1.2 — Portions of bar above and below an offset shall be parallel to axis of column.

7.8.1.3 — Horizontal support at offset bends shall be provided by lateral ties, spirals, or parts of the floor construction. Horizontal support provided shall be designed to resist $1^1/_2$ times the horizontal component of the computed force in the inclined portion of an offset bar. Lateral ties or spirals, if used, shall be placed not more than 6 in. from points of bend.

7.8.1.4 — Offset bars shall be bent before placement in the forms. See 7.3.

7.8.1.5 — Where a column face is offset 3 in. or greater, longitudinal bars shall not be offset bent. Separate dowels, lap spliced with the longitudinal bars adjacent to the offset column faces, shall be provided. Lap splices shall conform to 12.17.

7.8.2 — Steel cores

Load transfer in structural steel cores of composite compression members shall be provided by the following:

7.8.2.1 — Ends of structural steel cores shall be accurately finished to bear at end bearing splices, with positive provision for alignment of one core above the other in concentric contact.

COMMENTARY

R7.8 — Special reinforcement details for columns

R7.8.2 — Steel cores

The 50 percent limit on transfer of compressive load by end bearing on ends of structural steel cores is intended to provide some tensile capacity at such splices (up to 50 percent), since the remainder of the total compressive stress in the steel core must be transmitted by dowels, splice plates, welds, etc. This provision should ensure that splices in composite compression members meet essentially the same tensile capacity as required for conventionally reinforced concrete compression members.

CODE

7.8.2.2 — At end bearing splices, bearing shall be considered effective to transfer not more than 50 percent of the total compressive stress in the steel core.

7.8.2.3 — Transfer of stress between column base and footing shall be designed in accordance with 15.8.

7.8.2.4 — Base of structural steel section shall be designed to transfer the total load from the entire composite member to the footing; or, the base shall be designed to transfer the load from the steel core only, provided ample concrete section is available for transfer of the portion of the total load carried by the reinforced concrete section to the footing by compression in the concrete and by reinforcement.

7.9 — Connections

7.9.1 — At connections of principal framing elements (such as beams and columns), enclosure shall be provided for splices of continuing reinforcement and for anchorage of reinforcement terminating in such connections.

7.9.2 — Enclosure at connections shall consist of external concrete or internal closed ties, spirals, or stirrups.

7.10 — Lateral reinforcement for compression members

7.10.1 — Lateral reinforcement for compression members shall conform to the provisions of 7.10.4 and 7.10.5 and, where shear or torsion reinforcement is required, shall also conform to provisions of Chapter 11.

7.10.2 — Lateral reinforcement requirements for composite compression members shall conform to 10.16. Lateral reinforcement requirements for prestressing tendons shall conform to 18.11.

7.10.3 — It shall be permitted to waive the lateral reinforcement requirements of 7.10, 10.16, and 18.11 where tests and structural analysis show adequate strength and feasibility of construction.

COMMENTARY

R7.9 — Connections

Confinement is essential at connections to assure that the flexural capacity of the members can be developed without deterioration of the joint under repeated loadings.[7.9,7.10]

R7.10 — Lateral reinforcement for compression members

R7.10.3 — Precast columns with cover less than $1^1/_2$ in., prestressed columns without longitudinal bars, columns smaller than minimum dimensions prescribed in earlier ACI Building Codes, columns of concrete with small size coarse aggregate, wall-like columns, and other special cases may require special designs for lateral reinforcement. Plain or deformed wire, W4, D4, or larger, may be used for ties or spirals. If such special columns are considered as spiral columns for load strength in design, the ratio of spiral reinforcement ρ_s must conform to 10.9.3.

CODE

7.10.4 — Spirals

Spiral reinforcement for compression members shall conform to 10.9.3 and to the following:

7.10.4.1 — Spirals shall consist of evenly spaced continuous bar or wire of such size and so assembled to permit handling and placing without distortion from designed dimensions.

7.10.4.2 — For cast-in-place construction, size of spirals shall not be less than $^3/_8$ in. diameter.

7.10.4.3 — Clear spacing between spirals shall not exceed 3 in., nor be less than 1 in. See also 3.3.2.

7.10.4.4 — Anchorage of spiral reinforcement shall be provided by $1^1/_2$ extra turns of spiral bar or wire at each end of a spiral unit.

7.10.4.5 — Splices in spiral reinforcement shall be lap splices of $48d_b$ but not less than 12 in., or welded.

7.10.4.6 — Spirals shall extend from top of footing or slab in any story to level of lowest horizontal reinforcement in members supported above.

7.10.4.7 — Where beams or brackets do not frame into all sides of a column, ties shall extend above termination of spiral to bottom of slab or drop panel.

7.10.4.8 — In columns with capitals, spirals shall extend to a level at which the diameter or width of capital is two times that of the column.

7.10.4.9 — Spirals shall be held firmly in place and true to line.

7.10.5 — Ties

Tie reinforcement for compression members shall conform to the following:

7.10.5.1 — All nonprestressed bars shall be enclosed by lateral ties, at least No. 3 in size for longitudinal bars No. 10 or smaller, and at least No. 4 in size for No. 11, No. 14, No. 18, and bundled longitudinal bars. Deformed wire or welded wire fabric of equivalent area shall be permitted.

7.10.5.2 — Vertical spacing of ties shall not exceed 16 longitudinal bar diameters, 48 tie bar or wire diameters, or least dimension of the compression member.

COMMENTARY

R7.10.4 — Spirals

For practical considerations in cast-in-place construction, the minimum diameter of spiral reinforcement is $^3/_8$ in. ($^3/_8$" ϕ, No. 3 bar, or W11 or D11 wire). This is the smallest size that can be used in a column with $1^1/_2$ in. or more cover and having concrete strengths of 3000 psi or more if the minimum clear spacing for placing concrete is to be maintained.

Standard spiral sizes are $^3/_8$ in., $^1/_2$ in., and $^5/_8$ in. diameter for hot rolled or cold drawn material, plain or deformed.

The code allows spirals to be terminated at the level of lowest horizontal reinforcement framing into the column. However, if one or more sides of the column are not enclosed by beams or brackets, ties are required from the termination of the spiral to the bottom of the slab or drop panel. If beams or brackets enclose all sides of the column but are of different depths, the ties should extend from the spiral to the level of the horizontal reinforcement of the shallowest beam or bracket framing into the column. These additional ties are to enclose the longitudinal column reinforcement and the portion of bars from beams bent into the column for anchorage. See also 7.9.

Spirals must be held firmly in place, at proper pitch and alignment, to prevent displacement during concrete placement. The code has traditionally required spacers to hold the fabricated spiral cage in place but was changed in 1989 to allow alternate methods of installation. When spacers are used, the following may be used for guidance: For spiral bar or wire smaller than $^5/_8$ in. diameter, a minimum of two spacers should be used for spirals less than 20 in. in diameter, three spacers for spirals 20 to 30 in. in diameter, and four spacers for spirals greater than 30 in. in diameter. For spiral bar or wire $^5/_8$ in. diameter or larger, a minimum of three spacers should be used for spirals 24 in. or less in diameter, and four spacers for spirals greater than 24 in. in diameter. The project specifications or subcontract agreements should be clearly written to cover the supply of spacers or field tying of the spiral reinforcement.

R7.10.5 — Ties

All longitudinal bars in compression must be enclosed within lateral ties. Where longitudinal bars are arranged in a circular pattern, only one circular tie per specified spacing is required. This requirement can be satisfied by a continuous circular tie (helix) at larger pitch than required for spirals under 10.9.3, the maximum pitch being equal to the required tie spacing.

The 1956 ACI Building Code required "lateral support equivalent to that provided by a 90-deg corner of a tie," for every vertical bar. Tie requirements were liberalized in 1963 by increasing the permissible included angle from 90 to 135 deg and exempting bars which are located within 6 in. clear

CODE

7.10.5.3 — Ties shall be arranged such that every corner and alternate longitudinal bar shall have lateral support provided by the corner of a tie with an included angle of not more than 135 deg and no bar shall be farther than 6 in. clear on each side along the tie from such a laterally supported bar. Where longitudinal bars are located around the perimeter of a circle, a complete circular tie shall be permitted.

7.10.5.4 — Ties shall be located vertically not more than one-half a tie spacing above the top of footing or slab in any story, and shall be spaced as provided herein to not more than one-half a tie spacing below the lowest horizontal reinforcement in slab or drop panel above.

7.10.5.5 — Where beams or brackets frame from four directions into a column, termination of ties not more than 3 in. below lowest reinforcement in shallowest of such beams or brackets shall be permitted.

7.11 — Lateral reinforcement for flexural members

7.11.1 — Compression reinforcement in beams shall be enclosed by ties or stirrups satisfying the size and spacing limitations in 7.10.5 or by welded wire fabric of equivalent area. Such ties or stirrups shall be provided throughout the distance where compression reinforcement is required.

7.11.2 — Lateral reinforcement for flexural framing members subject to stress reversals or to torsion at

COMMENTARY

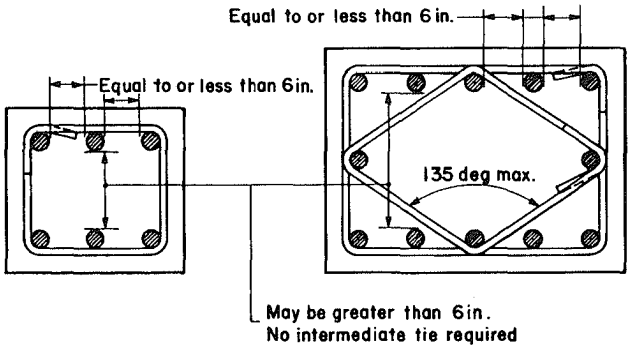

Fig. R7.10.5—Sketch to clarify measurements between laterally supported column bars

on each side along the tie from adequately tied bars (see Fig. R7.10.5). Limited tests[7.11] on full-size, axially-loaded, tied columns containing full-length bars (without splices) showed no appreciable difference between ultimate strengths of columns with full tie requirements and no ties at all.

Since spliced bars and bundled bars were not included in the tests of Reference 7.11, it would be prudent to provide a set of ties at each end of lap spliced bars, above and below end-bearing splices, and at minimum spacings immediately below sloping regions of offset bent bars.

Standard tie hooks are intended for use with deformed bars only, and should be staggered where possible. See also 7.9.

Continuously wound bars or wires can be used as ties provided their pitch and area are at least equivalent to the area and spacing of separate ties. Anchorage at the end of a continuously wound bar or wire should be by a standard hook as for separate bars or by one additional turn of the tie pattern. A circular continuously wound bar or wire is considered a spiral if it conforms to 7.10.4, otherwise it is considered a tie.

R7.10.5.5 — With the 1983 code, the wording of this section was modified to clarify that ties may be terminated only when elements frame into all four sides of square and rectangular columns; and, for round or polygonal columns, such elements frame into the column from four directions.

R7.11 — Lateral reinforcement for flexural members

R7.11.1 — Compression reinforcement in beams and girders must be enclosed to prevent buckling; similar requirements for such enclosure have remained essentially unchanged through several editions of the code, except for minor clarification.

CODE

supports shall consist of closed ties, closed stirrups, or spirals extending around the flexural reinforcement.

7.11.3 — Closed ties or stirrups shall be formed in one piece by overlapping standard stirrup or tie end hooks around a longitudinal bar, or formed in one or two pieces lap spliced with a Class B splice (lap of $1.3\ell_d$) or anchored in accordance with 12.13.

7.12 — Shrinkage and temperature reinforcement

7.12.1 — Reinforcement for shrinkage and temperature stresses normal to flexural reinforcement shall be provided in structural slabs where the flexural reinforcement extends in one direction only.

7.12.1.1 — Shrinkage and temperature reinforcement shall be provided in accordance with either 7.12.2 or 7.12.3.

7.12.1.2 — Where shrinkage and temperature movements are significantly restrained, the requirements of 8.2.4 and 9.2.7 shall be considered.

7.12.2 — Deformed reinforcement conforming to 3.5.3 used for shrinkage and temperature reinforcement shall be provided in accordance with the following:

7.12.2.1 — Area of shrinkage and temperature reinforcement shall provide at least the following ratios of reinforcement area to gross concrete area, but not less than 0.0014:

(a) Slabs where Grade 40 or 50 deformed bars are used 0.0020

(b) Slabs where Grade 60 deformed bars or welded wire fabric (plain or deformed) are used 0.0018

(c) Slabs where reinforcement with yield stress exceeding 60,000 psi measured at a yield strain of 0.35 percent is used ..... $\frac{0.0018 \times 60{,}000}{f_y}$

COMMENTARY

R7.12 — Shrinkage and temperature reinforcement

R7.12.1 — Shrinkage and temperature reinforcement is required at right angles to the principal reinforcement to minimize cracking and to tie the structure together to assure its acting as assumed in the design. The provisions of this section are intended for structural slabs only; they are not intended for soil supported "slabs on grade."

R7.12.1.2 — The area of shrinkage and temperature reinforcement required by 7.12 has been satisfactory where shrinkage and temperature movements are permitted to occur. For cases where structural walls or large columns provide significant restraints to shrinkage and temperature movements, it may be necessary to increase the amount of reinforcement normal to the flexural reinforcement in 7.12.1.2 (see Reference 7.12). Top and bottom reinforcement are both effective in controlling cracks. Control strips during the construction period, which permit initial shrinkage to occur without causing an increase in stresses, are also effective in reducing cracks caused by restraints.

R7.12.2 — The amounts specified for deformed bars and welded wire fabric are empirical but have been used satisfactorily for many years. Splices and end anchorages of shrinkage and temperature reinforcement must be designed for the full specified yield strength in accordance with 12.1, 12.15, 12.18, and 12.19.

CODE

7.12.2.2 — Shrinkage and temperature reinforcement shall be spaced not farther apart than five times the slab thickness, nor 18 in.

7.12.2.3 — At all sections where required, reinforcement for shrinkage and temperature stresses shall develop the specified yield strength f_y in tension in accordance with Chapter 12.

7.12.3 — Prestressing tendons conforming to 3.5.5 used for shrinkage and temperature reinforcement shall be provided in accordance with the following:

7.12.3.1 — Tendons shall be proportioned to provide a minimum average compressive stress of 100 psi on gross concrete area using effective prestress, after losses, in accordance with 18.6.

7.12.3.2 — Spacing of tendons shall not exceed 6 ft.

7.12.3.3 — When spacing of tendons exceeds 54 in., additional bonded shrinkage and temperature reinforcement conforming to 7.12.2 shall be provided between the tendons at slab edges extending from the slab edge for a distance equal to the tendon spacing.

COMMENTARY

R7.12.3 — Prestressed reinforcement requirements have been selected to provide an effective force on the slab approximately equal to the yield strength force for nonprestressed shrinkage and temperature reinforcement. This amount of prestressing, 100 psi on the gross concrete area, has been used successfully on a large number of projects. When the spacing of prestressing tendons used for shrinkage and temperature reinforcement exceeds 54 in., additional bonded reinforcement is required at slab edges where the prestressing forces are applied in order to adequately reinforce the area between the slab edge and the point where compressive stresses behind individual anchorages have "spread" sufficiently such that the slab is uniformly in compression. Application of the provisions of 7.12.3 to monolithic cast-in-place post-tensioned beam and slab construction is illustrated in Fig. R7.12.3.

Tendons used for shrinkage and temperature reinforcement should be positioned vertically in the slab as close as practicable to the center of the slab. In cases where the shrinkage and temperature tendons are used for supporting the principal tendons, variations from the slab centroid are permissible; however, the resultant of the shrinkage and temperature tendons should not fall outside the kern area of the slab.

The designer should evaluate the effects of slab shortening to assure proper action. In most cases, the low level of prestressing recommended should not cause difficulties in a properly detailed structure. Special attention may be required where thermal effects become significant.

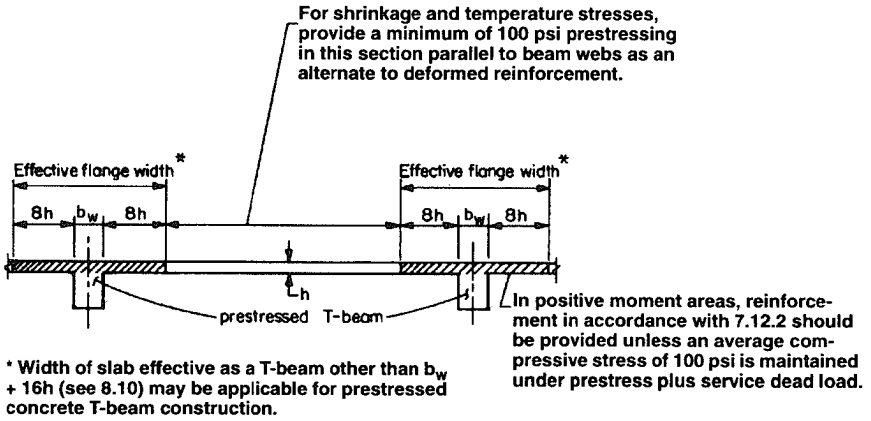

Fig. R7.12.3—Prestressing used for shrinkage and temperature

CODE

COMMENTARY

7.13 — Requirements for structural integrity

R7.13 — Requirements for structural integrity

Experience has shown that the overall integrity of a structure can be substantially enhanced by minor changes in detailing of reinforcement. It is the intent of this section of the code to improve the redundancy and ductility in structures so that in the event of damage to a major supporting element or an abnormal loading event, the resulting damage may be confined to a relatively small area and the structure will have a better chance to maintain overall stability.

7.13.1 — In the detailing of reinforcement and connections, members of a structure shall be effectively tied together to improve integrity of the overall structure.

7.13.2 — For cast-in-place construction, the following shall constitute minimum requirements:

7.13.2.1 — In joist construction, at least one bottom bar shall be continuous or shall be spliced over the support with a Class A tension splice and at noncontinuous supports be terminated with a standard hook.

7.13.2.2 — Beams at the perimeter of the structure shall have at least one-sixth of the tension reinforcement required for negative moment at the support and one-quarter of the positive moment reinforcement required at midspan made continuous around the perimeter and tied with closed stirrups, or stirrups anchored around the negative moment reinforcement with a hook having a bend of at least 135 deg. Stirrups need not be extended through any joints. When splices are needed, the required continuity shall be provided with top reinforcement spliced at midspan and bottom reinforcement spliced at or near the support with Class A tension splices.

7.13.2.3 — In other than perimeter beams, when closed stirrups are not provided, at least one-quarter of the positive moment reinforcement required at midspan shall be continuous or shall be spliced over the support with a Class A tension splice and at noncontinuous supports be terminated with a standard hook.

7.13.2.4 — For two-way slab construction, see 13.3.8.5.

R7.13.2 — With damage to a support, top reinforcement which is continuous over the support, but not confined by stirrups, will tend to tear out of the concrete and will not provide the catenary action needed to bridge the damaged support. By making a portion of the bottom reinforcement continuous, catenary action can be provided.

Requiring continuous top and bottom reinforcement in perimeter or spandrel beams provides a continuous tie around the structure. It is not the intent to require a tensile tie of continuous reinforcement of constant size around the entire perimeter of a structure, but simply to require that one half of the top flexural reinforcement required to extend past the point of inflection by 12.12.3 be further extended to lap splice at midspan. Similarly, the bottom reinforcement required to extend into the support by 12.11.1 must be made continuous or spliced with bottom reinforcement from the adjacent span. If the depth of a continuous beam changes at a support, the bottom reinforcement in the deeper member should be terminated with a standard hook and bottom reinforcement in the shallower member should be extended into and fully developed in the deeper member.

7.13.3 — For precast concrete construction, tension ties shall be provided in the transverse, longitudinal, and vertical directions and around the perimeter of the structure to effectively tie elements together. The provisions of 16.5 shall apply.

R7.13.3 — The code requires tension ties for precast concrete buildings of all heights. Details should provide connections to resist applied loads. Connection details that rely solely on friction caused by gravity forces are not permitted.

Connection details should be arranged so as to minimize the potential for cracking due to restrained creep, shrinkage and temperature movements. For information on connections and detailing requirements, see Reference 7.13.

Reference 7.14 recommends minimum tie requirements for precast concrete bearing wall buildings.

7.13.4 — For lift-slab construction, see 13.3.8.6 and 18.12.6.

PART 4 — GENERAL REQUIREMENTS

CHAPTER 8 — ANALYSIS AND DESIGN — GENERAL CONSIDERATIONS

CODE

8.0 — Notation

A_s = area of nonprestressed tension reinforcement, in.^{2}
A_s' = area of compression reinforcement, in.^{2}
b = width of compression face of member, in.
d = distance from extreme compression fiber to centroid of tension reinforcement, in.
E_c = modulus of elasticity of concrete, psi. See 8.5.1
E_s = modulus of elasticity of reinforcement, psi. See 8.5.2 and 8.5.3
f_c' = specified compressive strength of concrete, psi
f_y = specified yield strength of nonprestressed reinforcement, psi
ℓ_n = clear span for positive moment or shear and average of adjacent clear spans for negative moment
V_c = nominal shear strength provided by concrete
w_c = unit weight of concrete, lb/ft^3
w_u = factored load per unit length of beam or per unit area of slab
β_1 = factor defined in 10.2.7.3
ε_t = net tensile strain in extreme tension steel at nominal strength
ρ = ratio of nonprestressed tension reinforcement
= A_s/bd
ρ' = ratio of nonprestressed compression reinforcement
= A_s'/bd
ρ_b = reinforcement ratio producing balanced strain conditions. See 10.3.2
ϕ = strength reduction factor. See 9.3

8.1 — Design methods

8.1.1 — In design of structural concrete, members shall be proportioned for adequate strength in accordance with provisions of this code, using load factors and strength reduction factors ϕ specified in Chapter 9.

8.1.2 — Design of nonprestressed reinforced concrete members using Appendix A, Alternate Design Method, shall be permitted.

COMMENTARY

R8.0 — Notation

The definition of net tensile strain in 2.1 excludes strains due to effective prestress, creep, shrinkage, and temperature.

R8.1 — Design methods

R8.1.1 — The strength design method requires service loads or related internal moments and forces to be increased by specified load factors (required strength) and computed nominal strengths to be reduced by specified strength reduction factors ϕ (design strength).

R8.1.2 — The alternate method of design, outlined in Appendix A, is similar to the working stress design method of the 1963 ACI Building Code. The general serviceability requirements of the code, such as the requirements for

CODE

COMMENTARY

deflection and crack control must be met whether the strength design method of the code or the alternate design method of Appendix A is used.

Although prestressed members may not be designed under the provisions of the alternate design method, Chapter 18 requires linear stress-strain assumptions for computing service load stresses and prestress transfer stresses for investigation of behavior at service conditions, while using the strength design method for computing flexural strength (see 18.7).

An appendix may be judged not to be an official part of a legal document unless specifically adopted. Therefore specific reference is made to Appendix A in the main body of the code, to make it a legal part of the code.

8.1.3 — Design of reinforced concrete using the provisions of Appendix B, Unified Design Provisions for Reinforced and Prestressed Concrete Flexural and Compression Members, shall be permitted.

R8.1.3 — Designs made in accordance with Appendix B are equally acceptable, provided the provisions of Appendix B are used in their entirety.

An appendix may be judged not to be an official part of a legal document unless specifically adopted. Therefore, specific reference is made to Appendix B in the main body of the code, to make it a legal part of the code.

8.2 — Loading*

R8.2 — Loading

8.2.1 — Design provisions of this code are based on the assumption that structures shall be designed to resist all applicable loads.

8.2.2 — Service loads shall be in accordance with the general building code of which this code forms a part, with such live load reductions as are permitted in the general building code.

The provisions in the code are for live, wind, and earthquake loads such as those recommended in **"Minimum Design Loads for Buildings and Other Structures,"** (ASCE 7), of the American Society of Civil Engineers (ASCE)(formerly ANSI A58.1). If the service loads specified by the general building code (of which ACI 318 forms a part) differ from those of ASCE 7, the general building code governs. However, if the nature of the loads contained in a general building code differ considerably from ASCE 7 loads, some provisions of this code may need modification to reflect the difference.

Roofs should be designed with sufficient slope or camber to ensure adequate drainage accounting for any long-term deflection of the roof due to the dead loads, or the loads should be increased to account for all likely accumulations of water. If deflection of roof members may result in ponding of water accompanied by increased deflection and additional ponding, the design must ensure that this process is self-limiting.

* Provisions in this code are suitable for live, wind, and earthquake loads, such as those recommended in "Minimum Design Loads for Buildings and Other Structures," ASCE 7, of the American Society of Civil Engineers (formerly ANSI A58.1).

CODE

8.2.3 — In design for wind and earthquake loads, integral structural parts shall be designed to resist the total lateral loads.*

8.2.4 — Consideration shall be given to effects of forces due to prestressing, crane loads, vibration, impact, shrinkage, temperature changes, creep, expansion of shrinkage-compensating concrete, and unequal settlement of supports.

8.3 — Methods of analysis

8.3.1 — All members of frames or continuous construction shall be designed for the maximum effects of factored loads as determined by the theory of elastic analysis, except as modified according to 8.4. It shall be permitted to simplify design by using the assumptions specified in 8.6 through 8.9.

8.3.2 — Except for prestressed concrete, approximate methods of frame analysis shall be permitted for buildings of usual types of construction, spans, and story heights.

8.3.3 — As an alternate to frame analysis, the following approximate moments and shears shall be permitted for design of continuous beams and one-way slabs (slabs reinforced to resist flexural stresses in only one direction), provided:

(a) There are two or more spans,

(b) Spans are approximately equal, with the larger of two adjacent spans not greater than the shorter by more than 20 percent,

(c) Loads are uniformly distributed,

(d) Unit live load does not exceed three times unit dead load, and

(e) Members are prismatic.

Positive moment
End spans
Discontinuous end unrestrained ..... $w_u \ell_n^2/11$

*Special provisions for seismic design are given in Chapter 21.

COMMENTARY

R8.2.3 — Any reinforced concrete wall that is monolithic with other structural elements is considered to be an "integral part." Partition walls may or may not be integral structural parts. If partition walls may be removed, the primary lateral load resisting system must provide all of the required resistance without contribution of the removable partition. However, the effects of all partition walls attached to the structure must be considered in the analysis of the structure because they may lead to increased design forces in some or all elements.

R8.2.4 — Information is accumulating on the magnitudes of these various effects, especially the effects of column creep and shrinkage in tall structures,[8.1] and on procedures for including the forces resulting from these effects in design.

R8.3 — Methods of analysis

R8.3.1 — Factored loads are service loads multiplied by appropriate load factors. If the alternate design method of Appendix A is used, the loads used in design are service loads (load factors of unity). For both the strength design method and the alternate design method, elastic analysis is used to obtain moments, shears, reactions, etc.

R8.3.3 — The approximate moments and shears give reasonably conservative values for the stated conditions if the flexural members are part of a frame or continuous construction. Because the load patterns that produce critical values for moments in columns of frames differ from those for maximum negative moments in beams, column moments must be evaluated separately.

CODE	COMMENTARY
Discontinuous end integral with support ..... $w_u \ell_n^2/14$

Shear at face of all other supports ..... $w_u \ell_n/2$	

8.4 — Redistribution of negative moments in continuous nonprestressed flexural members*

8.4.1 — Except where approximate values for moments are used, it shall be permitted to increase or decrease negative moments calculated by elastic theory at supports of continuous flexural members for any assumed loading arrangement by not more than

$$20\left(1 - \frac{\rho - \rho'}{\rho_b}\right) \text{ percent}$$

8.4.2 — The modified negative moments shall be used for calculating moments at sections within the spans.

* For criteria on moment redistribution for prestressed concrete members, see 18.10.4.

R8.4 — Redistribution of negative moments in continuous nonprestressed flexural members

Moment redistribution is dependent on adequate ductility in plastic hinge regions. These plastic hinge regions develop at points of maximum moment and cause a shift in the elastic moment diagram. The usual result is a reduction in the values of negative moments in the plastic hinge region and an increase in the values of positive moments from those computed by elastic analysis. Since negative moments are determined for one loading arrangement and positive moments for another, each section has a reserve capacity that is not fully utilized for any one loading condition. The plastic hinges permit the utilization of the full capacity of more cross sections of a flexural member at ultimate loads.

CODE

8.4.3 — Redistribution of negative moments shall be made only when the section at which moment is reduced is so designed that ρ or $\rho - \rho'$ is not greater than **0.50** ρ_b, where

$$\rho_b = \frac{0.85\beta_1 f_c'}{f_y}\left(\frac{87{,}000}{87{,}000 + f_y}\right) \qquad (8\text{-}1)$$

COMMENTARY

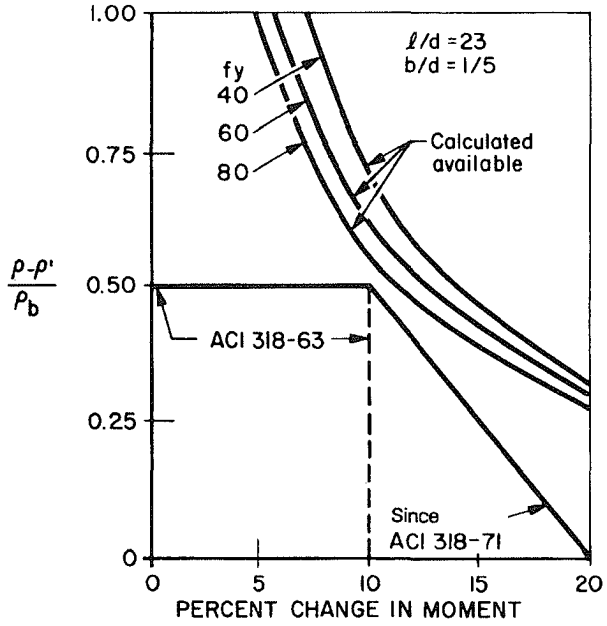

Fig R8.4—Permissible moment redistribution for minimum rotation capacity

Using conservative values of ultimate concrete strains and lengths of plastic hinges derived from extensive tests, flexural members with small rotation capacity were analyzed for moment redistribution varying from 10 to 20 percent, depending on the reinforcement ratio. The results were found to be conservative (see Fig. R8.4). Studies by Cohn[8.2] and Mattock[8.3] support this conclusion and indicate that cracking and deflection of beams designed for moment redistribution are not significantly greater at service loads than for beams designed by the elastic theory distribution of moments. Also, these studies indicated that adequate rotation capacity for the moment redistribution allowed by the code is available if the members satisfy the code requirements. This code maintains the same limit on redistribution as the 1971 and 1977 code editions.

Moment redistribution does not apply to members designed by the alternate design method of Appendix A; nor may it be used for slab systems designed by the Direct Design Method (see 13.6.1.7).

8.5 — Modulus of elasticity

8.5.1 — Modulus of elasticity E_c for concrete shall be permitted to be taken as $w_c^{1.5}\,33\sqrt{f_c'}$ (in psi) for values of w_c between 90 and 155 lb/ft.[3] For normal weight concrete, E_c shall be permitted to be taken as $57{,}000\sqrt{f_c'}$.

R8.5 — Modulus of elasticity

R8.5.1 — Studies leading to the expression for modulus of elasticity of concrete in 8.5.1 are summarized in Reference 8.4 where E_c was defined as the slope of the line drawn from a stress of zero to a compressive stress of $0.45 f_c'$. The modulus for concrete is sensitive to the modulus of the aggregate and may differ from the specified value. Measured values range typically from 120 to 80 percent of the specified value. Methods for determining Young's modulus for concrete are described in Reference 8.5.

CODE

8.5.2 — Modulus of elasticity E_s for nonprestressed reinforcement shall be permitted to be taken as 29,000,000 psi.

8.5.3 — Modulus of elasticity E_s for prestressing tendons shall be determined by tests or supplied by the manufacturer.

8.6 — Stiffness

8.6.1 — Use of any set of reasonable assumptions shall be permitted for computing relative flexural and torsional stiffnesses of columns, walls, floors, and roof systems. The assumptions adopted shall be consistent throughout analysis.

8.6.2 — Effect of haunches shall be considered both in determining moments and in design of members.

8.7 — Span length

8.7.1 — Span length of members not built integrally with supports shall be considered the clear span plus depth of member but need not exceed distance between centers of supports.

8.7.2 — In analysis of frames or continuous construction for determination of moments, span length shall be taken as the distance center-to-center of supports.

8.7.3 — For beams built integrally with supports, design on the basis of moments at faces of support shall be permitted.

COMMENTARY

R8.6 — Stiffness

R8.6.1 — Ideally, the member stiffnesses ***EI*** and ***GJ*** should reflect the degree of cracking and inelastic action which has occurred along each member before yielding. However, the complexities involved in selecting different stiffnesses for all members of a frame would make frame analyses inefficient in design offices. Simpler assumptions are required to define flexural and torsional stiffnesses.

For braced frames, relative values of stiffness are important. Two usual assumptions are to use gross ***EI*** values for all members or, to use half the gross ***EI*** of the beam stem for beams and the gross ***EI*** for the columns.

For frames that are free to sway, a realistic estimate of ***EI*** is desirable and should be used if second-order analyses are carried out. Guidance for the choice of ***EI*** for this case is given in the commentary to 10.11.1.

Two conditions determine whether it is necessary to consider torsional stiffness in the analysis of a given structure: (1) the relative magnitude of the torsional and flexural stiffnesses, and (2) whether torsion is required for equilibrium of the structure (equilibrium torsion) or is due to members twisting to maintain deformation compatibility (compatibility torsion). In the case of compatibility torsion, the torsional stiffness may be neglected. For cases involving equilibrium torsion, torsional stiffness should be considered.

R8.6.2 — Stiffness and fixed-end moment coefficients for haunched members may be obtained from Reference 8.6.

R8.7 — Span length

Beam moments calculated at support centers may be reduced to the moments at support faces for design of beams. Reference 8.7 provides an acceptable method of reducing moments at support centers to those at support faces.

CODE

8.7.4 — It shall be permitted to analyze solid or ribbed slabs built integrally with supports, with clear spans not more than 10 ft, as continuous slabs on knife edge supports with spans equal to the clear spans of the slab and width of beams otherwise neglected.

8.8 — Columns

8.8.1 — Columns shall be designed to resist the axial forces from factored loads on all floors or roof and the maximum moment from factored loads on a single adjacent span of the floor or roof under consideration. Loading condition giving the maximum ratio of moment to axial load shall also be considered.

8.8.2 — In frames or continuous construction, consideration shall be given to the effect of unbalanced floor or roof loads on both exterior and interior columns and of eccentric loading due to other causes.

8.8.3 — In computing gravity load moments in columns, it shall be permitted to assume far ends of columns built integrally with the structure to be fixed.

8.8.4 — Resistance to moments at any floor or roof level shall be provided by distributing the moment between columns immediately above and below the given floor in proportion to the relative column stiffnesses and conditions of restraint.

8.9 — Arrangement of live load

8.9.1 — It shall be permitted to assume that:

(a) The live load is applied only to the floor or roof under consideration, and

(b) The far ends of columns built integrally with the structure are considered to be fixed.

8.9.2 — It shall be permitted to assume that the arrangement of live load is limited to combinations of:

(a) Factored dead load on all spans with full factored live load on two adjacent spans, and

(b) Factored dead load on all spans with full factored live load on alternate spans.

COMMENTARY

R8.8 — Columns

Section 8.8 has been developed with the intent of making certain that the most demanding combinations of axial load and moments be identified for design.

Section 8.8.4 has been included to make certain that moments in columns are recognized in design if the girders have been proportioned using 8.3.3. The "moment" in 8.8.4 refers to the difference between the moments in a given vertical plane, exerted at column centerline by members framing into that column.

R8.9 — Arrangement of live load

For determining column, wall, and beam moments and shears caused by gravity loads, the code permits the use of a model limited to the beams in the level considered and the columns above and below that level. Far ends of columns are to be considered as fixed for the purpose of analysis under gravity loads. This assumption does not apply to lateral load analysis. However in analysis for lateral loads, simplified methods (such as the portal method) may be used to obtain the moments, shears, and reactions for structures that are symmetrical and satisfy the assumptions used for such simplified methods. For unsymmetrical and high-rise structures, rigorous methods recognizing all structural displacements should be used.

The engineer is expected to establish the most demanding sets of design forces by investigating the effects of live load placed in various critical patterns.

Most approximate methods of analysis neglect effects of deflections on geometry and axial flexibility. Therefore, beam and column moments may have to be amplified for column slenderness in accordance with 10.11, 10.12, and 10.13.

CODE

8.10 — T-beam construction

8.10.1 — In T-beam construction, the flange and web shall be built integrally or otherwise effectively bonded together.

8.10.2 — Width of slab effective as a T-beam flange shall not exceed one-quarter of the span length of the beam, and the effective overhanging flange width on each side of the web shall not exceed:

(a) eight times the slab thickness, and

(b) one-half the clear distance to the next web.

8.10.3 — For beams with a slab on one side only, the effective overhanging flange width shall not exceed:

(a) one-twelfth the span length of the beam,

(b) six times the slab thickness, and

(c) one-half the clear distance to the next web.

8.10.4 — Isolated beams, in which the T-shape is used to provide a flange for additional compression area, shall have a flange thickness not less than one-half the width of web and an effective flange width not more than four times the width of web.

8.10.5 — Where primary flexural reinforcement in a slab that is considered as a T-beam flange (excluding joist construction) is parallel to the beam, reinforcement perpendicular to the beam shall be provided in the top of the slab in accordance with the following:

8.10.5.1 — Transverse reinforcement shall be designed to carry the factored load on the overhanging slab width assumed to act as a cantilever. For isolated beams, the full width of overhanging flange shall be considered. For other T-beams, only the effective overhanging slab width need be considered.

8.10.5.2 — Transverse reinforcement shall be spaced not farther apart than five times the slab thickness, nor 18 in.

8.11 — Joist construction

8.11.1 — Joist construction consists of a monolithic combination of regularly spaced ribs and a top slab arranged to span in one direction or two orthogonal directions.

8.11.2 — Ribs shall be not less than 4 in. in width, and shall have a depth of not more than $3^1/_2$ times the minimum width of rib.

COMMENTARY

R8.10 — T-beam construction

This section contains provisions identical to those of previous ACI Building Codes for limiting dimensions related to stiffness and flexural calculations. Special provisions related to T-beams and other flanged members are stated in 11.6.1 with regard to torsion.

R8.11 — Joist construction

The size and spacing limitations for concrete joist construction meeting the limitations of 8.11.1 through 8.11.3 are based on successful performance in the past.

CODE

8.11.3 — Clear spacing between ribs shall not exceed 30 in.

8.11.4 — Joist construction not meeting the limitations of 8.11.1 through 8.11.3 shall be designed as slabs and beams.

8.11.5 — When permanent burned clay or concrete tile fillers of material having a unit compressive strength at least equal to that of the specified strength of concrete in the joists are used:

8.11.5.1 — For shear and negative moment strength computations, it shall be permitted to include the vertical shells of fillers in contact with the ribs. Other portions of fillers shall not be included in strength computations.

8.11.5.2 — Slab thickness over permanent fillers shall be not less than one-twelfth the clear distance between ribs, nor less than $1^1/_2$ in.

8.11.5.3 — In one-way joists, reinforcement normal to the ribs shall be provided in the slab as required by 7.12.

8.11.6 — When removable forms or fillers not complying with 8.11.5 are used:

8.11.6.1 — Slab thickness shall be not less than one-twelfth the clear distance between ribs, nor less than 2 in.

8.11.6.2 — Reinforcement normal to the ribs shall be provided in the slab as required for flexure, considering load concentrations, if any, but not less than required by 7.12.

8.11.7 — Where conduits or pipes as permitted by 6.3 are embedded within the slab, slab thickness shall be at least 1 in. greater than the total overall depth of the conduits or pipes at any point. Conduits or pipes shall not impair significantly the strength of the construction.

8.11.8 — For joist construction, contribution of concrete to shear strength V_c shall be permitted to be 10 percent more than that specified in Chapter 11. It shall be permitted to increase shear strength using shear reinforcement or by widening the ends of ribs.

8.12 — Separate floor finish

8.12.1 — A floor finish shall not be included as part of a structural member unless placed monolithically with

COMMENTARY

R8.11.3 — A limit on the maximum spacing of ribs is required because of the special provisions permitting higher shear strengths and less concrete protection for the reinforcement for these relatively small, repetitive members.

R8.11.8 — The increase in shear strength permitted by 8.11.8 is justified on the basis of: (1) satisfactory performance of joist construction with higher shear strengths, designed under previous ACI Building Codes, which allowed comparable shear stresses, and (2) redistribution of local overloads to adjacent joists.

R8.12 — Separate floor finish

The code does not specify an additional thickness for wearing surfaces subjected to unusual conditions of wear. The

CODE

the floor slab or designed in accordance with requirements of Chapter 17.

8.12.2 — It shall be permitted to consider all concrete floor finishes as part of required cover or total thickness for nonstructural considerations.

COMMENTARY

need for added thickness for unusual wear is left to the discretion of the designer.

As in previous editions of the code, a floor finish may be considered for strength purposes only if it is cast monolithically with the slab. Permission is given to include a separate finish in the structural thickness if composite action is provided for in accordance with Chapter 17.

All floor finishes may be considered for nonstructural purposes such as cover for reinforcement, fire protection, etc. Provisions should be made, however, to ensure that the finish will not spall off, thus causing decreased cover. Furthermore, development of reinforcement considerations require minimum monolithic concrete cover according to 7.7.

CHAPTER 9 — STRENGTH AND SERVICEABILITY REQUIREMENTS

CODE

9.0 — Notation

A_g = gross area of section, in.^{2}
A_s' = area of compression reinforcement, in.^{2}
b = width of compression face of member, in.
c = distance from extreme compression fiber to neutral axis, in.
d = distance from extreme compression fiber to centroid of tension reinforcement, in.
d' = distance from extreme compression fiber to centroid of compression reinforcement, in.
d_s = distance from extreme tension fiber to centroid of tension reinforcement, in.
d_t = distance from extreme compression fiber to extreme tension steel, in.
D = dead loads, or related internal moments and forces
E = load effects of earthquake, or related internal moments and forces
E_c = modulus of elasticity of concrete, psi. See 8.5.1
f_c' = specified compressive strength of concrete, psi
$\sqrt{f_c'}$ = square root of specified compressive strength of concrete, psi
f_{ct} = average splitting tensile strength of lightweight aggregate concrete, psi
f_r = modulus of rupture of concrete, psi
f_y = specified yield strength of nonprestressed reinforcement, psi
F = loads due to weight and pressures of fluids with well-defined densities and controllable maximum heights, or related internal moments and forces
h = overall thickness of member, in.
H = loads due to weight and pressure of soil, water in soil, or other materials, or related internal moments and forces
I_{cr} = moment of inertia of cracked section transformed to concrete
I_e = effective moment of inertia for computation of deflection
I_g = moment of inertia of gross concrete section about centroidal axis, neglecting reinforcement
ℓ = span length of beam or one-way slab, as defined in 8.7; clear projection of cantilever, in.
ℓ_n = length of clear span in long direction of two-way construction, measured face-to-face of

COMMENTARY

R9. 0 — Notation

CODE

supports in slabs without beams and face-to-face of beams or other supports in other cases

L = live loads, or related internal moments and forces

M_a = maximum moment in member at stage deflection is computed

M_{cr} = cracking moment. See 9.5.2.3

P_b = nominal axial load strength at balanced strain conditions. See 10.3.2

P_n = nominal axial load strength at given eccentricity

T = cumulative effect of temperature, creep, shrinkage, differential settlement, and shrinkage-compensating concrete

U = required strength to resist factored loads or related internal moments and forces

W = wind load, or related internal moments and forces

w_c = weight of concrete, lb/ft^3

y_t = distance from centroidal axis of gross section, neglecting reinforcement, to extreme fiber in tension

α = ratio of flexural stiffness of beam section to flexural stiffness of a width of slab bounded laterally by centerlines of adjacent panels (if any) on each side of beam. See Chapter 13

α_m = average value of α for all beams on edges of a panel

β = ratio of clear spans in long to short direction of two-way slabs

ε_t = net tensile strain in extreme tension steel at nominal strength

λ = multiplier for additional long-term deflection as defined in 9.5.2.5

ξ = time-dependent factor for sustained load. See 9.5.2.5

ρ = ratio of nonprestressed tension reinforcement, A_s/bd

ρ' = reinforcement ratio for nonprestressed compression reinforcement, A_s'/bd

ρ_b = reinforcement ratio producing balanced strain conditions. See B.10.3.2

ϕ = strength reduction factor. See 9.3

COMMENTARY

The definition of net tensile strain in 2.1 excludes strains due to effective prestress, creep, shrinkage, and temperature.

9.1 — General

9.1.1 — Structures and structural members shall be designed to have design strengths at all sections at least equal to the required strengths calculated for the factored loads and forces in such combinations as are stipulated in this code.

9.1.2 — Members also shall meet all other requirements of this code to ensure adequate performance at service load levels.

R9.1 — General

R9.1.1 — Chapter 9 defines the basic strength and serviceability conditions for proportioning reinforced concrete members.

The basic requirement for strength design may be expressed as follows:

Design Strength ≥ Required Strength

CODE

COMMENTARY

$$\phi \text{ (Nominal Strength)} \geq U$$

In the strength design procedure, the margin of safety is provided by multiplying the service load by a load factor and the nominal strength by a strength reduction factor as described below.

1. The "required strength" U is computed by multiplying the service loads by load factors. Thus, for example, the factored moment M_u or "required moment strength" for dead and live load is computed as:

$$U = 1.4D + 1.7L$$

or

$$M_u = 1.4M_d + 1.7M_\ell$$

where M_d and M_ℓ are the moments caused by service dead and live loads. The required strength is discussed in detail in the commentary for 9.2. The definition and notations for required strength are discussed in the commentary for Chapter 2.

2. The "design strength" of a structural element is computed by multiplying the "nominal strength" by a strength reduction factor ϕ which is less than one. The strength reduction factor accounts for uncertainties in design computations and the relative importance of various types of members. This factor also reflects the effect of variations in material strengths, workmanship, and dimensions that may combine to result in understrength. The "nominal strength" is computed by the code procedures assuming the member will have the exact dimensions and material properties used in the computations.[9.1] For example, the design strength in flexure of a cross section (without compression reinforcement) may be expressed as:

$$\phi M_n = \phi\left[A_s f_y\left(d - \frac{a}{2}\right)\right]$$

The design strength and the strength reduction factor ϕ are discussed in detail in the commentary for 9.3.

Combining these two safety provisions, the basic requirement for the design of a beam cross section can be stated as:

$$\text{Design Strength} \geq \text{Required Strength}$$

$$\phi M_n \geq M_u$$

$$\phi\left[A_s f_y\left(d - \frac{a}{2}\right)\right] \geq 1.4M_d + 1.7\,M_\ell$$

All notations with the subscript **u** such as M_u, P_u, and V_u, refer only to the required strength values. The design strength values are noted by ϕ times nominal strength, such as ϕM_n, ϕP_n, and ϕV_n.

CODE

9.2 — Required strength

9.2.1 — Required strength ***U*** to resist dead load ***D*** and live load ***L*** shall be at least equal to

$$U = 1.4D + 1.7L \quad (9\text{-}1)$$

9.2.2 — If resistance to structural effects of a specified wind load ***W*** are included in design, the following combinations of ***D***, ***L***, and ***W*** shall be investigated to determine the greatest required strength ***U***

$$U = 0.75\,(1.4D + 1.7L + 1.7W) \quad (9\text{-}2)$$

where load combinations shall include both full value and zero value of ***L*** to determine the more severe condition, and

$$U = 0.9D + 1.3W \quad (9\text{-}3)$$

but for any combination of ***D***, ***L***, and ***W***, required strength ***U*** shall not be less than Eq. (9-1).

9.2.3 — If resistance to specified earthquake loads or forces ***E*** are included in design, load combinations of 9.2.2 shall apply, except that **1.1*E*** shall be substituted for ***W***.

9.2.4 — If resistance to earth pressure ***H*** is included in design, required strength ***U*** shall be at least equal to

$$U = 1.4D + 1.7L + 1.7H \quad (9\text{-}4)$$

except that where ***D*** or ***L*** reduce the effect of ***H***, **0.9*D***

COMMENTARY

R9.2 — Required strength

The required strength U is expressed in terms of factored loads, or related internal moments and forces. Factored loads are the loads specified in the general building code multiplied by appropriate load factors.

The factor assigned to each load is influenced by the degree of accuracy to which the load effect usually can be calculated and the variation that might be expected in the load during the lifetime of the structure. Dead loads, because they are more accurately determined and less variable, are assigned a lower load factor than live loads. Load factors also account for variability in the structural analysis used to compute moments and shears.

The code gives load factors for specific combinations of loads. In assigning factors to combinations of loading, some consideration is given to the probability of simultaneous occurrence. While most of the usual combinations of loadings are included, the designer should not assume that all cases are covered.

Due regard is to be given to sign in determining U for combinations of loadings, as one type of loading may produce effects of opposite sense to that produced by another type. The load combinations with **0.9*D*** are specifically included for the case where a higher dead load reduces the effects of other loads.

Consideration must be given to various combinations of loading to determine the most critical design condition. This is particularly true when strength is dependent on more than one load effect, such as strength for combined flexure and axial load or shear strength in members with axial load.

If special circumstances require greater reliance on the strength of particular members than encountered in usual practice, some reduction in the stipulated strength reduction factors ϕ or increase in the stipulated load factors U may be appropriate for such members.

R9.2.3 — If earthquake effects must be considered in design, Eq. (9-2) and (9-3) become:

$$U = 1.05D + 1.28L + 1.40E$$

and

$$U = 0.90D + 1.43E$$

R9.2.4 — If effects H caused by earth pressure, groundwater pressure, or pressure caused by granular materials are included in design, the required strength equations become:

$$U = 1.4D + 1.7L + 1.7H$$

and where D or L reduce the effect of H

CODE

shall be substituted for **1.4*D*** and zero value of ***L*** shall be used to determine the greatest required strength ***U***. For any combination of ***D***, ***L***, and ***H***, required strength **U** shall not be less than Eq. (9-1).

9.2.5 — If resistance to loadings due to weight and pressure of fluids with well-defined densities and controllable maximum heights ***F*** is included in design, such loading shall have a load factor of 1.4, and be added to all loading combinations that include live load.

9.2.6 — If resistance to impact effects is taken into account in design, such effects shall be included with live load ***L***.

9.2.7 — Where structural effects ***T*** of differential settlement, creep, shrinkage, expansion of shrinkage-compensating concrete, or temperature change are significant in design, required strength ***U*** shall be at least equal to

$$U = 0.75(1.4D + 1.4T + 1.7L) \quad (9\text{-}5)$$

but required strength ***U*** shall not be less than

$$U = 1.4(D + T) \quad (9\text{-}6)$$

Estimations of differential settlement, creep, shrinkage, expansion of shrinkage-compensating concrete, or temperature change shall be based on a realistic assessment of such effects occurring in service.

9.3 — Design strength

9.3.1 — Design strength provided by a member, its connections to other members, and its cross sections, in terms of flexure, axial load, shear, and torsion, shall

COMMENTARY

$$U = 0.9D + 1.7H$$

but for any combination of ***D***, ***L***, or ***H***

$$U = 1.4D + 1.7L$$

R9.2.5 — This section addresses the need to consider loading due to weight of liquid or liquid pressure. It specifies a load factor for such loadings with well-defined densities and controllable maximum heights equivalent to that used for dead load. Such reduced factors would not be appropriate where there is considerable uncertainty of pressures, as with groundwater pressures or uncertainty as to the possible maximum liquid depth as in ponding of water. See discussion on ponding in R8.2.

For well-defined fluid pressures, the required strength equations become:

$$U = 1.4D + 1.7L + 1.4F$$

and where ***D*** or ***L*** reduce the effect of ***F***

$$U = 0.9D + 1.4F$$

but for any combination of ***D***, ***L***, or ***F***

$$U = 1.4D + 1.7L$$

R9.2.6 — If the live load is applied rapidly, as may be the case for parking structures, loading docks, warehouse floors, elevator shafts, etc., impact effects should be considered. In all equations substitute (***L*** + impact) for ***L*** when impact must be considered.

R9.2.7 — The designer should consider the effects of differential settlement, creep, shrinkage, temperature, and shrinkage-compensating concrete. The term "realistic assessment" is used to indicate that the most probable values rather than the upper bound values of the variables should be used.

Eq. (9-6) is to prevent a design for load

$$U = 0.75\ (1.4D + 1.4T + 1.7L)$$

to approach

$$U = 1.05\ (D + T)$$

when live load is negligible.

R9.3 — Design strength

R9.3.1 — The term "design strength" of a member, refers to the nominal strength calculated in accordance with the requirements stipulated in this code multiplied by a strength

CODE

be taken as the nominal strength calculated in accordance with requirements and assumptions of this code, multiplied by the strength reduction factors ϕ in 9.3.2 and 9.3.4.

9.3.1.1 — If the structural framing includes primary members of other materials proportioned to satisfy the load factor combinations in Section 2.4 of ASCE 7, it shall be permitted to proportion the concrete members using the set of strength reduction factors ϕ listed in Appendix C and the load factor combinations in ASCE 7.

9.3.2 — Strength reduction factor ϕ shall be as follows:

9.3.2.1 — Flexure, without axial load 0.90

9.3.2.2 — Axial load, and axial load with flexure. (For axial load with flexure, both axial load and moment nominal strength shall be multiplied by appropriate single value of ϕ)

(a) Axial tension, and axial tension with flexure 0.90

(b) Axial compression, and axial compression with flexure:
Members with spiral reinforcement conforming to 10.9.3 ..... 0.75
Other reinforced members 0.70

except that for low values of axial compression ϕ shall be permitted to be increased in accordance with the following:

For members in which f_y does not exceed 60,000 psi, with symmetric reinforcement, and with $(h-d'-d_s)/h$ not less than 0.70, ϕ shall be permitted to be increased linearly to 0.90 as ϕP_n decreases from $0.10 f_c' A_g$ to zero.

For other reinforced members, ϕ shall be permitted to be increased linearly to 0.90 as ϕP_n decreases from $0.10 f_c' A_g$ or ϕP_b, whichever is smaller, to zero.

9.3.2.3 — Shear and torsion 0.85

9.3.2.4 — Bearing on concrete (See also 18.13) 0.70

COMMENTARY

reduction factor ϕ, which is always less than one.

The purposes of the strength reduction factor ϕ are (1) to allow for the probability of understrength members due to variations in material strengths and dimensions, (2) to allow for inaccuracies in the design equations, (3) to reflect the degree of ductility and required reliability of the member under the load effects being considered, and (4) to reflect the importance of the member in the structure.[9.2,9.3] For example, a lower ϕ is used for columns than for beams because columns generally have less ductility, are more sensitive to variations in concrete strength, and generally support larger loaded areas than beams. Furthermore, spiral columns are assigned a higher ϕ than tied columns since they have greater ductility or toughness.

R9.3.1.1 — Appendix C has been included in order to facilitate computations for buildings with substantial portions of their structural framing provided by elements other than concrete. If the strength reduction factors in Appendix C are used for the concrete elements, the required strengths are to be determined using the load factor combinations in Section 2.4 of ASCE 7.

R9.3.2.2 — For members subjected to axial load with flexure, design strengths are determined by multiplying both P_n and M_n by the appropriate single value of ϕ. For members subjected to flexure and relatively small axial compression loads, failure is initiated by yielding of the tension reinforcement and takes place in an increasingly more ductile manner as the ratio of axial load to moment decreases. At the same time the variability of the strength also decreases. For small axial loads the value of ϕ may be increased from that for compression members to 0.90 permitted for flexure as the design axial load strength ϕP_n decreases from a specified value to zero.

For members meeting the limitations specified for $(h-d'-d_s)/h$ and f_y, the transition starts at a design axial load strength, ϕP_n of $0.10 f_c' A_g$. For other conditions, P_b must be calculated to determine the upper value of design axial load strength ϕP_n (the smaller of $0.10 f_c' A_g$ and ϕP_b) below which an increase in ϕ can be made.

The ϕ-factor for bearing on concrete in this section does not apply to post-tensioning anchorage bearing plates (see commentary on 18.13).

CODE

9.3.3 — Development lengths specified in Chapter 12 do not require a ϕ-factor.

9.3.4 — In regions of high seismic risk, strength reduction factors ϕ shall be given as above except for the following:

9.3.4.1 — Except for determining the strength of joints, the shear strength reduction factor shall be 0.6 for any structural member if its nominal shear strength is less than the shear corresponding to the development of the nominal flexural strength of the member. The nominal flexural strength shall be determined considering the most critical factored axial loads and including earthquake effects. Shear strength reduction factor for joints shall be 0.85.

9.3.5 — Strength reduction factor ϕ for flexure, compression, shear, and bearing of structural plain concrete in Chapter 22 shall be 0.65.

9.4 — Design strength for reinforcement

Designs shall not be based on a yield strength of reinforcement f_y in excess of 80,000 psi, except for prestressing tendons.

9.5 — Control of deflections

9.5.1 — Reinforced concrete members subjected to flexure shall be designed to have adequate stiffness to limit deflections or any deformations that affect strength or serviceability of a structure adversely.

COMMENTARY

R9.3.4 — Strength reduction factors in 9.3.4 are intended to compensate for uncertainties in estimation of strength of structural members in buildings. They are based primarily on experience with constant or steadily increasing applied load. For construction in regions of high seismic risk, some of the strength reduction factors have been modified in 9.3.4 to account for the effects on strength of displacements into the nonlinear range of response.

Section 9.3.4.1 refers to brittle members such as low-rise walls or portions of walls between openings of which proportions are such that it becomes impractical to reinforce them to raise their nominal shear strength above the shear corresponding to nominal flexural strength for the pertinent loading conditions. This requirement does not apply to calculations for evaluating the shear strength of connections.

R9.3.5 — The strength reduction factor ϕ for structural plain concrete design is made the same for all strength conditions. Since both flexural tension strength and shear strength for plain concrete depend on the tensile strength characteristics of the concrete, with no reserve strength or ductility possible due to the absence of reinforcement, equal strength reduction factors for both bending and shear are considered appropriate.

R9.4 — Design strength for reinforcement

Reinforcing bars with a yield strength of 75,000 psi in sizes No. 11, 14, and 18 and yield measured at a strain of 0.0035 and so meeting the requirements of this code were first included in ASTM A 615-87.

In addition to the upper limit of 80,000 psi for yield strength of nonprestressed reinforcement, there are limitations on yield strength in other sections of the code:

Sections 11.5.2, 11.6.3.4, and 11.7.6: the maximum f_y that may be used in design for shear and torsion reinforcement is 60,000 psi, except that f_y up to 80,000 psi may be used for shear reinforcement meeting the requirements of ASTM A 497.

Sections 19.3.2 and 21.2.5: the maximum specified f_y is 60,000 psi in shells, folded plates, and structures governed by the special seismic provisions of Chapter 21.

The deflection provisions of 9.5 and the limitations on distribution of flexural reinforcement of 10.6 become increasingly critical as f_y increases.

R9.5 — Control of deflections[9.4]

R9.5.1 — The provisions of 9.5 are concerned only with deflections or deformations which may occur at service load levels. Where long-term deflections are computed, only the dead load and that portion of the live load which is sustained need be considered.

CODE

COMMENTARY

Two methods are given for controlling deflections. For nonprestressed beams and one-way slabs, and for composite members, provision of a minimum overall thickness as required by Table 9.5(a) will satisfy the requirements of the code for members not supporting or attached to partitions or other construction likely to be damaged by large deflections. For nonprestressed two-way construction, minimum thickness as required by 9.5.3.1, 9.5.3.2, and 9.5.3.3 will satisfy the requirements of the code.

For nonprestressed members which do not meet these minimum thickness requirements or which support or are attached to partitions or other construction likely to be damaged by large deflections, and for all prestressed concrete flexural members, deflections must be calculated by the procedures described or referred to in the appropriate sections of the code, and are limited to the values in Table 9.5(b).

9.5.2 — One-way construction (nonprestressed)

9.5.2.1 — Minimum thickness stipulated in Table 9.5(a) shall apply for one-way construction not supporting or attached to partitions or other construction likely to be damaged by large deflections, unless computation of deflection indicates a lesser thickness can be used without adverse effects.

TABLE 9.5(a)—MINIMUM THICKNESS OF NONPRESTRESSED BEAMS OR ONE-WAY SLABS UNLESS DEFLECTIONS ARE COMPUTED*

	Minimum thickness, h			
	Simply supported	One end continuous	Both ends continuous	Cantilever
Member	Members not supporting or attached to partitions or other construction likely to be damaged by large deflections.			
Solid one-way slabs	$\ell/20$	$\ell/24$	$\ell/28$	$\ell/10$
Beams or ribbed one-way slabs	$\ell/16$	$\ell/18.5$	$\ell/21$	$\ell/8$

* Span length ℓ is in inches.
Values given shall be used directly for members with normal weight concrete (w_c = 145 lb/ft^3) and Grade 60 reinforcement. For other conditions, the values shall be modified as follows:
a) For structural lightweight concrete having unit weight in the range 90-120 lb/ft^3, the values shall be multiplied by $(1.65 - 0.005 w_c)$ but not less than 1.09, where w_c is the unit weight in lb/ft^3.
b) For f_y other than 60,000 psi, the values shall be multiplied by $(0.4 + f_y/100{,}000)$.

9.5.2.2 — Where deflections are to be computed, deflections that occur immediately on application of load shall be computed by usual methods or formulas for elastic deflections, considering effects of cracking and reinforcement on member stiffness.

R9.5.2 — One-way construction (nonprestressed)

R9.5.2.1 — The minimum thicknesses of Table 9.5(a) apply for nonprestressed beams and one-way slabs (see 9.5.2), and for composite members (see 9.5.5).

It should be emphasized that these minimum thicknesses apply only to members not supporting or attached to partitions and other construction likely to be damaged by deflection.

Values of minimum thickness must be modified if other than normal weight concrete and Grade 60 reinforcement are used. The notes beneath the table are essential to its use for reinforced concrete members constructed with structural lightweight concrete and/or with reinforcement having a yield strength other than 60,000 psi. If both of these conditions exist, the corrections in footnotes (a) and (b) shall both be applied.

The modification for lightweight concrete in footnote (a) is based on studies of the results and discussions in Reference 9.5. No correction is specified for concretes weighing between 120 and 145 lb/ft^3 because the correction term would be close to unity in this range.

The modification for yield strength in footnote (b) is approximate but should yield conservative results for the type of members considered in the table, for typical reinforcement ratios, and for values of f_y between 40,000 and 80,000 psi.

R9.5.2.2 — For calculation of immediate deflections of uncracked prismatic members, the usual methods or formulas for elastic deflections may be used with a constant value of $E_c I_g$ along the length of the member. However, if the member is cracked at one or more sections, or if its depth

CODE

9.5.2.3 — Unless stiffness values are obtained by a more comprehensive analysis, immediate deflection shall be computed with the modulus of elasticity E_c for concrete as specified in 8.5.1 (normal weight or lightweight concrete) and with the effective moment of inertia as follows, but not greater than I_g.

$$I_e = \left(\frac{M_{cr}}{M_a}\right)^3 I_g + \left[1 - \left(\frac{M_{cr}}{M_a}\right)^3\right] I_{cr} \qquad (9\text{-}7)$$

where

$$M_{cr} = \frac{f_r I_g}{y_t} \qquad (9\text{-}8)$$

and for normal weight concrete,

$$f_r = 7.5\sqrt{f_c'} \qquad (9\text{-}9)$$

When lightweight aggregate concrete is used, one of the following modifications shall apply:

(a) When f_{ct} is specified and concrete is proportioned in accordance with 5.2, f_r shall be modified by substituting $f_{ct}/6.7$ for $\sqrt{f_c'}$, but the value of $f_{ct}/6.7$ shall not exceed $\sqrt{f_c'}$.

(b) When f_{ct} is not specified, f_r shall be multiplied by 0.75 for "all-lightweight" concrete, and 0.85 for "sand-lightweight" concrete. Linear interpolation shall be permitted if partial sand replacement is used.

9.5.2.4 — For continuous members, effective moment of inertia shall be permitted to be taken as the average of values obtained from Eq. (9-7) for the critical positive and negative moment sections. For prismatic members, effective moment of inertia shall be permitted to be taken as the value obtained from Eq. (9-7) at midspan for simple and continuous spans, and at support for cantilevers.

9.5.2.5 — Unless values are obtained by a more comprehensive analysis, additional long-term deflection resulting from creep and shrinkage of flexural members (normal weight or lightweight concrete) shall be determined by multiplying the immediate deflection caused by the sustained load considered, by the factor

$$\lambda = \frac{\xi}{1 + 50\rho'} \qquad (9\text{-}10)$$

where ρ' shall be the value at midspan for simple and

COMMENTARY

varies along the span, a more exact calculation becomes necessary.

R9.5.2.3 — The effective moment of inertia procedure described in the code and developed in Reference 9.6 was selected as being sufficiently accurate for use to control deflections.[9.7-9.9] The effective I_e was developed to provide a transition between the upper and lower bounds of I_g and I_{cr} as a function of the ratio M_{cr}/M_a. For most practical cases I_e will be less than I_g.

R9.5.2.4 — For continuous members, the code procedure suggests a simple averaging of I_e values for the positive and negative moment sections. The use of the midspan section properties for continuous prismatic members is considered satisfactory in approximate calculations primarily because the midspan rigidity (including the effect of cracking) has the dominant effect on deflections, as shown by ACI Committee 435[9.10,9.11] and SP-43.[9.4]

R9.5.2.5 — Shrinkage and creep due to sustained loads cause additional "long-term deflections" over and above those which occur when loads are first placed on the structure. Such deflections are influenced by temperature, humidity, curing conditions, age at time of loading, quantity of compression reinforcement, magnitude of the sustained load, and other factors. The expression given in this section is considered satisfactory for use with the code procedures for the calculation of immediate deflections, and with the limits given in Table 9.5(b). It should also be noted that the deflection computed in accordance with this section is the

CODE

continuous spans, and at support for cantilevers. It shall be permitted to assume the time-dependent factor ξ for sustained loads to be equal to

5 years or more	2.0
12 months	1.4
6 months	1.2
3 months	1.0

9.5.2.6 — Deflection computed in accordance with 9.5.2.2 through 9.5.2.5 shall not exceed limits stipulated in Table 9.5(b).

COMMENTARY

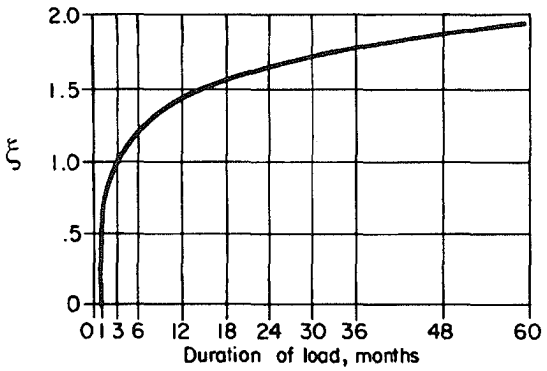

Fig. R9.5.2.5—Multipliers for long-term deflections

additional long-term deflection due to the dead load and that portion of the live load which will be sustained for a sufficient period to cause significant time-dependent deflections.

Equation (9-10) was developed in Reference 9.13. In Eq. (9-10) the multiplier on ξ accounts for the effect of compression reinforcement in reducing long-term deflections, and $\xi = 2.0$ represents a nominal time-dependent factor for 5 years duration of loading. The curve in Fig. R9.5.2.5 may be used to estimate values of ξ for loading periods less than five years.

If it is desired to consider creep and shrinkage separately, approximate equations provided in References 9.6, 9.7, 9.13, and 9.14 may be used.

R9.5.2.6 — It should be noted that the limitations given in this table relate only to supported or attached nonstructural elements. For those structures in which structural members are likely to be affected by deflection or deformation of members to which they are attached in such a manner as to affect adversely the strength of the structure, these deflections and the resulting forces should be considered

TABLE 9.5(b)—MAXIMUM PERMISSIBLE COMPUTED DEFLECTIONS

Type of member	Deflection to be considered	Deflection limitation
Flat roofs not supporting or attached to nonstructural elements likely to be damaged by large deflections	Immediate deflection due to live load *L*	$\frac{\ell^*}{180}$
Floors not supporting or attached to nonstructural elements likely to be damaged by large deflections	Immediate deflection due to live load *L*	$\frac{\ell}{360}$
Roof or floor construction supporting or attached to nonstructural elements likely to be damaged by large deflections	That part of the total deflection occurring after attachment of nonstructural elements (sum of the long-term deflection due to all sustained loads and the immediate deflection due to any additional live load)†	$\frac{\ell^‡}{480}$
Roof or floor construction supporting or attached to nonstructural elements not likely to be damaged by large deflections		$\frac{\ell^§}{240}$

* Limit not intended to safeguard against ponding. Ponding should be checked by suitable calculations of deflection, including added deflections due to ponded water, and considering long-term effects of all sustained loads, camber, construction tolerances, and reliability of provisions for drainage.

† Long-term deflection shall be determined in accordance with 9.5.2.5 or 9.5.4.2, but may be reduced by amount of deflection calculated to occur before attachment of nonstructural elements. This amount shall be determined on basis of accepted engineering data relating to time-deflection characteristics of members similar to those being considered.

‡ Limit may be exceeded if adequate measures are taken to prevent damage to supported or attached elements.

§ But not greater than tolerance provided for nonstructural elements. Limit may be exceeded if camber is provided so that total deflection minus camber does not exceed limit.

CODE

COMMENTARY

explicitly in the analysis and design of the structures as required by 9.5.1. (See Reference 9.9.)

Where long-term deflections are computed, the portion of the deflection before attachment of the nonstructural elements may be deducted. In making this correction use may be made of the curve in Fig. R9.5.2.5 for members of usual sizes and shapes.

9.5.3 — Two-way construction (nonprestressed)

R9.5.3 — Two-way construction (nonprestressed)

9.5.3.1 — Section 9.5.3 shall govern the minimum thickness of slabs or other two-way construction designed in accordance with the provisions of Chapter 13 and conforming with the requirements of 13.6.1.2. The thickness of slabs without interior beams spanning between the supports on all sides shall satisfy the requirements of 9.5.3.2 or 9.5.3.4. The thickness of slabs with beams spanning between the supports on all sides shall satisfy requirements of 9.5.3.3 or 9.5.3.4.

9.5.3.2 — For slabs without interior beams spanning between the supports and having a ratio of long to short span not greater than 2, the minimum thickness shall be in accordance with the provisions of Table 9.5(c) and shall not be less than the following values:

(a) Slabs without drop panels as defined in 13.3.7.1 and 13.3.7.2 ..... 5 in.

(b) Slabs with drop panels as defined in 13.3.7.1 and 13.3.7.2 ..... 4 in.

R9.5.3.2 — The minimum thicknesses in Table 9.5(c) are those that have evolved through the years in building codes. It is assumed that slabs conforming to those limits have not resulted in systematic problems related to stiffness for short- and long-term loads. Naturally, this conclusion applies in only the domain of previous experience in loads, environment, materials, boundary conditions, and spans.

EQ 9.13 has been dropped from '89 code.

TABLE 9.5(c)—MINIMUM THICKNESS OF SLABS WITHOUT INTERIOR BEAMS

Yield strength, f_y, psi*	Without drop panels†			With drop panels†		
	Exterior panels		Interior panels	Exterior panels		Interior panels
	Without edge beams	With edge beams‡		Without edge beams	With edge beams‡	
40,000	$\frac{\ell_n}{33}$	$\frac{\ell_n}{36}$	$\frac{\ell_n}{36}$	$\frac{\ell_n}{36}$	$\frac{\ell_n}{40}$	$\frac{\ell_n}{40}$
60,000	$\frac{\ell_n}{30}$	$\frac{\ell_n}{33}$	$\frac{\ell_n}{33}$	$\frac{\ell_n}{33}$	$\frac{\ell_n}{36}$	$\frac{\ell_n}{36}$
75,000	$\frac{\ell_n}{28}$	$\frac{\ell_n}{31}$	$\frac{\ell_n}{31}$	$\frac{\ell_n}{31}$	$\frac{\ell_n}{34}$	$\frac{\ell_n}{34}$

* For values of reinforcement yield strength between the values given in the table, minimum thickness shall be determined by linear interpolation.

† Drop panel is defined in 13.3.7.1 and 13.3.7.2.

‡ Slabs with beams between columns along exterior edges. The value of α for the edge beam shall not be less than 0.8.

9.5.3.3 — For slabs with beams spanning between the supports on all sides, the minimum thickness shall be as follows:

(a) For α_m equal to or less than 0.2, the provisions of 9.5.3.2 shall apply.

R9.5.3.3 — For panels having a ratio of long to short span greater than 2, the use of Eq. (9-11) and (9-12), which express the minimum thickness as a fraction of the long span, may give unreasonable results. For such panels, the rules applying to one-way construction in 9.5.2 should be used.

CODE

(b) For α_m greater than 0.2 but not greater than 2.0, the thickness shall not be less than

$$h = \frac{\ell_n\left(0.8 + \frac{f_y}{200{,}000}\right)}{36 + 5\beta(\alpha_m - 0.2)} \quad (9\text{-}11)$$

and not less than 5 in.

(c) For α_m greater than 2.0, the thickness shall not be less than

$$h = \frac{\ell_n\left(0.8 + \frac{f_y}{200{,}000}\right)}{36 + 9\beta} \quad (9\text{-}12)$$

and not less than 3.5 in.

(d) At discontinuous edges, an edge beam shall be provided with a stiffness ratio α not less than 0.80 or the minimum thickness required by Eq. (9-11) or (9-12) shall be increased by at least 10 percent in the panel with a discontinuous edge.

9.5.3.4 — Slab thickness less than the minimum thickness required by 9.5.3.1, 9.5.3.2, and 9.5.3.3 shall be permitted to be used if shown by computation that the deflection will not exceed the limits stipulated in Table 9.5(b). Deflections shall be computed taking into account size and shape of the panel, conditions of support, and nature of restraints at the panel edges. The modulus of elasticity of concrete E_c shall be as specified in 8.5.1. The effective moment of inertia shall be that given by Eq. (9-7); other values shall be permitted to be used if they result in computed deflections in reasonable agreement with results of comprehensive tests. Additional long-term deflection shall be computed in accordance with 9.5.2.5.

9.5.4 — Prestressed concrete construction

9.5.4.1 — For flexural members designed in accordance with provisions of Chapter 18, immediate deflection shall be computed by usual methods or formulas for elastic deflections, and the moment of inertia of the gross concrete section shall be permitted to be used for uncracked sections.

COMMENTARY

The requirement in 9.5.3.3(a) for α_m equal to 0.2 makes it possible to eliminate Eq. (9-13) of ACI 318-89. That equation gave values essentially the same as those in Table 9.5(c), as does Eq. (9-11) at a value of α_m equal to 0.2.

In '89 +0.2 was β, was found to have little effect on h

R9.5.3.4 — The calculation of deflections for slabs is complicated even if linear elastic behavior can be assumed. For immediate deflections, the values of E_c and I_e specified in 9.5.2.3 may be used.[9.9] However, other procedures and other values of the stiffness EI may be used if they result in predictions of deflection in reasonable agreement with the results of comprehensive tests.

Since available data on long-term deflections of slabs are too limited to justify more elaborate procedures, the additional long-term deflection for two-way construction is required to be computed using the multipliers given in 9.5.2.5.

R9.5.4 — Prestressed concrete construction

The code requires deflections for all prestressed concrete flexural members to be computed and compared with the allowable values in Table 9.5(b).

R9.5.4.1 — Immediate deflections of prestressed concrete members may be calculated by the usual methods or formulas for elastic deflections using the moment of inertia of the gross (uncracked) concrete section and the modulus of elasticity for concrete specified in 8.5.1. Since this method assumes that the concrete is uncracked, it may be unconservative for members having a relatively high concrete tensile stress as permitted by 18.4.2(d). Hence, 18.4.2(d) requires calculation of deflection based on the transformed cracked section for members designed for a tensile stress in the precompressed tension zone equal to $12\sqrt{f_c'}$.

CODE

COMMENTARY

It has also been shown in Reference 9.15 that the I_e method can be used to compute deflections of partially prestressed members loaded above the cracking load. For this case, the cracking moment must take into account the effect of prestress. A method for predicting the effect of nonprestressed tension steel in reducing creep camber is also given in Reference 9.15 with approximate forms referred to in References 9.9 and 9.16.

9.5.4.2 — Additional long-term deflection of prestressed concrete members shall be computed taking into account stresses in concrete and steel under sustained load and including effects of creep and shrinkage of concrete and relaxation of steel.

R9.5.4.2 — Calculation of long-term deflections of prestressed concrete flexural members is complicated. The calculations must consider not only the increased deflections due to flexural stresses, but also the additional long-term deflections resulting from time-dependent shortening of the flexural member.

Prestressed concrete generally shortens more with time than similar nonprestressed members. This is due to the precompression in the slab or beam which causes axial creep. This creep together with shrinkage of the concrete results in significant shortening of the flexural members which continues for several years after construction and must be considered in design. The shortening tends to reduce the tension in the prestressing tendons, thus reducing the precompression in the member and thereby causing increased long-term deflections.

Another factor that can influence long-term deflections of prestressed flexural members is adjacent concrete or masonry nonprestressed in the direction of the prestressed member. This can be a slab nonprestressed in the beam direction adjacent to a prestressed beam or a nonprestressed slab system. As the prestressed member tends to shrink and creep more than the adjacent nonprestressed concrete, the structure will tend to reach a compatibility of the shortening effects. This results in a reduction of the precompression in the prestressed member as the adjacent concrete absorbs the compression. This reduction in precompression of the prestressed member can occur over a period of years and will result in additional long-term deflections, and in increased stresses in the prestressed member.

Any suitable method for calculating long-term deflections of prestressed members may be used, provided all effects are considered. Guidance may be found in References 9.9, 9.12, 9.15, 9.17, and 9.18.

9.5.4.3 — Deflection computed in accordance with 9.5.4.1 and 9.5.4.2 shall not exceed limits stipulated in Table 9.5(b).

9.5.5 — Composite construction

9.5.5.1 — Shored construction

If composite flexural members are supported during construction so that, after removal of temporary sup-

R9.5.5 — Composite construction

Since few tests have been made to study the immediate and long-term deflections of composite members, the rules given in 9.5.5.1 and 9.5.5.2 are based on the judgment of

CODE

ports, dead load is resisted by the full composite section, it shall be permitted to consider the composite member equivalent to a monolithically cast member for computation of deflection. For nonprestressed members, the portion of the member in compression shall determine whether values in Table 9.5(a) for normal weight or lightweight concrete shall apply. If deflection is computed, account shall be taken of curvatures resulting from differential shrinkage of precast and cast-in-place components, and of axial creep effects in a prestressed concrete member.

9.5.5.2 — Unshored construction

If the thickness of a nonprestressed precast flexural member meets the requirements of Table 9.5(a), deflection need not be computed. If the thickness of a nonprestressed composite member meets the requirements of Table 9.5(a), it is not required to compute deflection occurring after the member becomes composite, but the long-term deflection of the precast member shall be investigated for magnitude and duration of load prior to beginning of effective composite action.

9.5.5.3 — Deflection computed in accordance with 9.5.5.1 and 9.5.5.2 shall not exceed limits stipulated in Table 9.5(b).

COMMENTARY

ACI Committee 318 and on experience.

If any portion of a composite member is prestressed or if the member is prestressed after the components have been cast, the provisions of 9.5.4 apply and deflections must be calculated. For nonprestressed composite members, deflections need to be calculated and compared with the limiting values in Table 9.5(b) only when the thickness of the member or the precast part of the member is less than the minimum thickness given in Table 9.5(a). In unshored construction the thickness of concern depends on whether the deflection before or after the attainment of effective composite action is being considered. (In Chapter 17, it is stated that distinction need not be made between shored and unshored members. This refers to strength calculations, not to deflections.)

CHAPTER 10 — FLEXURE AND AXIAL LOADS

CODE

COMMENTARY

10.0 — Notation

R10.0 — Notation

a = depth of equivalent rectangular stress block as defined in 10.2.7.1

A = effective tension area of concrete surrounding the flexural tension reinforcement and having the same centroid as that reinforcement, divided by the number of bars or wires, in.^{2} When the flexural reinforcement consists of different bar or wire sizes the number of bars or wires shall be computed as the total area of reinforcement divided by the area of the largest bar or wire used

A_c = area of core of spirally reinforced compression member measured to outside diameter of spiral, in.^{2}

A_g = gross area of section, in.^{2}

A_s = area of nonprestressed tension reinforcement, in.^{2}

A_{sk} = area of skin reinforcement per unit height in one side face, in.^{2}/ft. See 10.6.7

$A_{s,min}$ = minimum amount of flexural reinforcement, in.^{2} See 10.5

A_{st} = total area of longitudinal reinforcement, (bars or steel shapes), in.^{2}

A_t = area of structural steel shape, pipe, or tubing in a composite section, in.^{2}

A_1 = loaded area

A_2 = the area of the lower base of the largest frustum of a pyramid, cone, or tapered wedge contained wholly within the support and having for its upper base the loaded area, and having side slopes of 1 vertical to 2 horizontal

b = width of compression face of member, in.

b_w = web width, in.

c = distance from extreme compression fiber to neutral axis, in.

C_m = a factor relating actual moment diagram to an equivalent uniform moment diagram

d = distance from extreme compression fiber to centroid of tension reinforcement, in.

d_c = thickness of concrete cover measured from extreme tension fiber to center of bar or wire located closest thereto, in.

d_t = distance from extreme compression fiber to extreme tension steel, in.

E_c = modulus of elasticity of concrete, psi. See 8.5.1

E_s = modulus of elasticity of reinforcement, psi. See 8.5.2 or 8.5.3

EI = flexural stiffness of compression member. See Eq. (10-12) and Eq. (10-13)

CODE

f_c' = specified compressive strength of concrete, psi

f_s = calculated stress in reinforcement at service loads, ksi

f_y = specified yield strength of nonprestressed reinforcement, psi

h = overall thickness of member, in.

I_g = moment of inertia of gross concrete section about centroidal axis, neglecting reinforcement

I_{se} = moment of inertia of reinforcement about centroidal axis of member cross section

I_t = moment of inertia of structural steel shape, pipe, or tubing about centroidal axis of composite member cross section

k = effective length factor for compression members

ℓ_c = length of compression member in a frame, measured from center to center of the joints in the frame

ℓ_u = unsupported length of compression member

M_c = factored moment to be used for design of compression member

M_s = moment due to loads causing appreciable sway

M_u = factored moment at section

M_1 = smaller factored end moment on a compression member, positive if member is bent in single curvature, negative if bent in double curvature

M_{1ns} = factored end moment on a compression member at the end at which M_1 acts, due to loads that cause no appreciable sidesway, calculated using a first-order elastic frame analysis

M_{1s} = factored end moment on compression member at the end at which M_1 acts, due to loads that cause appreciable sidesway, calculated using a first-order elastic frame analysis

M_2 = larger factored end moment on compression member, always positive

$M_{2,\,min}$ = minimum value of M_2

M_{2ns} = factored end moment on compression member at the end at which M_2 acts, due to loads that cause no appreciable sidesway, calculated using a first-order elastic frame analysis

M_{2s} = factored end moment on compression member at the end at which M_2 acts, due to loads that cause appreciable sidesway, calculated using a first-order elastic frame analysis

P_b = nominal axial load strength at balanced strain conditions. See 10.3.2

P_c = critical load. See Eq. (10-11)

COMMENTARY

CODE

P_n = nominal axial load strength at given eccentricity

P_o = nominal axial load strength at zero eccentricity

P_u = factored axial load at given eccentricity $\leq \phi P_n$

Q = stability index for a story. See 10.11.4

r = radius of gyration of cross section of a compression member

V_u = factored horizontal shear in a story

z = quantity limiting distribution of flexural reinforcement. See 10.6

β_1 = factor defined in 10.2.7.3

β_d = (a) for non-sway frames, β_d is the ratio of the maximum factored axial dead load to the total factored axial load
(b) for sway frames, except as required in (c), β_d is the ratio of the maximum factored sustained shear within a story to the total factored shear in that story
(c) for stability checks of sway frames carried out in accordance with 10.13.6, β_d is the ratio of the maximum factored sustained axial load to the total factored axial load

δ_{ns} = moment magnification factor for frames braced against sidesway, to reflect effects of member curvature between ends of compression member

δ_s = moment magnification factor for frames not braced against sidesway, to reflect lateral drift resulting from lateral and gravity loads

Δ_o = relative lateral deflection between the top and bottom of a story due to V_u, computed using a first-order elastic frame analysis and stiffness values satisfying 10.11.1

ε_t = net tensile strain in extreme tension steel at nominal strength

ρ = ratio of nonprestressed tension reinforcement
$= A_s/bd$

ρ_b = reinforcement ratio producing balanced strain conditions. See 10.3.2

ρ_s = ratio of volume of spiral reinforcement to total volume of core (out-to-out of spirals) of a spirally reinforced compression member

ϕ = strength reduction factor. See 9.3

ϕ_K = stiffness reduction factor. See R10.12.3

10.1 — Scope

Provisions of Chapter 10 shall apply for design of members subject to flexure or axial loads or to combined flexure and axial loads.

COMMENTARY

The definition of net tensile strain in 2.1 excludes strains due to effective prestress, creep, shrinkage, and temperature.

CODE

10.2 — Design assumptions

10.2.1 — Strength design of members for flexure and axial loads shall be based on assumptions given in 10.2.2 through 10.2.7, and on satisfaction of applicable conditions of equilibrium and compatibility of strains.

10.2.2 — Strain in reinforcement and concrete shall be assumed directly proportional to the distance from the neutral axis, except, for deep flexural members with overall depth to clear span ratios greater than $^2/_5$ for continuous spans and $^4/_5$ for simple spans, a nonlinear distribution of strain shall be considered. See 10.7.

10.2.3 — Maximum usable strain at extreme concrete compression fiber shall be assumed equal to 0.003.

10.2.4 — Stress in reinforcement below specified yield strength f_y for grade of reinforcement used shall be taken as E_s times steel strain. For strains greater than that corresponding to f_y, stress in reinforcement shall be considered independent of strain and equal to f_y.

10.2.5 — Tensile strength of concrete shall be neglected in axial and flexural calculations of reinforced concrete, except when meeting requirements of 18.4.

COMMENTARY

R10.2 — Design assumptions

R10.2.1 — The strength of a member computed by the strength design method of the code requires that two basic conditions be satisfied: (1) static equilibrium and (2) compatibility of strains. Equilibrium between the compressive and tensile forces acting on the cross section at nominal strength must be satisfied. Compatibility between the stress and strain for the concrete and the reinforcement at nominal strength conditions must also be established within the design assumptions allowed by 10.2.

R10.2.2—Many tests have confirmed that the distribution of strain is essentially linear across a reinforced concrete cross section, even near ultimate strength.

Both the strain in reinforcement and in concrete are assumed to be directly proportional to the distance from the neutral axis. This assumption is of primary importance in design for determining the strain and corresponding stress in the reinforcement.

R10.2.3 — The maximum concrete compressive strain at crushing of the concrete has been observed in tests of various kinds to vary from 0.003 to higher than 0.008 under special conditions. However, the strain at which ultimate moments are developed is usually about 0.003 to 0.004 for members of normal proportions and materials.

R10.2.4 — For deformed reinforcement, it is reasonably accurate to assume that the stress in reinforcement is proportional to strain below the yield strength f_y. The increase in strength due to the effect of strain hardening of the reinforcement is neglected for strength computations. In strength computations, the force developed in tensile or compressive reinforcement is computed as,

when $\varepsilon_s < \varepsilon_y$ (yield strain)

$$A_s f_s = A_s E_s \varepsilon_s$$

when $\varepsilon_s \geq \varepsilon_y$

$$A_s f_s = A_s f_y$$

where ε_s is the value from the strain diagram at the location of the reinforcement. For design, the modulus of elasticity of steel reinforcement E_s may be taken as 29,000,000 psi (see 8.5.2).

R10.2.5 — The tensile strength of concrete in flexure (modulus of rupture) is a more variable property than the compressive strength and is about 10 to 15 percent of the compressive strength. Tensile strength of concrete in flexure is neglected in strength design. For members with normal

CODE

COMMENTARY

percentages of reinforcement, this assumption is in good agreement with tests. For very small percentages of reinforcement, neglect of the tensile strength at ultimate is usually correct.

The strength of concrete in tension, however, is important in cracking and deflection considerations at service loads.

10.2.6 — Relationship between concrete compressive stress distribution and concrete strain shall be assumed to be rectangular, trapezoidal, parabolic, or any other shape that results in prediction of strength in substantial agreement with results of comprehensive tests.

R10.2.6 — This assumption recognizes the inelastic stress distribution of concrete at high stress. As maximum stress is approached, the stress-strain relationship for concrete is not a straight line but some form of a curve (stress is not proportional to strain). The general shape of a stress-strain curve is primarily a function of concrete strength and consists of a rising curve from zero to a maximum at a compressive strain between 0.0015 and 0.002 followed by a descending curve to an ultimate strain (crushing of the concrete) from 0.003 to higher than 0.008. As discussed under R10.2.3. the code sets the maximum usable strain at 0.003 for design.

The actual distribution of concrete compressive stress in a practical case is complex and usually not known explicitly. However, research has shown that the important properties of the concrete stress distribution can be approximated closely using any one of several different assumptions as to the form of stress distribution. The code permits any particular stress distribution to be assumed in design if shown to result in predictions of ultimate strength in reasonable agreement with the results of comprehensive tests. Many stress distributions have been proposed. The three most common are the parabola, trapezoid, and rectangle.

10.2.7 — Requirements of 10.2.6 are satisfied by an equivalent rectangular concrete stress distribution defined by the following:

10.2.7.1 — Concrete stress of $0.85f_c'$ shall be assumed uniformly distributed over an equivalent compression zone bounded by edges of the cross section and a straight line located parallel to the neutral axis at a distance $a = \beta_1 c$ from the fiber of maximum compressive strain.

10.2.7.2 — Distance c from fiber of maximum strain to the neutral axis shall be measured in a direction perpendicular to that axis.

10.2.7.3 — Factor β_1 shall be taken as 0.85 for concrete strengths f_c' up to and including 4000 psi. For strengths above 4000 psi, β_1 shall be reduced continuously at a rate of 0.05 for each 1000 psi of strength in excess of 4000 psi, but β_1 shall not be taken less than 0.65.

R10.2.7 — For practical design, the code allows the use of a rectangular compressive stress distribution (stress block) to replace the more exact concrete stress distributions. In the equivalent rectangular stress block, an average stress of $0.85f_c'$ is used with a rectangle of depth $a = \beta_1 c$. The β_1 of 0.85 for concrete with $f_c' \leq 4000$ psi and 0.05 less for each 1000 psi of f_c' in excess of 4000 was determined experimentally.

In the 1976 supplement to ACI 318-71, a lower limit of β_1 equal to 0.65 was adopted for concrete strengths greater than 8000 psi. Research data from tests with high strength concretes[10.1,10.2] supported the equivalent rectangular stress block for concrete strengths exceeding 8000 psi, with a β_1 equal to 0.65. Use of the equivalent rectangular stress distribution specified in ACI 318-71, with no lower limit on β_1, resulted in inconsistent designs for high strength concrete for members subject to combined flexure and axial load.

The rectangular stress distribution does not represent the actual stress distribution in the compression zone at ultimate, but does provide essentially the same results as those obtained in tests.[10.3]

CODE

10.3 — General principles and requirements

10.3.1 — Design of cross section subject to flexure or axial loads or to combined flexure and axial loads shall be based on stress and strain compatibility using assumptions in 10.2.

10.3.2 — Balanced strain conditions exist at a cross section when tension reinforcement reaches the strain corresponding to its specified yield strength f_y just as concrete in compression reaches its assumed ultimate strain of 0.003.

10.3.3 — For flexural members, and for members subject to combined flexure and compressive axial load when the design axial load strength ϕP_n is less than the smaller of $0.10 f_c' A_g$ or ϕP_b, the ratio of reinforcement ρ provided shall not exceed 0.75 of the ratio ρ_b that would produce balanced strain conditions for the section under flexure without axial load. For members with compression reinforcement, the portion of ρ_b equalized by compression reinforcement need not be reduced by the 0.75 factor.

COMMENTARY

R10.3 — General principles and requirements

R10.3.1 — Design strength equations for members subject to flexure or combined flexure and axial load are derived in the paper, "Rectangular Concrete Stress Distribution in Ultimate Strength Design."[10.3] Reference 10.3 and previous editions of this commentary also give the derivations of strength equations for cross sections other than rectangular.

R10.3.2 — A balanced strain condition exists at a cross section when the maximum strain at the extreme compression fiber just reaches 0.003 simultaneously with the first yield strain f_y/E_s in the tension reinforcement. The reinforcement ratio ρ_b, which produces balanced conditions under flexure, depends on the shape of the cross section and the location of the reinforcement.

R10.3.3 — The maximum amount of tension reinforcement in flexural members is limited to ensure a level of ductile behavior.

The ultimate flexural strength of a member is reached when the strain in the extreme compression fiber reaches the ultimate (crushing) strain of the concrete. At ultimate strain of the concrete, the strain in the tension reinforcement could just reach the strain at first yield, be less than the yield strain (elastic), or exceed the yield strain (inelastic). Which steel strain condition exists at ultimate concrete strain depends on the relative proportion of steel to concrete and material strengths f_c' and f_y. If $\rho(f_y/f_c')$ is sufficiently low, the strain in the tension steel will greatly exceed the yield strain when the concrete strain reaches its ultimate, with large deflection and ample warning of impending failure (ductile failure condition). With a larger $\rho(f_y/f_c')$, the strain in the tension steel may not reach the yield strain when the concrete strain reaches its ultimate, with consequent small deflection and little warning of impending failure (brittle failure condition). For design it is considered more conservative to restrict the ultimate strength condition so that a ductile failure mode can be expected.

Unless unusual amounts of ductility are required, the $0.75\ \rho_b$ limitation will provide ductile behavior for most designs. One condition where greater ductile behavior is required is in design for redistribution of moments in continuous members and frames. Code Section 8.4 permits negative moment redistribution. Since moment redistribution is dependent on adequate ductility in hinge regions, the amount of tension reinforcement in hinging regions is limited to $0.5\rho_b$.

For ductile behavior of beams with compression reinforcement, only that portion of the total tension steel balanced by compression in the concrete need be limited; that portion of the total tension steel where force is balanced by compression reinforcement need not be limited by the 0.75 factor.

CODE

10.3.4 — Use of compression reinforcement shall be permitted in conjunction with additional tension reinforcement to increase the strength of flexural members.

10.3.5 — Design axial load strength ϕP_n of compression members shall not be taken greater than the following:

10.3.5.1 — For nonprestressed members with spiral reinforcement conforming to 7.10.4 or composite members conforming to 10.16:

$$\phi P_{n(max)} = 0.85\phi\left[0.85f_c'\left(A_g - A_{st}\right) + f_y A_{st}\right] \quad (10\text{-}1)$$

10.3.5.2—For nonprestressed members with tie reinforcement conforming to 7.10.5:

$$\phi P_{n(max)} = 0.80\phi\left[0.85f_c'\left(A_g - A_{st}\right) + f_y A_{st}\right] \quad (10\text{-}2)$$

10.3.5.3 — For prestressed members, design axial load strength ϕP_n shall not be taken greater than 0.85 (for members with spiral reinforcement) or 0.80 (for members with tie reinforcement) of the design axial load strength at zero eccentricity ϕP_o.

10.3.6 — Members subject to compressive axial load shall be designed for the maximum moment that can accompany the axial load. The factored axial load P_u at given eccentricity shall not exceed that given in 10.3.5. The maximum factored moment M_u shall be magnified for slenderness effects in accordance with 10.10.

COMMENTARY

R10.3.5 and R10.3.6 — The minimum design eccentricities included in the 1963 and 1971 codes were deleted from the 1977 code except for consideration of slenderness effects in compression members with small or zero computed end moments (see 10.12.3.2). The specified minimum eccentricities were originally intended to serve as a means of reducing the axial load design strength of a section in pure compression to account for accidental eccentricities not considered in the analysis that may exist in a compression member, and to recognize that concrete strength may be less than f_c' under sustained high loads. The primary purpose of the minimum eccentricity requirement was to limit the maximum design axial load strength of a compression member. This is now accomplished directly in 10.3.5 by limiting the design axial load strength of a section in pure compression to 85 or 80 percent of the nominal strength. These percentage values approximate the axial load strengths at e/h ratios of 0.05 and 0.10, specified in the earlier codes for the spirally reinforced and tied members respectively. The same axial load limitation applies to both cast-in-place and precast compression members. Design aids and computer programs based on the minimum eccentricity requirement of the 1963 and 1971 codes are equally applicable for usage.

For prestressed members, the design axial load strength in pure compression is computed by the strength design methods of Chapter 10, including the effect of the prestressing force.

Compression member end moments must be considered in the design of adjacent flexural members. In braced frames, the effects of magnifying the end moments need not be considered in the design of the adjacent beams. In frames which are not braced against sidesway, the magnified end moments must be considered in designing the flexural members, as required in 10.13.7.

Corner and other columns exposed to known moments about each axis simultaneously should be designed for biaxial bending and axial load. Satisfactory methods are available in the ACI *Design Handbook*[10.4] and the CRSI *Handbook.*[10.5] The reciprocal load method[10.6] and the load contour method[10.7] are the methods used in those two handbooks. Research[10.8,10.9] indicates that using the rectangular stress block provisions of 10.2.7 produces satisfactory strength estimates for doubly symmetric sections. A simple and somewhat conservative estimate of nominal strength P_{ni} can be obtained from the reciprocal load relationship[10.6]

$$\frac{1}{P_{ni}} = \frac{1}{P_{nx}} + \frac{1}{P_{ny}} - \frac{1}{P_o}$$

CODE

COMMENTARY

where

P_{ni} = nominal axial load strength at given eccentricity along both axes
P_o = nominal axial load strength at zero eccentricity
P_{nx} = nominal axial load strength at given eccentricity along x-axis
P_{ny} = nominal axial load strength at given eccentricity along y-axis

This relationship is most suitable when values P_{nx} and P_{ny} are greater than the balanced axial force P_b for the particular axis.

10.4 — Distance between lateral supports of flexural members

10.4.1 — Spacing of lateral supports for a beam shall not exceed 50 times the least width ***b*** of compression flange or face.

10.4.2 — Effects of lateral eccentricity of load shall be taken into account in determining spacing of lateral supports.

R10.4 — Distance between lateral supports of flexural members

Tests have shown that laterally unbraced reinforced concrete beams of any reasonable dimensions, even when very deep and narrow, will not fail prematurely by lateral buckling provided the beams are loaded without lateral eccentricity that could cause torsion[10.10,10.11]

Laterally unbraced beams are frequently loaded off center (lateral eccentricity) or with slight inclination. Stresses and deformations set up by such loading become detrimental for narrow, deep beams, the more so as the unsupported length increases. Lateral supports spaced closer than **50*b*** may be required by actual loading conditions.

10.5 — Minimum reinforcement of flexural members

10.5.1 — At every section of a flexural member where tensile reinforcement is required by analysis, except as provided in 10.5.2, 10.5.3, and 10.5.4, the area A_s provided shall not be less than that given by

$$A_{s,min} = \frac{3\sqrt{f_c'}}{f_y} b_w d \qquad \text{(10-3)}$$

f_c' in psi

and not less than $200\, b_w d/f_y$.

10.5.2 — For a statically determinate T-section with flange in tension, the area $A_{s,min}$ shall be equal to or greater than the smaller value given either by

$$A_{s,min} = \frac{6\sqrt{f_c'}}{f_y} b_w d \qquad \text{(10-4)}$$

or Eq. (10-3) with b_w set equal to the width of the flange.

R10.5 — Minimum reinforcement of flexural members

The provision for a minimum amount of reinforcement applies to flexural members, which for architectural or other reasons, are larger in cross section than required for strength. With a very small amount of tensile reinforcement, the computed moment strength as a reinforced concrete section using cracked section analysis becomes less than that of the corresponding unreinforced concrete section computed from its modulus of rupture. Failure in such a case can be sudden.

To prevent such a failure, a minimum amount of tensile reinforcement is required by 10.5.1. This is required in both positive and negative moment regions. The $200/f_y$ value formerly used was originally derived to provide the same 0.5 percent minimum (for mild grade steel) as required in earlier editions of the ACI Building Code. When concrete strength higher than about 5000 psi is used, the $200/f_y$ value previously used may not be sufficient. The value given by Eq. (10-3) gives the same amount as $200/f_y$ when f_c' equals 4440 psi. When the flange of a T-section is in tension, the amount of tensile reinforcement needed to make the

CODE

COMMENTARY

strength of a reinforced concrete section equal that of an unreinforced section is about twice that for a rectangular section or that of a T-section with the flange in compression. It was concluded that this higher amount is necessary, particularly for cantilevers and other statically determinate situations where the flange is in tension.

10.5.3 — The requirements of 10.5.1 and 10.5.2 need not be applied if at every section the area of tensile reinforcement provided is at least one-third greater than that required by analysis.

R10.5.3 — The minimum reinforcement required by Eq. (10-3) or (10-4) must be provided wherever reinforcement is needed, except where such reinforcement is at least one-third greater than that required by analysis. This exception provides sufficient additional reinforcement in large members where the amount required by 10.5.1 or 10.5.2 would be excessive.

10.5.4 — For structural slabs and footings of uniform thickness the minimum area of tensile reinforcement in the direction of the span shall be the same as that required by 7.12. Maximum spacing of this reinforcement shall not exceed the lesser of three times the thickness and 18 in.

R10.5.4 — The minimum reinforcement required for slabs should be equal to the same amount as that required by 7.12 for shrinkage and temperature reinforcement.

Soil-supported slabs such as slabs on grade are not considered to be structural slabs in the context of this section, unless they transmit vertical loads from other parts of the structure to the soil. Reinforcement, if any, in soil-supported slabs should be proportioned with due consideration of all design forces. Mat foundations and other slabs which help support the structure vertically should meet the requirements of this section.

In reevaluating the overall treatment of 10.5, the maximum spacing for reinforcement in structural slabs (including footings) was reduced from the ***5h*** for temperature and shrinkage reinforcement to the compromise value of ***3h***, which is somewhat larger than the ***2h*** limit of 13.3.2 for two-way slab systems.

10.6 — Distribution of flexural reinforcement in beams and one-way slabs

R10.6 — Distribution of flexural reinforcement in beams and one-way slabs

10.6.1 — This section prescribes rules for distribution of flexural reinforcement to control flexural cracking in beams and in one-way slabs (slabs reinforced to resist flexural stresses in only one direction).

R10.6.1 — Many structures designed by working stress methods and with low steel stress served their intended functions with very limited flexural cracking. When high strength reinforcing steels are used at high service load stresses, however, visible cracks must be expected, and steps must be taken in detailing of the reinforcement to control cracking. To assure protection of reinforcement against corrosion, and for aesthetic reasons, many fine hairline cracks are preferable to a few wide cracks.

Control of cracking is particularly important when reinforcement with a yield strength in excess of 40,000 psi is used. Current good detailing practices will usually lead to adequate crack control even when reinforcement of 60,000 psi yield is used.

Extensive laboratory work[10.12-10.14] involving modern deformed bars has confirmed that crack width at service

CODE

10.6.2 — Distribution of flexural reinforcement in two-way slabs shall be as required by 13.3.

10.6.3 — Flexural tension reinforcement shall be well distributed within maximum flexural tension zones of a member cross section as required by 10.6.4.

10.6.4 — When design yield strength f_y for tension reinforcement exceeds 40,000 psi, cross sections of maximum positive and negative moment shall be so proportioned that the quantity z given by

$$z = f_s \sqrt[3]{d_c A} \qquad (10\text{-}5)$$

does not exceed 175 kips/in. for interior exposure and 145 kips/in. for exterior exposure. Calculated stress in reinforcement at service load f_s (kips/in.^{2}) shall be computed as the moment divided by the product of steel area and internal moment arm. Alternatively, it shall be permitted to take f_s as 60 percent of specified yield strength f_y.

COMMENTARY

loads is proportional to steel stress. However, the significant variables reflecting steel detailing were found to be thickness of concrete cover and the area of concrete in the zone of maximum tension surrounding each individual reinforcing bar.

Crack width is inherently subject to wide scatter even in careful laboratory work and is influenced by shrinkage and other time-dependent effects. The best crack control is obtained when the steel reinforcement is well distributed over the zone of maximum concrete tension.

R10.6.3 — Several bars at moderate spacing are much more effective in controlling cracking than one or two larger bars of equivalent area.

R10.6.4 — Eq. (10-5) will provide a distribution that will reasonably control flexural cracking. The equation is written in a form emphasizing reinforcement details rather than crack width w, per se. It is based on the Gergely-Lutz expression:

$$w = 0.076 \beta f_s \sqrt[3]{d_c A}$$

in which w is in units of 0.001 in. To simplify practical design, an approximate value of 1.2 is used for β (ratio of distances to the neutral axis from the extreme tension fiber and from the centroid of the main reinforcement). Laboratory tests[10.15] have shown that the Gergely-Lutz expression

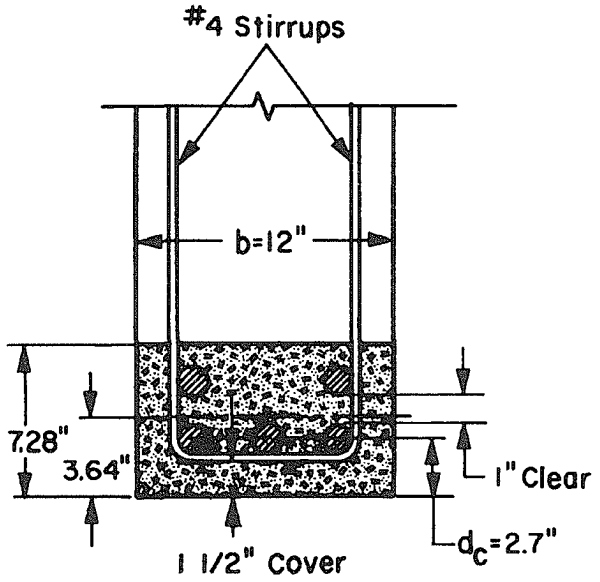

Fig. R10.6.4—Effective tension area of concrete (beam with five No. 11 bars)

CODE

COMMENTARY

applies reasonably to one-way slabs. The average ratio β is about 1.35 for floor slabs, rather than the value 1.2 used for beams. Accordingly it would be consistent to reduce the maximum values for z by the factor 1.2/1.35.

The numerical limitations of z = **175 and 145** kips/in. for interior and exterior exposure, respectively, correspond to limiting crack widths of 0.016 and 0.013 in.

The effective tension area of concrete surrounding the principal reinforcement is defined as having the same centroid as the reinforcement. Moreover, this area is to be bounded by the surfaces of the cross section and a straight line parallel to the neutral axis. Computation of the effective area per bar, A (see notation definition), is illustrated by the example shown in Fig. R10.6.4 in which the centroid of the main reinforcement is located 3.64 in. from the bottom of the beam. The effective tension area is then taken as twice 3.64 in. times the beam width b. Divided by the number of bars, this gives 17.6 in.^{2} per bar.

10.6.5 — Provisions of 10.6.4 are not sufficient for structures subject to very aggressive exposure or designed to be watertight. For such structures, special investigations and precautions are required.

R10.6.5 — Although a number of studies have been conducted, clear experimental evidence is not available regarding the crack width beyond which a corrosion danger exists. Exposure tests indicate that concrete quality, adequate compaction, and ample concrete cover may be of greater importance for corrosion protection than crack width at the concrete surface. The limiting values for z were, therefore, chosen primarily to give reasonable reinforcement details in terms of practical experiences with existing structures.

10.6.6 — Where flanges of T-beam construction are in tension, part of the flexural tension reinforcement shall be distributed over an effective flange width as defined in 8.10, or a width equal to $1/10$ the span, whichever is smaller. If the effective flange width exceeds $1/10$ the span, some longitudinal reinforcement shall be provided in the outer portions of the flange.

R10.6.6 — In major T-beams, distribution of the negative reinforcement for control of cracking must take into account two considerations: (1) wide spacing of the reinforcement across the full effective width of flange may cause some wide cracks to form in the slab near the web and, (2) close spacing near the web leaves the outer regions of the flange unprotected. The $1/10$ limitation is to guard against too wide a spacing, with some additional reinforcement required to protect the outer portions of the flange.

10.6.7 — If the effective depth d of a beam or joist exceeds 36 in., longitudinal skin reinforcement shall be uniformly distributed along both side faces of the member for a distance $d/2$ nearest the flexural tension reinforcement. The area of skin reinforcement A_{sk} per foot of height on each side face shall be $\geq 0.012(d-30)$. The maximum spacing of the skin reinforcement shall not exceed the lesser of $d/6$ and 12 in. It shall be permitted to include such reinforcement in strength computations if a strain compatibility analysis is made to determine stress in the individual bars or wires. The total area of longitudinal skin reinforcement in both faces need not exceed one-half of the required flexural tensile reinforcement.

R10.6.7 — For relatively deep flexural members, some reinforcement should be placed near the vertical faces in the tension zone to control cracking in the web. Without such auxiliary steel, the width of the cracks in the web may greatly exceed the crack widths at the level of the flexural tension reinforcement.

The requirements for skin reinforcement were modified in the 1989 edition of the code, as the previous requirements were found to be inadequate in some cases. See Reference 10.16. For lightly reinforced members, these requirements may be reduced to one-half of the main flexural reinforcement. Where the provisions for deep beams, walls, or precast panels require more steel, those provisions (along with their spacing requirements) will govern.

CODE

10.7 — Deep flexural members

10.7.1 — Flexural members with overall depth to clear span ratios greater than $^2/_5$ for continuous spans, or $^4/_5$ for simple spans, shall be designed as deep flexural members taking into account nonlinear distribution of strain and lateral buckling. (See also 12.10.6.)

10.7.2 — Shear strength of deep flexural members shall be in accordance with 11.8.

10.7.3 — Minimum flexural tension reinforcement shall conform to 10.5.

10.7.4 — Minimum horizontal and vertical reinforcement in the side faces of deep flexural members shall be the greater of the requirements of 11.8.8, 11.8.9, and 11.8.10 or 14.3.2 and 14.3.3.

10.8 — Design dimensions for compression members

10.8.1 — Isolated compression member with multiple spirals

Outer limits of the effective cross section of a compression member with two or more interlocking spirals shall be taken at a distance outside the extreme limits of the spirals equal to the minimum concrete cover required by 7.7.

10.8.2 — Compression member built monolithically with wall

Outer limits of the effective cross section of a spirally reinforced or tied reinforced compression member built monolithically with a concrete wall or pier shall be taken not greater than $1^1/_2$ in. outside the spiral or tie reinforcement.

10.8.3 — Equivalent circular compression member

As an alternative to using the full gross area for design of a compression member with a square, octagonal, or other shaped cross section, it shall be permitted to use a circular section with a diameter equal to the least lateral dimension of the actual shape. Gross area considered, required percentage of reinforcement, and design strength shall be based on that circular section.

10.8.4 — Limits of section

For a compression member with a cross section larger than required by considerations of loading, it shall be permitted to base the minimum reinforcement and

COMMENTARY

R10.7 — Deep flexural members

The code does not contain detailed requirements for designing deep beams for flexure except that nonlinearity of strain distribution and lateral buckling must be considered.

Suggestions for the design of deep beams for flexure are given in References 10.17, 10.18, and 10.19.

R10.8 — Design dimensions for compression members

With the 1971 edition of the ACI Building Code, minimum sizes for compression members were eliminated to allow wider utilization of reinforced concrete compression members in smaller size and lightly loaded structures, such as low rise residential and light office buildings. The engineer should recognize the need for careful workmanship, as well as the increased significance of shrinkage stresses with small sections.

R10.8.2, R10.8.3, R10.8.4 — For column design,[10.20] the code provisions for quantity of reinforcement, both vertical and spiral, are based on the gross column area and core area, and the design strength of the column is based on the gross area of the column section. In some cases, however, the gross area is larger than necessary to carry the factored load. The basis of 10.8.2, 10.8.3, and 10.8.4 is that it is satisfactory to design a column of sufficient size to carry the factored load and then simply add concrete around the designed section without increasing the reinforcement to meet the minimum percentages required by 10.9.1. The additional concrete must not be considered as carrying load; however, the effects of the additional concrete on member stiffness must be included in the structural analysis. The effects of the additional concrete also must be considered in design of the other parts of the structure that interact with the oversize member.

CODE

strength on a reduced effective area A_g not less than one-half the total area. This provision shall not apply in regions of high seismic risk.

10.9 — Limits for reinforcement of compression members

10.9.1 — Area of longitudinal reinforcement for noncomposite compression members shall be not less than 0.01 nor more than 0.08 times gross area A_g of section.

COMMENTARY

UBC ZONES 3,4

R10.9 — Limits for reinforcement of compression members

R10.9.1 — This section prescribes the limits on the amount of longitudinal reinforcement for noncomposite compression members. If the use of high reinforcement ratios would involve practical difficulties in the placing of concrete, a lower percentage and hence a larger column, or higher strength concrete or reinforcement (see R9.4) should be considered. The percentage of reinforcement in columns should usually not exceed 4 percent if the column bars are required to be lap spliced.

Minimum reinforcement. Since the design methods for columns incorporate separate terms for the load carried by concrete and by reinforcement, it is necessary to specify some minimum amount of reinforcement to ensure that only reinforced concrete columns are designed by these procedures. Reinforcement is necessary to provide resistance to bending, which may exist whether or not computations show that bending exists, and to reduce the effects of creep and shrinkage of the concrete under sustained compressive stresses. Tests have shown that creep and shrinkage tend to transfer load from the concrete to the reinforcement, with a consequent increase in stress in the reinforcement, and that this increase is greater as the ratio of reinforcement decreases. Unless a lower limit is placed on this ratio, the stress in the reinforcement may increase to the yield level under sustained service loads. This phenomenon was emphasized in the report of ACI Committee 105[10.21] and minimum reinforcement ratios of 0.01 and 0.005 were recommended for spiral and tied columns, respectively. However, in all editions of the code since 1936, the minimum ratio has been 0.01 for both types of laterally reinforced columns.

Maximum reinforcement. Extensive tests of the ACI column investigation[10.21] included reinforcement ratios no greater than 0.06. Although other tests with as much as 17 percent reinforcement in the form of bars produced results similar to those obtained previously, it is necessary to note that the loads in these tests were applied through bearing plates on the ends of the columns and the problem of transferring a proportional amount of the load to the bars was thus minimized or avoided. Maximum ratios of 0.08 and 0.03 were recommended by ACI Committee 105[10.21] for spiral and tied columns, respectively. In the 1936 ACI Building Code, these limits were made 0.08 and 0.04, respectively. In the 1956 code, the limit for tied columns with bending was raised to 0.08. Since the 1963 code, it has been required that bending be considered in the design of all

CODE

10.9.2 — Minimum number of longitudinal bars in compression members shall be 4 for bars within rectangular or circular ties, 3 for bars within triangular ties, and 6 for bars enclosed by spirals conforming to 10.9.3.

10.9.3 — Ratio of spiral reinforcement ρ_s shall be not less than the value given by

$$\rho_s = 0.45\left(\frac{A_g}{A_c} - 1\right)\frac{f_c'}{f_y} \qquad (10\text{-}6)$$

where f_y is the specified yield strength of spiral reinforcement but not more than 60,000 psi.

10.10 — Slenderness effects in compression members

*COMPLETE REWRITE

10.10.1 — Except as allowed in 10.10.2, the design of compression members, restraining beams, and other supporting members shall be based on the factored forces and moments from a second-order analysis considering material nonlinearity and cracking, as well as the effects of member curvature and lateral drift,

COMMENTARY

columns, and the maximum ratio of 0.08 has been applied to both types of columns. This limit can be considered a practical maximum for reinforcement in terms of economy and requirements for placing.

R10.9.2 — For compression members, a minimum of four longitudinal bars are required when bars are enclosed by rectangular or circular ties. For other shapes, one bar should be provided at each apex or corner and proper lateral reinforcement provided. For example, tied triangular columns require three longitudinal bars, one at each apex of the triangular ties. For bars enclosed by spirals, six bars are required.

When the number of bars in a circular arrangement is less than eight, the orientation of the bars will affect the moment strength of eccentrically loaded columns and must be considered in design.

R10.9.3 — The effect of spiral reinforcement in increasing the load-carrying strength of the concrete within the core is not realized until the column has been subjected to a load and deformation sufficient to cause the concrete shell outside the core to spall off. The amount of spiral reinforcement required by Eq. (10-6) is intended to provide additional load-carrying strength for concentrically loaded columns equal to or slightly greater than the strength lost when the shell spalls off. This principle was recommended by ACI Committee 105[10.21] and has been a part of the code since 1963. The derivation of Eq. (10-6) is given in the ACI Committee 105 report. Tests and experience show that columns containing the amount of spiral reinforcement required by this section exhibit considerable toughness and ductility.

R10.10 — Slenderness effects in compression members

Provisions for slenderness effects in compression members and frames were revised in the 1995 code to better recognize the use of second-order analyses and to improve the arrangement of the provisions dealing with braced and sway frames.[10.22] The use of a refined nonlinear second-order analysis is permitted in 10.10.1. Sections 10.11, 10.12, and 10.13 present an approximate design method based on the traditional moment magnifier method. For sway frames, the magnified sway moment $\delta_s M_s$ may be calculated using a second-order elastic analysis, by an approximation to such an analysis, or by the traditional sway moment magnifier.

R10.10.1 — Two limits are placed on the use of the refined second-order analysis. First, the structure which is analyzed must have members similar to those in the final structure. If the members in the final structure have cross-sectional dimensions more than 10 percent different from those assumed in the analysis, new member properties should be

CODE

duration of the loads, shrinkage and creep, and interaction with the supporting foundation. The dimensions of each member cross section used in the analysis shall be within 10 percent of the dimensions of the members shown on the design drawings or the analysis shall be repeated. The analysis procedure shall have been shown to result in prediction of strength in substantial agreement with the results of comprehensive tests of columns in statically indeterminate reinforced concrete structures.

Analysis procedure Predicts test Results Within 15%

10.10.2 — As an alternate to the procedure prescribed in 10.10.1, it shall be permitted to base the design of compression members, restraining beams, and other supporting members on axial forces and moments from the analyses described in 10.11.

10.11 — Magnified moments — General

10.11.1 — The factored axial forces P_u, the factored moments M_1 and M_2 at the ends of the column, and, where required, the relative lateral story deflections Δ_o shall be computed using an elastic first-order frame analysis with the section properties determined taking into account the influence of axial loads, the presence of cracked regions along the length of the member, and effects of duration of the loads. Alternatively, it shall be permitted to use the following properties for the members in the structure:

(a)	Modulus of elasticity	E_c from 8.5.1
(b)	Moments of inertia	
	Beams	$0.35\ I_g$
	Columns	$0.70\ I_g$
	Walls—Uncracked	$0.70\ I_g$
	—Cracked	$0.35\ I_g$
	Flat plates and flat slabs	$0.25\ I_g$
(c)	Area	$1.0\ A_g$

COMMENTARY

computed and the analysis repeated. Second, the refined second-order analysis procedure should have been shown to predict ultimate loads within 15 percent of those reported in tests of indeterminate reinforced concrete structures. At the very least, the comparison should include tests of columns in planar braced frames, sway frames, and frames with varying column stiffnesses. To allow for variability in the actual member properties and in the analysis, the member properties used in analysis should be multiplied by a stiffness reduction factor ϕ_K less than one. For consistency with the second-order analysis in 10.13.4.1, the stiffness reduction factor ϕ_K can be taken as 0.80. The concept of a stiffness reduction factor ϕ_K is discussed in R10.12.3.

R10.10.2 — As an alternate to the refined second-order analysis of 10.10.1, design may be based on elastic analyses and the moment magnifier approach.[10.23,10.24] For sway frames the magnified sway moments may be calculated using a second-order elastic analysis based on realistic stiffness values. See R10.13.4.1.

R10.11 — Magnified moments — General

This section describes an approximate design procedure which uses the moment magnifier concept to account for slenderness effects. Moments computed using an ordinary first-order frame analysis are multiplied by a "moment magnifier" which is a function of the factored axial load P_u and the critical buckling load P_c for the column. Nonsway and sway frames are treated separately in 10.12 and 10.13. Provisions applicable to both non-sway and sway columns are given in 10.11. A first-order frame analysis is an elastic analysis which does not include the internal force effects resulting from deflections.

R10.11.1 — The stiffnesses EI used in an elastic analysis used for strength design should represent the stiffnesses of the members immediately prior to failure. This is particularly true for a second-order analysis which should predict the lateral deflections at loads approaching ultimate. The EI values should not be based totally on the moment-curvature relationship for the most highly loaded section along the length of each member. Instead, they should correspond to the moment-end rotation relationship for a complete member.

The alternative values of E, I, and A given in 10.11.1 have been chosen from the results of frame tests and analyses and include an allowance for the variability of the computed deflections. The modulus of elasticity E is based on the specified concrete strength while the sway deflections are a function of the average concrete strength which is higher. The moments of inertia were taken as $^7/_8$ of those in Reference 10.25. These two effects result in an overestimation of the second-order deflections in the order of 20 to 25 percent, corresponding to an implicit stiffness reduction factor ϕ_K of

CODE

The moments of inertia shall be divided by $(1 + \beta_d)$

(a) When sustained lateral loads act, or

(b) For stability checks made in accordance with 10.13.6.

10.11.2 — It shall be permitted to take the radius of gyration r equal to 0.30 times the overall dimension in the direction stability is being considered for rectangular compression members and 0.25 times the diameter for circular compression members. For other shapes, it shall be permitted to compute the radius of gyration for the gross concrete section.

COMMENTARY

0.80 to 0.85 on the stability calculation. The concept of a stiffness reduction factor ϕ_K is discussed in R10.12.3

The moment of inertia of T-beams should be based on the effective flange width defined in 8.10. It is generally sufficiently accurate to take I_g of a T-beam as two times the I_g for the web, $2(b_w h^3/12)$.

If the factored moments and shears from an analysis based on the moment of inertia of a wall taken equal to $0.70I_g$ indicate that the wall will crack in flexure, based on the modulus of rupture, the analysis should be repeated with $I = 0.35I_g$ in those stories where cracking is predicted at factored loads.

The alternative values of the moments of inertia given in 10.11.1 were derived for nonprestressed members. For prestressed members, the moments of inertia may differ from the values in 10.11.1 depending on the amount, location, and type of the reinforcement and the degree of cracking prior to ultimate. The stiffness values for prestressed concrete members should include an allowance for the variability of the stiffnesses.

Sections 10.11 through 10.13 provide requirements for strength and assume frame analyses will be carried out using factored loads. Analyses of deflections, vibrations, and building periods are needed at various service (unfactored) load levels[10.26,10.27] to determine the serviceability of the structure and to estimate the wind forces in wind tunnel laboratories. The seismic base shear is also based on the service load periods of vibration. The magnified service loads and deflections by a second-order analysis should also be computed using service loads. The moments of inertia of the structural members in the service load analyses should, therefore, be representative of the degree of cracking at the various service load levels investigated. Unless a more accurate estimate of the degree of cracking at design service load level is available, it is satisfactory to use $1/0.70 = 1.43$ times the moments of inertia given in 10.11.1 for service load analyses.

The last sentence in 10.11.1 refers to the unusual case of sustained lateral loads. Such a case might exist, for example, if there were permanent lateral loads resulting from unequal earth pressures on two sides of a building.

CODE

10.11.3 — Unsupported length of compression members

10.11.3.1 — The unsupported length ℓ_u of a compression member shall be taken as the clear distance between floor slabs, beams, or other members capable of providing lateral support in the direction being considered.

10.11.3.2 — Where column capitals or haunches are present, the unsupported length shall be measured to the lower extremity of the capital or haunch in the plane considered.

10.11.4 — Columns and stories in structures shall be designated as non-sway or sway columns or stories. The design of columns in non-sway frames or stories shall be based on 10.12. The design of columns in sway frames or stories shall be based on 10.13.

10.11.4.1 — It shall be permitted to assume a column in a structure is non-sway if the increase in column end moments due to second-order effects does not exceed 5 percent of the first-order end moments.

10.11.4.2 — It also shall be permitted to assume a story within a structure is non-sway if:

$$Q = \frac{\Sigma P_u \Delta_o}{V_u \ell_c} \qquad (10\text{-}7)$$

is less than or equal to 0.05, where ΣP_u and V_u are the total vertical load and the story shear, respectively, in the story in question and Δ_o is the first-order relative deflection between the top and bottom of that story due to V_u.

10.11.5 — Where an individual compression member in the frame has a slenderness $k\ell_u/r$ of more than 100, 10.10.1 shall be used to compute the forces and moments in the frame.

10.11.6 — For compression members subject to bending about both principal axes, the moment about each axis shall be magnified separately based on the conditions of restraint corresponding to that axis.

COMMENTARY

Non Sway Sway

Col $\frac{M_{2nd} - M_{1st}}{M_{1st}} \leq 0.05$ > 0.05

Story $Q = \frac{\Sigma P_u \Delta_o}{V_u \ell_c} \leq 0.05$ > 0.05

R10.11.4 — The moment magnifier design method requires the designer to distinguish between non-sway frames which are designed according to 10.12 and sway frames which are designed according to 10.13. Frequently this can be done by inspection by comparing the total lateral stiffness of the columns in a story to that of the bracing elements. A compression member may be assumed braced by inspection if it is located in a story in which the bracing elements (shearwalls, shear trusses, or other types of lateral bracing) have such substantial lateral stiffness to resist the lateral deflections of the story that any resulting lateral deflection is not large enough to affect the column strength substantially. If not readily apparent by inspection, 10.11.4.1 and 10.11.4.2 give two possible ways of doing this. In 10.11.4.1, a story in a frame is said to be non-sway if the increase in the lateral load moments resulting from $P\Delta$ effects does not exceed 5 percent of the first-order moments.[10.25] Section 10.11.4.2 gives an alternative method of determining this based on the stability index for a story Q. In computing Q, ΣP_u should correspond to the lateral loading case for which ΣP_u is greatest. It should be noted that a frame may contain both non-sway and sway stories. This test would not be suitable if V_u were zero.

If the lateral load deflections of the frame have been computed using service loads and the service load moments of inertia given in 10.11.1, it is permissible to compute Q in Eq. (10-7) using 1.2 times the sum of the service gravity loads, the service load story shear, and 1.43 times the first-order service load story deflections.

R10.11.5 — An upper limit is imposed on the slenderness ratio of columns designed by the moment magnifier method of 10.11 to 10.13. No similar limit is imposed if design is carried out according to 10.10.1. The limit of $k\ell_u/r = 100$ represents the upper range of actual tests of slender compression members in frames.

R10.11.6 — When biaxial bending occurs in a compression member, the computed moments about each of the principal axes must be magnified. The magnification factors δ are computed considering the buckling load P_c about each axis

CODE

10.12 — Magnified moments — Non-sway frames

10.12.1 — For compression members in non-sway frames, the effective length factor k shall be taken as 1.0, unless analysis shows that a lower value is justified. The calculation of k shall be based on the E and I values used in 10.11.1.

COMMENTARY

separately based on the appropriate effective length $k\ell_u$ and the stiffness EI. If the buckling capacities are different about the two axes different magnification factors will result.

R10.12 — Magnified moments — Non-sway frames

R10.12.1 — The moment magnifier equations were derived for hinged end columns and must be modified to account for the effect of end restraints. This is done by using an "effective length" $k\ell_u$ in the computation of P_c.

The primary design aid to estimate the effective length factor k is the Jackson and Moreland Alignment Charts (Fig. R10.12.1) which allow a graphical determination of k for a column of constant cross section in a multibay frame.[10.28,10.29]

The effective length is a function of the relative stiffness at each end of the compression member. Studies have indicated that the effects of varying beam and column reinforcement percentages and beam cracking should be considered in determining the relative end stiffnesses. In determining ψ for use in evaluating the effective length factor k, the rigidity of the flexural members may be calculated on the basis of $\mathbf{0.35}I_g$ for flexural members to account for the effect of cracking and reinforcement on relative stiffness, and $\mathbf{0.70}I_g$ for compression members.

The following simplified equations for computing the effective length factors for braced and unbraced members may be used. Eq. (A), (B), and (E) are taken from the 1972 British Standard Code of Practice.[10.30,10.31] Eq. (C) and (D) for unbraced members were developed in Reference 10.29.

For braced compression members, an upper bound to the effective length factor may be taken as the smaller of the following two expressions:

$$k = 0.7 + 0.05\,(\psi_A + \psi_B) \le 1.0 \qquad \text{(A)}$$

$$k = 0.85 + 0.05\psi_{min} \le 1.0 \qquad \text{(B)}$$

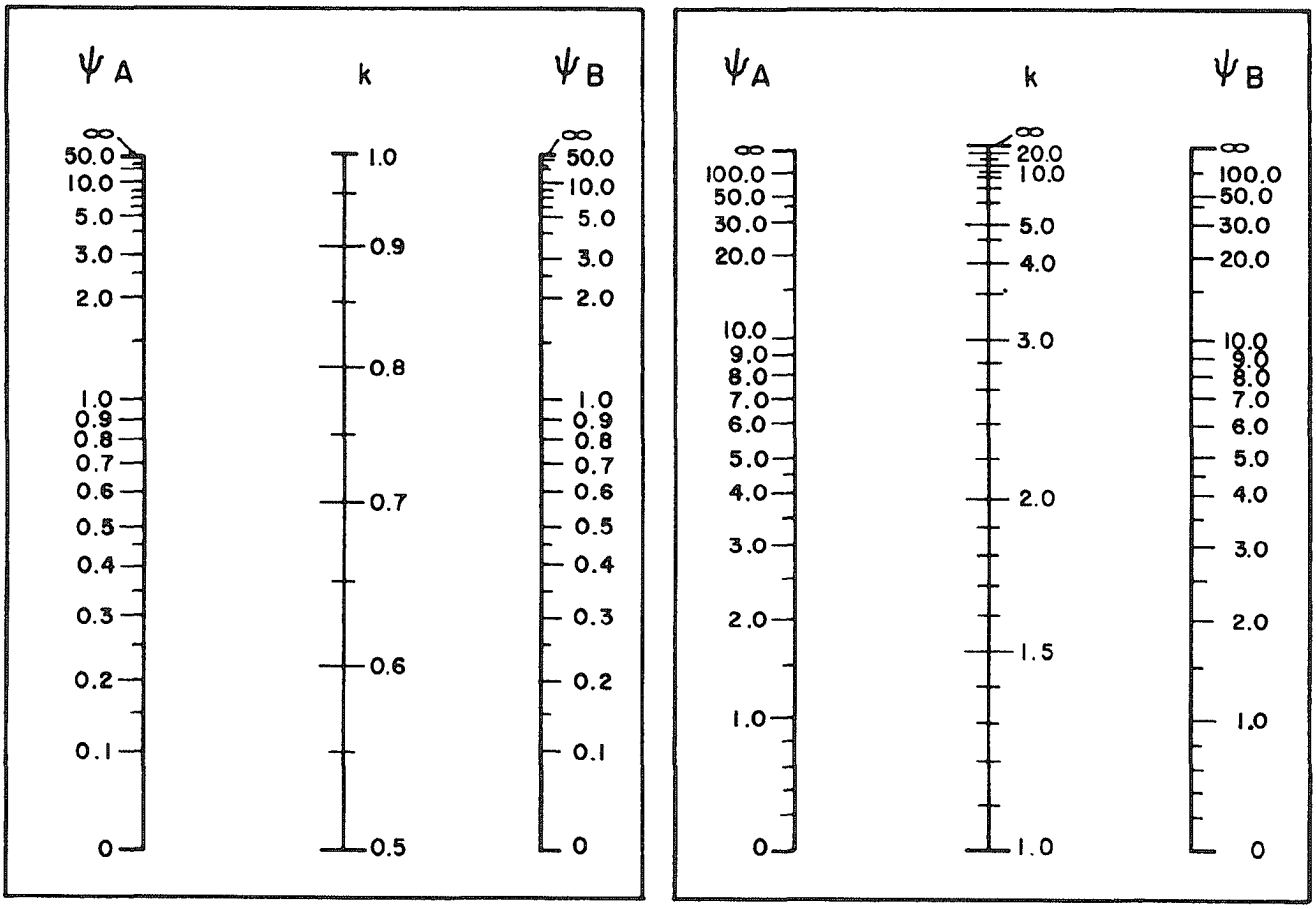
where ψ_A and ψ_B are the values of ψ at the two ends of the column and ψ_{min} is the smaller of the two values.

For unbraced compression members restrained at both ends, the effective length factor may be taken as:

For $\psi_m < 2$

$$k = \frac{20 - \psi_m}{20}\sqrt{1 + \psi_m} \qquad \text{(C)}$$

CODE COMMENTARY



ψ = ratio of $\Sigma(EI/\ell_c)$ of compression members to $\Sigma(EI/\ell)$ of flexural members in a plane at one end of a compression member

ℓ = span length of flexural member measured center-to-center of joints

Fig. R10.12.1—Effective length factors, k

For $\psi_m \geq 2$

$$k = 0.9\sqrt{1 + \psi_m} \quad \text{(D)}$$

where ψ_m is the average of the ψ-values at the two ends of the compression member.

For unbraced compression members hinged at one end, the effective length factor may be taken as:

$$k = 2.0 + 0.3\psi \quad \text{(E)}$$

where ψ is the value at the restrained end.

The use of the charts in Fig. R10.12.1, or the equations in this section, may be considered as satisfying the requirements of the code to justify k less than 1.0.

CODE

10.12.2 — In non-sway frames it shall be permitted to ignore slenderness effects for compression members which satisfy:

$$\frac{k\ell_u}{r} \le 34 - 12\,(M_1/M_2) \qquad (10\text{-}8)$$

where M_1/M_2 is not taken less than -0.5. The term M_1/M_2 is positive if the column is bent in single curvature.

10.12.3 — Compression members shall be designed for the factored axial load P_u and the moment amplified for the effects of member curvature M_c as follows:

$$M_c = \delta_{ns} M_2 \qquad (10\text{-}9)$$

where

$$\delta_{ns} = \frac{C_m}{1 - \dfrac{P_u}{0.75 P_c}} \ge 1.0 \qquad (10\text{-}10)$$

$$P_c = \frac{\pi^2 EI}{(k\ell_u)^2} \qquad (10\text{-}11)$$

EI shall be taken as

$$EI = \frac{(0.2 E_c I_g + E_s I_{se})}{1 + \beta_d} \qquad (10\text{-}12)$$

or

$$EI = \frac{0.4 E_c I_g}{1 + \beta_d} \qquad (10\text{-}13)$$

COMMENTARY

R10.12.2 — Eq. (10-8) is derived from Eq. (10-10) assuming that a 5 percent increase in moments due to slenderness is acceptable.[10.23] The derivation did not include ϕ in the calculation of the moment magnifier. As a first approximation, k may be taken equal to 1.0 in Eq. (10-8).

R10.12.3 — The ϕ-factors used in the design of slender columns represent two different sources of variability. First, the stiffness reduction ϕ-factors in the magnifier equations in the 1989 and earlier codes were intended to account for the variability in the stiffness EI and the moment magnification analysis. Second, the variability of the strength of the cross section is accounted for by strength reduction ϕ-factors of 0.70 for tied columns and 0.75 for spiral columns. Studies reported in Reference 10.32 indicate that the stiffness reduction factor ϕ_K, and the cross-sectional strength reduction ϕ-factors do not have the same values, contrary to the assumption in the 1989 and earlier codes. These studies suggest the stiffness reduction factor ϕ_K for an isolated column should be 0.75 for both tied and spiral columns. The 0.75 factors in Eq. (10-10) and (10-19) are stiffness reduction factors ϕ_K and replace the ϕ-factors in these equations in the 1989 and earlier codes. This has been done to avoid confusion between a stiffness reduction factor ϕ_K in Eq. (10-10) and (10-19), and the cross-sectional strength reduction ϕ-factors.

In defining the critical load, the main problem is the choice of a stiffness EI which reasonably approximates the variations in stiffness due to cracking, creep, and the nonlinearity of the concrete stress-strain curve. Eq. (10-12) was derived for small eccentricity ratios and high levels of axial load where the slenderness effects are most pronounced.

Creep due to sustained load will increase the lateral deflections of a column and hence the moment magnification. This is approximated for design by reducing the stiffness EI used to compute P_c and hence δ_{ns} by dividing EI by $(1 + \beta_d)$. Both the concrete and steel terms in Eq. (10-12) are divided by $(1 + \beta_d)$. This reflects the premature yielding of steel in columns subjected to sustained load.

Either Eq. (10-12) or (10-13) may be used to compute EI. Eq. (10-13) is a simplified approximation to Eq. (10-12). It is less accurate than Eq. (10-12).[10.33] Eq. (10-13) may be simplified further by assuming $\beta_d = 0.6$. When this is done Eq. (10-13) becomes

$$EI = 0.25 E_c I_g \qquad (F)$$

The term β_d is defined differently for non-sway and sway

CODE

10.12.3.1 — For members without transverse loads between supports, C_m shall be taken as

$$C_m = 0.6 + 0.4\frac{M_1}{M_2} \geq 0.4 \qquad (10\text{-}14)$$

where M_1/M_2 is positive if the column is bent in single curvature. For members with transverse loads between supports, C_m shall be taken as 1.0.

10.12.3.2 — The factored moment M_2 in Eq. (10-9) shall not be taken less than

$$M_{2,min} = P_u(0.6 + 0.03h) \qquad (10\text{-}15)$$

about each axis separately, where 0.6 and h are in inches. For members for which $M_{2,min}$ exceeds M_2, the value of C_m in Eq. (10-14) shall either be taken equal to 1.0, or shall be based on the ratio of the computed end moments M_1 and M_2.

10.13 — Magnified moments — Sway frames

COMMENTARY

frames. See 10.0. For non-sway frames, β_d is the ratio of the maximum factored axial dead load to the total factored axial load.

R10.12.3.1 — The factor C_m is an equivalent moment correction factor. The derivation of the moment magnifier assumes that the maximum moment is at or near midheight of the column. If the maximum moment occurs at one end of the column, design must be based on an "equivalent uniform moment" C_mM_2 which would lead to the same maximum moment when magnified.[10.23]

In the case of compression members that are subjected to transverse loading between supports, it is possible that the maximum moment will occur at a section away from the end of the member. If this occurs, the value of the largest calculated moment occurring anywhere along the member should be used for the value of M_2 in Eq. (10-9). In accordance with the last sentence of 10.12.3.1, C_m must be taken as 1.0 for this case.

R10.12.3.2 — In this code, slenderness is accounted for by magnifying the column end moments. If the factored column moments are very small or zero, the design of slender columns must be based on the minimum eccentricity given in this section. It is not intended that the minimum eccentricity be applied about both axes simultaneously.

The factored column end moments from the structural analysis are used in Eq. (10-14) in determining the ratio M_1/M_2 for the column when the design must be based on minimum eccentricity. This eliminates what would otherwise be a discontinuity between columns with computed eccentricities less than the minimum eccentricity and columns with computed eccentricities equal to or greater than the minimum eccentricity.

R10.13 — Magnified moments — Sway frames

The design of sway frames for slenderness has been revised in the 1995 ACI Building Code. The revised procedure consists of three steps:

(1) The magnified sway moments $\delta_s M_s$ are computed. This should be done in one of three ways. First, a second-order elastic frame analysis may be used (10.13.4.1). Second, an approximation to such analysis (10.13.4.2) may be used. The third option is to use the sway magnifier δ_s from previous editions of the ACI Building Code (10.13.4.3).

(2) The magnified sway moments $\delta_s M_s$ are added to the unmagnified non-sway moment M_{ns} at each end of each column (10.13.3). The non-sway moments may be computed using a first-order elastic analysis.

CODE

10.13.1 — For compression members not braced against sidesway, the effective length factor k shall be determined using E and I values in accordance with 10.11.1 and shall be greater than 1.0.

10.13.2 — For compression members not braced against sidesway, effects of slenderness may be neglected when $k\ell_u/r$ is less than 22.

10.13.3 — The moments M_1 and M_2 at the ends of an individual compression member shall be taken as

$$M_1 = M_{1ns} + \delta_s M_{1s} \quad (10\text{-}16)$$

$$M_2 = M_{2ns} + \delta_s M_{2s} \quad (10\text{-}17)$$

where $\delta_s M_{1s}$ and $\delta_s M_{2s}$ shall be computed according to 10.13.4.

10.13.4 — Calculation of $\delta_s M_s$

10.13.4.1 — The magnified sway moments $\delta_s M_s$ shall be taken as the column end moments calculated using a second-order elastic analysis based on the member stiffnesses given in 10.11.1.

COMMENTARY

(3) If the column is slender and the loads on it are high, it is checked to see whether the moments at points between the ends of the column exceed those at the ends of the column. As specified in 10.13.5 this is done using the non-sway frame magnifier δ_{ns} with P_c computed assuming $k = 1.0$ or less.

R10.13.1 — See R10.12.1.

R10.13.3 — The analysis described in this section deals only with plane frames subjected to loads causing deflections in that plane. If torsional displacements are significant, a three-dimensional second-order analysis should be used.

10.13.4 — Calculation of $\delta_s M_s$

R10.13.4.1 — A second-order analysis is a frame analysis which includes the internal force effects resulting from deflections. When a second-order elastic analysis is used to compute $\delta_s M_s$ the deflections must be representative of the stage immediately prior to the ultimate load. For this reason the reduced EI values given in 10.11.1 must be used in the second-order analysis.

The term β_d is defined differently for non-sway and sway frames. See 10.0. Sway deflections due to short-term loads such as wind or earthquake are a function of the short-term stiffness of the columns following a period of sustained gravity load. For this case the definition of β_d in 10.0 gives $\beta_d = 0$. In the unusual case of a sway frame where the lateral loads are sustained, β_d will not be zero. This might occur if a building on a sloping site is subjected to earth pressure on one side but not on the other.

In a second-order analysis the axial loads in all columns which are not part of the lateral load resisting elements and depend on these elements for stability must be included.

In the 1989 and earlier codes, the moment magnifier equations for δ_b and δ_s included a stiffness reduction factor ϕ_K to cover the variability in the stability calculation. The second-order analysis method is based on the values of E and I

CODE

10.13.4.2 — Alternatively it shall be permitted to calculate $\delta_s M_s$ as

$$\delta_s M_s = \frac{M_s}{1-Q} \geq M_s \qquad (10\text{-}18)$$

$Q \leq$ Stability Index

If δ_s calculated in this way exceeds 1.5, $\delta_s M_s$ shall be calculated using 10.13.4.1 or 10.13.4.3.

10.13.4.3 — Alternatively it shall be permitted to calculate the magnified sway moment $\delta_s M_s$ as

$$\delta_s M_s = \frac{M_s}{1-\dfrac{\Sigma P_u}{0.75\Sigma P_c}} \geq M_s \qquad (10\text{-}19)$$

where ΣP_u is the summation for all the vertical loads in a story and ΣP_c is the summation for all sway resisting columns in a story. P_c is calculated using Eq. (10-11) using k from 10.13.1 and EI from Eq. (10-12) or Eq. (10-13).

COMMENTARY

from 10.11.1. These lead to a 20 to 25 percent overestimation of the lateral deflections which corresponds to a stiffness reduction factor ϕ_K between 0.80 and 0.85 on the $P\Delta$ moments. No additional ϕ-factor is needed in the stability calculation. Once the moments are established, selection of the cross sections of the columns involves the strength reduction factors ϕ from 9.3.2.2.

R10.13.4.2 — The iterative $P\Delta$ analysis for second-order moments can be represented by an infinite series. The solution of this series is given by Eq. (10-18).[10.25] Reference 10.34 shows that Eq. (10-18) closely predicts the second-order moments in an unbraced frame until δ_s exceeds 1.5.

The $P\Delta$ moment diagrams for deflected columns are curved, with Δ related to the deflected shape of the columns. Eq. (10-18) and most commercially available second-order frame analyses have been derived assuming that the $P\Delta$ moments result from equal and opposite forces of $P\Delta/\ell_c$ applied at the bottom and top of the story. These forces give a straight line $P\Delta$ moment diagram. The curved $P\Delta$ moment diagrams lead to lateral displacements in the order of 15 percent larger than those from the straight line $P\Delta$ moment diagrams. This effect can be included in Eq. (10-18) by writing the denominator as $(1-1.15Q)$ rather than $(1-Q)$. The 1.15 factor has been left out of Eq. (10-18) to maintain consistency with commercially available computer programs.

If deflections have been calculated using service loads, Q in Eq. (10-18) should be calculated in the manner explained in R10.11.4.

In the 1989 and earlier codes, the moment magnifier equations for δ_b and δ_s included a stiffness reduction factor ϕ_K to cover the variability in the stability calculation. The Q factor analysis is based on deflections calculated using the values of E and I from 10.11.1 which include the equivalent of a stiffness reduction factor ϕ_K as explained in R10.13.4.1. As a result, no additional ϕ-factor is needed in the stability calculation. Once the moments are established using Eq. (10-18), selection of the cross sections of the columns involves the strength reduction factors ϕ from 9.3.2.2.

R10.13.4.3 — To check the effects of story stability, δ_s is computed as an averaged value for the entire story based on use of $\Sigma P_u / \Sigma P_c$. This reflects the interaction of all sway resisting columns in the story in the $P\Delta$ effects since the lateral deflection of all columns in the story must be equal in the absence of torsional displacements about a vertical axis. In addition, it is possible that a particularly slender individual column in an unbraced frame could have substantial midheight deflections even if adequately braced against lateral end deflections by other columns in the story. Such a column will have ℓ_u/r greater than the value given in Eq. (10-20) and would have to be checked using 10.13.5.

CODE

10.13.5 — If an individual compression member has

$$\frac{\ell_u}{r} > \frac{35}{\sqrt{\frac{P_u}{f_c' A_g}}} \qquad (10\text{-}20)$$

it shall be designed for the factored axial load P_u and the moment M_c calculated using 10.12.3 in which M_1 and M_2 are computed in accordance with 10.13.3, β_d as defined for the load combination under consideration, and k as defined in 10.12.1.

10.13.6 — In addition to load cases involving lateral loads, the strength and stability of the structure as a whole under factored gravity loads shall be considered.

(a) When $\delta_s M_s$ is computed from 10.13.4.1, the ratio of second-order lateral deflections to first-order lateral deflections for 1.4 dead load and 1.7 live load plus lateral load applied to the structure shall not exceed 2.5.

(b) When $\delta_s M_s$ is computed according to 10.13.4.2, the value of Q computed using ΣP_u for 1.4 dead load plus 1.7 live load shall not exceed 0.60.

(c) When $\delta_s M_s$ is computed from 10.13.4.3, δ_s computed using ΣP_u and ΣP_c corresponding to the factored dead and live loads shall be positive and shall not exceed 2.5.

In cases (a), (b), and (c) above, β_d shall be taken as the ratio of the maximum factored sustained axial load to the total factored axial load.

COMMENTARY

If the lateral load deflections involve a significant torsional displacement, the moment magnification in the columns farthest from the center of twist may be underestimated by the moment magnifier procedure. In such cases a three-dimensional second-order analysis should be considered.

The 0.75 in the denominator of Eq. (10-19) is a stiffness reduction factor ϕ_K as explained in R10.12.3.

In the calculation of EI, β_d will normally be zero for an unbraced frame because the lateral loads are generally of short duration. (See R10.13.4.1).

R10.13.5 — The unmagnified non-sway moments at the ends of the columns are added to the magnified sway moments at the same points. Generally one of the resulting end moments is the maximum moment in the column. However, for slender columns with high axial loads the point of maximum moment may be between the ends of the column so that the end moments are no longer the maximum moments. If ℓ_u/r is less than the value given by Eq. (10-20) the maximum moment at any point along the height of such a column will be less than 1.05 times the maximum end moment. When ℓ_u/r exceeds the value given by Eq. (10-20), the maximum moment will occur at a point between the ends of the column and will exceed the maximum end moment by more than 5 percent.[10.22] In such a case the maximum moment is calculated by magnifying the end moments using Eq. (10-9).

R10.13.6 — The possibility of sidesway instability under gravity loads alone must be investigated. When using second-order analyses to compile $\delta_s M_s$ (10.13.4.1), the frame should be analyzed twice for the case of factored gravity loads plus a lateral load applied to the frame. This load may be the lateral load used in design or it may be a single lateral load applied to the top of the frame. The first analysis should be a first-order analysis, the second analysis should be a second-order analysis. The deflection from the second-order analysis should not exceed 2.5 times the deflection from the first-order analysis. If one story is much more flexible than the others the deflection ratio should be computed in that story. The lateral load should be large enough to give deflections of size that can be compared accurately. In unsymmetrical frames which deflect laterally under gravity loads alone, the lateral load should act in the direction for which it will increase the lateral deflections.

When using 10.13.4.2 to compute $\delta_s M_s$, the value of Q evaluated using factored gravity loads should not exceed 0.60. This is equivalent to $\delta_s = 2.5$. The values of V_u and Δ_o used to compute Q can result from assuming any real or arbitrary set of lateral loads provided that V_u and Δ_o are both from the same loading. If Q as computed in 10.11.4.2 is 0.2 or less, the stability check in 10.13.6 is satisfied.

CODE

COMMENTARY

When $\delta_s M_s$ is computed using Eq. (10-19), an upper limit of 2.5 is placed on δ_s. For higher δ_s values the frame will be very susceptible to variations in EI, foundation rotations, and the like. If δ_s exceeds 2.5 the frame must be stiffened to reduce δ_s. ΣP_u shall include the axial load in all columns and walls including columns which are not part of the lateral load resisting system. The value $\delta_s = 2.5$ is a very high magnifier. It has been chosen to offset the conservatism inherent in the moment magnifier procedure.

The value of β_d should be an overall value for each story calculated as the ratio of the maximum factored sustained axial load in that story to the total factored axial load in that story.

10.13.7 — In sway frames, flexural members shall be designed for the total magnified end moments of the compression members at the joint.

R10.13.7 — The strength of a laterally unbraced frame is governed by the stability of the columns and by the degree of end restraint provided by the beams in the frame. If plastic hinges form in the restraining beam, the structure approaches a mechanism and its axial load capacity is drastically reduced. Section 10.13.7 provides that the designer make certain that the restraining flexural members have the capacity to resist the magnified column moments.

10.14 — Axially loaded members supporting slab system

Axially loaded members supporting a slab system included within the scope of 13.1 shall be designed as provided in Chapter 10 and in accordance with the additional requirements of Chapter 13.

10.15 — Transmission of column loads through floor system

When the specified compressive strength of concrete in a column is greater than 1.4 times that specified for a floor system, transmission of load through the floor system shall be provided by one of the following.

R10.15 — Transmission of column loads through floor system

The requirements of this section are based on a paper on the effect of floor concrete strength on column strength.[10.35] The provisions mean that where the column concrete strength does not exceed the floor concrete strength by more than 40 percent, no special precautions need be taken. For higher column concrete strengths, methods in 10.15.1 or 10.15.2 must be used for corner or edge columns and methods in 10.15.1, 10.15.2, or 10.15.3 for interior columns with adequate restraint on all four sides.

10.15.1 — Concrete of strength specified for the column shall be placed in the floor at the column location. Top surface of the column concrete shall extend 2 ft into the slab from face of column. Column concrete shall be well integrated with floor concrete, and shall be placed in accordance with 6.4.5 and 6.4.6.

R10.15.1 — Application of the concrete placement procedure described in 10.15.1 requires the placing of two different concrete mixes in the floor system. The lower strength mix must be placed while the higher strength concrete is still plastic and must be adequately vibrated to ensure the concretes are well integrated. This requires careful coordination of the concrete deliveries and possible use of retarders. In some cases, additional inspection services will be required when this procedure is used. It is important that the

CODE

COMMENTARY

higher strength concrete in the floor in the region of the column be placed before the lower strength concrete in the remainder of the floor to prevent accidental placing of the low strength concrete in the column area. It is the designer's responsibility to indicate on the drawings where the high and low strength concretes are to be placed.

With the 1983 code, the amount of column concrete to be placed within the floor is expressed as a simple 2-ft extension from face of column. Since the concrete placement requirement must be carried out in the field, it is now expressed in a way that is directly evident to workers. The new requirement will also locate the interface between column and floor concrete farther out into the floor, away from regions of very high shear.

10.15.2 — Strength of a column through a floor system shall be based on the lower value of concrete strength with vertical dowels and spirals as required.

10.15.3 — For columns laterally supported on four sides by beams of approximately equal depth or by slabs, strength of the column may be based on an assumed concrete strength in the column joint equal to 75 percent of column concrete strength plus 35 percent of floor concrete strength.

10.16 — Composite compression members

R10.16 — Composite compression members

10.16.1 — Composite compression members shall include all such members reinforced longitudinally with structural steel shapes, pipe, or tubing with or without longitudinal bars.

R10.16.1 — Composite columns are defined without reference to classifications of combination, composite, or concrete-filled pipe column. Reference to other metals used for reinforcement has been omitted because they are seldom used with concrete in construction.

10.16.2 — Strength of a composite member shall be computed for the same limiting conditions applicable to ordinary reinforced concrete members.

R10.16.2 — The same rules used for computing the load-moment interaction strength for reinforced concrete sections can be applied to composite sections. Interaction charts for concrete-filled tubing would have a form identical to those of ACI SP-7[10.36] and the *Design Handbook*, V.2, Columns,[10.29] but with γ slightly greater than 1.0.

10.16.3 — Any axial load strength assigned to concrete of a composite member shall be transferred to the concrete by members or brackets in direct bearing on the composite member concrete.

10.16.4 — All axial load strength not assigned to concrete of a composite member shall be developed by direct connection to the structural steel shape, pipe, or tube.

R10.16.3 and R10.16.4 — Direct bearing or direct connection for transfer of forces between steel and concrete can be developed through lugs, plates, or reinforcing bars welded to the structural shape or tubing before the concrete is cast. Flexural compressive stress need not be considered a part of direct compression load to be developed by bearing. A concrete encasement around a structural steel shape may stiffen the shape, but it would not necessarily increase its strength.

CODE

10.16.5 — For evaluation of slenderness effects, radius of gyration of a composite section shall be not greater than the value given by

$$r = \sqrt{\frac{(E_c I_g/5) + E_s I_t}{(E_c A_g/5) + E_s A_t}} \quad (10\text{-}21)$$

and, as an alternative to a more accurate calculation, EI in Eq. (10-11) shall be taken either as Eq. (10-12) or

$$EI = \frac{(E_c I_g/5)}{1 + \beta_d} + E_s I_t \quad (10\text{-}22)$$

10.16.6 — Structural steel encased concrete core

10.16.6.1 — For a composite member with concrete core encased by structural steel, thickness of the steel encasement shall be not less than

$$b\sqrt{\frac{f_y}{3E_s}} \text{ for each face of width } b$$

nor

$$h\sqrt{\frac{f_y}{8E_s}} \text{ for circular sections of diameter } h$$

10.16.6.2 — Longitudinal bars located within the encased concrete core shall be permitted to be used in computing A_t and I_t.

10.16.7 — Spiral reinforcement around structural steel core

A composite member with spirally reinforced concrete around a structural steel core shall conform to the following.

10.16.7.1 — Specified compressive strength of concrete f_c' shall be not less than 2500 psi.

10.16.7.2 — Design yield strength of structural steel core shall be the specified minimum yield strength for grade of structural steel used but not to exceed 50,000 psi.

COMMENTARY

R10.16.5 — Eq. (10-21) is given because the rules of 10.11.2 for estimating the radius of gyration are overly conservative for concrete filled tubing and are not applicable for members with enclosed structural shapes.

In reinforced concrete columns subject to sustained loads, creep transfers some of the load from the concrete to the steel thus increasing the steel stresses. In the case of lightly reinforced columns, this load transfer may cause the compression steel to yield prematurely, resulting in a loss in the effective EI. Accordingly, both the concrete and steel terms in Eq. (10-12) are reduced to account for creep. For heavily reinforced columns or for composite columns in which the pipe or structural shape makes up a large percentage of the cross section, the load transfer due to creep is not significant. Accordingly, Eq. (10-22) was revised in the 1980 code supplement so that only the EI of the concrete is reduced for sustained load effects.

R10.16.6 — Structural steel encased concrete core

Steel encased concrete sections should have a metal wall thickness large enough to attain longitudinal yield stress before buckling outward.

R10.16.7 — Spiral reinforcement around structural steel core

Concrete that is laterally contained by a spiral has increased load-carrying strength, and the size of spiral required can be regulated on the basis of the strength of the concrete outside the spiral by means of the same reasoning that applies for columns reinforced only with longitudinal bars. The radial pressure provided by the spiral ensures interaction between concrete, reinforcing bars, and steel core such that longitudinal bars will both stiffen and strengthen the cross section.

CODE

10.16.7.3 — Spiral reinforcement shall conform to 10.9.3.

10.16.7.4 — Longitudinal bars located within the spiral shall be not less than 0.01 nor more than 0.08 times net area of concrete section.

10.16.7.5 — Longitudinal bars located within the spiral shall be permitted to be used in computing A_t and I_t.

10.16.8 — Tie reinforcement around structural steel core

A composite member with laterally tied concrete around a structural steel core shall conform to the following.

10.16.8.1 — Specified compressive strength of concrete f_c' shall be not less than 2500 psi.

10.16.8.2 — Design yield strength of structural steel core shall be the specified minimum yield strength for grade of structural steel used but not to exceed 50,000 psi.

10.16.8.3 — Lateral ties shall extend completely around the structural steel core.

10.16.8.4 — Lateral ties shall have a diameter not less than $^1/_{50}$ times the greatest side dimension of composite member, except that ties shall not be smaller than No. 3 and are not required to be larger than No. 5. Welded wire fabric of equivalent area shall be permitted.

10.16.8.5 — Vertical spacing of lateral ties shall not exceed 16 longitudinal bar diameters, 48 tie bar diameters, or $^1/_2$ times the least side dimension of the composite member.

10.16.8.6 — Longitudinal bars located within the ties shall be not less than 0.01 nor more than 0.08 times net area of concrete section.

10.16.8.7 — A longitudinal bar shall be located at every corner of a rectangular cross section, with other longitudinal bars spaced not farther apart than one-half the least side dimension of the composite member.

10.16.8.8 — Longitudinal bars located within the ties shall be permitted to be used in computing A_t for strength but not in computing I_t for evaluation of slenderness effects.

COMMENTARY

R10.16.8 — Tie reinforcement around structural steel core

Concrete that is laterally contained by tie bars is likely to be rather thin along at least one face of a steel core section, and complete interaction between the core, the concrete, and any longitudinal reinforcement should not be assumed. Concrete will probably separate from smooth faces of the steel core. To maintain the concrete around the structural steel core, it is reasonable to require more lateral ties than needed for ordinary reinforced concrete columns. Because of probable separation at high strains between the steel core and the concrete, longitudinal bars will be ineffective in stiffening cross sections even though they would be useful in sustaining compression forces. Finally, the yield strength of the steel core should be limited to that which exists at strains below those that can be sustained without spalling of the concrete. It has been assumed that axially-compressed concrete will not spall at strains less than 0.0018. The yield strength of 0.0018 x 29,000,000, or 52,000 psi, represents an upper limit of the useful maximum steel stress.

CODE

10.17 — Bearing strength

10.17.1 — Design bearing strength on concrete shall not exceed ϕ $(0.85f_c'A_1)$, except when the supporting surface is wider on all sides than the loaded area, design bearing strength on the loaded area shall be permitted to be multiplied by $\sqrt{A_2/A_1}$ but not more than 2.

COMMENTARY

R10.17 — Bearing strength

R10.17.1 — This section deals with bearing strength on concrete supports. The permissible bearing stress of $0.85f_c'$ is based on tests reported in Reference 10.37. (See also 15.8).

When the supporting area is wider than the loaded area on all sides, the surrounding concrete confines the bearing area, resulting in an increase in bearing strength. No minimum depth is given for a supporting member. The minimum depth of support will be controlled by the shear requirements of 11.11.

When the top of the support is sloped or stepped, advantage may still be taken of the condition that the supporting member is larger than the loaded area, provided the supporting member does not slope at too great an angle. Fig. R10.17 illustrates the application of the frustum to find A_2. The frustum should not be confused with the path by which a

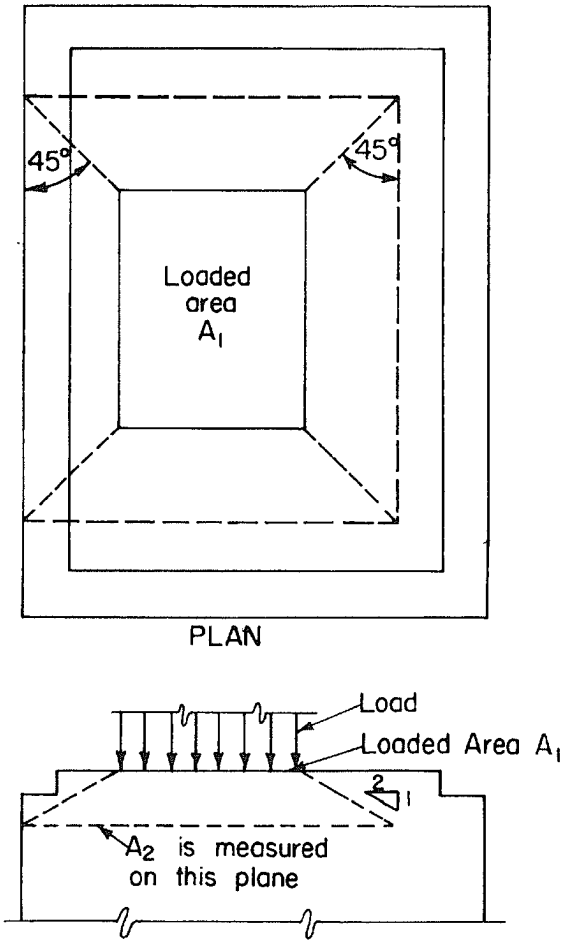


Fig. R10.17—Application of frustum to find A_2 in stepped or sloped supports

CODE

COMMENTARY

load spreads out as it travels downward through the support. Such a load path would have steeper sides. However, the frustum described has somewhat flat side slopes to ensure that there is concrete immediately surrounding the zone of high stress at the bearing. A_1 is the loaded area but not greater than the bearing plate or bearing cross-sectional area.

10.17.2 — Section 10.17 does not apply to post-tensioning anchorages.

R10.17.2 — Post-tensioning anchorages are normally laterally reinforced, in accordance with 18.13.

CHAPTER 11 — SHEAR AND TORSION

CODE

11.0 — Notation

a = shear span, distance between concentrated load and face of support

A_c = area of concrete section resisting shear transfer, in.^{2}

A_{cp} = area enclosed by outside perimeter of concrete cross section, in.^{2} See 11.6.1

A_f = area of reinforcement in bracket or corbel resisting factored moment, $[V_u a + N_{uc} (h - d)]$, in.^{2}

A_g = gross area of section, in.^{2}

A_h = area of shear reinforcement parallel to flexural tension reinforcement, in.^{2}

A_l = total area of longitudinal reinforcement to resist torsion, in.^{2}

A_n = area of reinforcement in bracket or corbel resisting tensile force N_{uc}, in.^{2}

A_o = gross area enclosed by shear flow path, in.^{2}

A_{oh} = area enclosed by centerline of the outermost closed transverse torsional reinforcement, in.^{2}

A_{ps} = area of prestressed reinforcement in tension zone, in.^{2}

A_s = area of nonprestressed tension reinforcement, in.^{2}

A_t = area of one leg of a closed stirrup resisting torsion within a distance s, in.^{2}

A_v = area of shear reinforcement within a distance s, or area of shear reinforcement perpendicular to flexural tension reinforcement within a distance s for deep flexural members, in.^{2}

A_{vf} = area of shear-friction reinforcement, in.^{2}

A_{vh} = area of shear reinforcement parallel to flexural tension reinforcement within a distance s_2, in.^{2}

b = width of compression face of member, in.

b_o = perimeter of critical section for slabs and footings, in.

b_t = width of that part of cross section containing the closed stirrups resisting torsion

b_w = web width, or diameter of circular section, in.

COMMENTARY

This chapter includes shear and torsion provisions for both nonprestressed and prestressed concrete members. The shear-friction concept (11.7) is particularly applicable to design of reinforcement details in precast structures. Special provisions are included for deep flexural members (11.8), brackets and corbels (11.9), and shearwalls (11.10). Shear provisions for slabs and footings are given in 11.12.

R11.0 — Notation

Tests[11.1] have indicated that the average shear over the full effective section also may be applied for circular sections. Note the special definition of d for such sections.

CODE

b_1 = width of the critical section defined in 11.12.1.2 measured in the direction of the span for which moments are determined, in.

b_2 = width of the critical section defined in 11.12.1.2 measured in the direction perpendicular to b_1, in.

c_1 = size of rectangular or equivalent rectangular column, capital, or bracket measured in the direction of the span for which moments are being determined, in.

c_2 = size of rectangular or equivalent rectangular column, capital, or bracket measured transverse to the direction of the span for which moments are being determined, in.

d = distance from extreme compression fiber to centroid of longitudinal tension reinforcement, but need not be less than $0.80h$ for prestressed members, in. (For circular sections, d need not be less than the distance from extreme compression fiber to centroid of tension reinforcement in opposite half of member.)

f_c' = specified compressive strength of concrete, psi

$\sqrt{f_c'}$ = square root of specified compressive strength of concrete, psi

f_{ct} = average splitting tensile strength of lightweight aggregate concrete, psi

f_d = stress due to unfactored dead load, at extreme fiber of section where tensile stress is caused by externally applied loads, psi

f_{pc} = compressive stress in concrete (after allowance for all prestress losses) at centroid of cross section resisting externally applied loads or at junction of web and flange when the centroid lies within the flange, psi. (In a composite member, f_{pc} is resultant compressive stress at centroid of composite section, or at junction of web and flange when the centroid lies within the flange, due to both prestress and moments resisted by precast member acting alone)

f_{pe} = compressive stress in concrete due to effective prestress forces only (after allowance for all prestress losses) at extreme fiber of section where tensile stress is caused by externally applied loads, psi

f_{pu} = specified tensile strength of prestressing tendons, psi

f_y = specified yield strength of nonprestressed reinforcement, psi

f_{yv} = yield strength of closed transverse torsional reinforcement, psi

$f_{y\ell}$ = yield strength of longitudinal torsional reinforcement, psi

h = overall thickness of member, in.

h_v = total depth of shearhead cross section, in.

COMMENTARY

Although the value of d may vary along the span of a prestressed beam, studies[11.2] showed that, for prestressed concrete members, d need not be taken less than $0.8h$. The beams considered had some straight tendons or reinforcing bars at the bottom of the section and had stirrups which enclosed those tendons.

CODE

COMMENTARY

h_w = total height of wall from base to top, in.
I = moment of inertia of section resisting externally applied factored loads
ℓ_n = clear span measured face-to-face of supports
ℓ_v = length of shearhead arm from centroid of concentrated load or reaction, in.
ℓ_w = horizontal length of wall, in.
M_{cr} = moment causing flexural cracking at section due to externally applied loads. See 11.4.2.1
M_m = modified moment
M_{max} = maximum factored moment at section due to externally applied loads
M_p = required plastic moment strength of shearhead cross section
M_u = factored moment at section
M_v = moment resistance contributed by shearhead reinforcement
N_u = factored axial load normal to cross section occurring simultaneously with V_u; to be taken as positive for compression, negative for tension, and to include effects of tension due to creep and shrinkage
N_{uc} = factored tensile force applied at top of bracket or corbel acting simultaneously with V_u, to be taken as positive for tension
p_{cp} = outside perimeter of the concrete cross section, in. See 11.6.1.
p_h = perimeter of centerline of outermost closed transverse torsional reinforcement, in.
s = spacing of shear or torsion reinforcement in direction parallel to longitudinal reinforcement, in.
s_1 = spacing of vertical reinforcement in wall, in.
s_2 = spacing of shear or torsion reinforcement in direction perpendicular to longitudinal reinforcement—or spacing of horizontal reinforcement in wall, in.
t = thickness of a wall of a hollow section, in.
T_n = nominal torsional moment strength
T_u = factored torsional moment at section
V_c = nominal shear strength provided by concrete
V_{ci} = nominal shear strength provided by concrete when diagonal cracking results from combined shear and moment
V_{cw} = nominal shear strength provided by concrete when diagonal cracking results from excessive principal tensile stress in web
V_d = shear force at section due to unfactored dead load
V_i = factored shear force at section due to externally applied loads occurring simultaneously with M_{max}
V_n = nominal shear strength
V_p = vertical component of effective prestress force at section
V_s = nominal shear strength provided by shear reinforcement

CODE

V_u = factored shear force at section
v_n = nominal shear stress, psi. See 11.12.6.2
y_t = distance from centroidal axis of gross section, neglecting reinforcement, to extreme fiber in tension
α = angle between inclined stirrups and longitudinal axis of member
α_f = angle between shear-friction reinforcement and shear plane
α_s = constant used to compute V_c in slabs and footings
α_v = ratio of stiffness of shearhead arm to surrounding composite slab section. See 11.12.4.5
β_c = ratio of long side to short side of concentrated load or reaction area
β_p = constant used to compute V_c in prestressed slabs
γ_f = fraction of unbalanced moment transferred by flexure at slab-column connections. See 13.5.3.2
γ_v = fraction of unbalanced moment transferred by eccentricity of shear at slab-column connections. See 11.12.6.1
= $1 - \gamma_f$
η = number of identical arms of shearhead
θ = angle of compression diagonals in truss analogy for torsion
λ = correction factor related to unit weight of concrete
μ = coefficient of friction. See 11.7.4.3
ρ = ratio of nonprestressed tension reinforcement
= A_s/bd
ρ_h = ratio of horizontal shear reinforcement area to gross concrete area of vertical section
ρ_n = ratio of vertical shear reinforcement area to gross concrete area of horizontal section
ρ_w = $A_s/b_w d$
ϕ = strength reduction factor. See 9.3

11.1 — Shear strength

11.1.1 — Design of cross sections subject to shear shall be based on:

$$\phi V_n \geq V_u \qquad (11\text{-}1)$$

where V_u is factored shear force at section considered and V_n is nominal shear strength computed by:

$$V_n = V_c + V_s \qquad (11\text{-}2)$$

where V_c is nominal shear strength provided by concrete in accordance with 11.3 or 11.4, and V_s is nominal shear strength provided by shear reinforcement in accordance with 11.5.6.

COMMENTARY

R11.1 — Shear strength

The shear strength is based on an average shear stress on the full effective cross section $b_w d$. In a member without shear reinforcement, shear is assumed to be carried by the concrete web. In a member with shear reinforcement, a portion of the shear is assumed to be provided by the concrete and the remainder by the shear reinforcement.

The shear strength provided by concrete V_c is assumed to be the same for beams with and without shear reinforcement and is taken as the shear causing significant inclined cracking. These assumptions are discussed in the ACI-ASCE Committee 426 reports[11.1,11.3] and in Reference 11.2.

CODE

11.1.1.1 — In determining shear strength V_n, effect of any openings in members shall be considered.

11.1.1.2 — In determining shear strength V_c, whenever applicable, effects of axial tension due to creep and shrinkage in restrained members shall be considered and effects of inclined flexural compression in variable depth members shall be permitted to be included.

11.1.2 — The values of $\sqrt{f_c'}$ used in this chapter shall not exceed 100 psi except as allowed in 11.1.2.1.

11.1.2.1 — Values of $\sqrt{f_c'}$ greater than 100 psi shall be permitted in computing V_c, V_{ci}, and V_{cw} for reinforced or prestressed concrete beams and concrete joist construction having minimum web reinforcement equal to $f_c'/5000$ times, but not more than three times, the amounts required by 11.5.5.3, 11.5.5.4, or 11.6.5.2.

11.1.3 — Computation of maximum factored shear force V_u at supports in accordance with 11.1.3.1 or 11.1.3.2 shall be permitted when both of the following conditions are satisfied:

(a) Support reaction, in direction of applied shear, introduces compression into the end regions of member, and

(b) No concentrated load occurs between face of support and location of critical section defined in 11.1.3.1 or 11.1.3.2.

11.1.3.1 — For nonprestressed members, sections located less than a distance d from face of support shall be permitted to be designed for the same shear V_u as that computed at a distance d.

COMMENTARY

R11.1.1.1 — Openings in the web of a member can reduce its shear strength. The effects of openings are discussed in Section 4.7 of Reference 11.1 and in References 11.4 and 11.5.

R11.1.1.2 — In a member of variable depth, the internal shear at any section is increased or decreased by the vertical component of the inclined flexural stresses. Computation methods are outlined in various textbooks and in the 1940 Joint Committee Report.[11.6]

R11.1.2 — A limited number of tests[11.7,11.8] of reinforced concrete beams made with high strength concrete (f_c' greater than about 8000 psi) suggest that the inclined cracking load increases less rapidly than Eq. (11-3) or (11-5) would suggest. This was offset by an increased effectiveness of the stirrups compared to the strength predicted by Eq. (11-15), (11-16), and (11-17). Other unpublished tests of high strength concrete girders with minimum web reinforcement indicated that this amount of web reinforcement was inadequate to prevent brittle shear failures when inclined cracking occurs. There are no test data on the two-way shear strength of high strength concrete slabs or torsional strength. Until more practical experience is obtained with beams and slabs built with concretes with strengths greater than 10,000 psi, the committee thought it was prudent to limit $\sqrt{f_c'}$ to 100 psi in calculations of shear strength and development length. For beams with enough stirrups to allow post-cracking capacity this limit is not imposed.

R11.1.3 — The closest inclined crack to the support of the beam in Fig. R11.1.3 will extend upwards from the face of the support reaching the compression zone about d from the face of the support. If loads are applied to the top of this beam, the stirrups across this crack are stressed by loads acting on the lower freebody in Fig. R11.1.3. The loads applied to the beam between the face of the column and the point d away from the face are transferred directly to the support by compression in the web above the crack. Accordingly, the code permits design for a maximum factored shear force V_u at a distance d from the support for nonprestressed members, and at a distance $h/2$ for prestressed members. Two things must be emphasized: first, stirrups are required across the potential crack designed for the shear at d from the support, and second, a tension force exists in the longitudinal reinforcement at the face of the support.

Typical support conditions where the shear force at a distance d from the support may be used include: (1) members supported by bearing at the bottom of the member, such as shown in Fig. R11.1.3.1(a); and (2) members framing monolithically into another member as illustrated in Fig. R11.1.3.1(b).

CODE

COMMENTARY

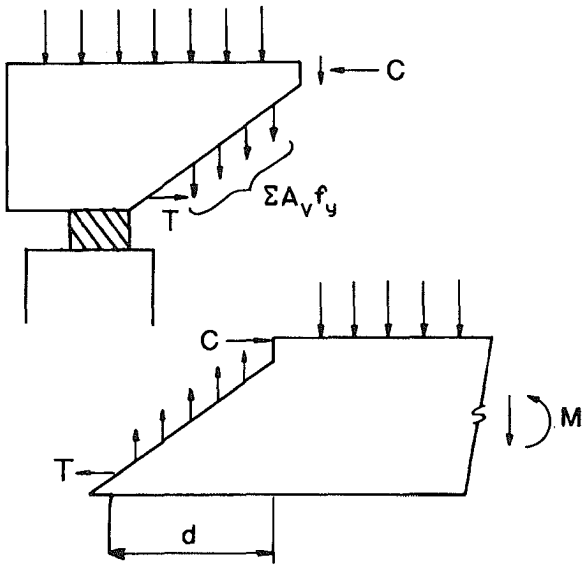

Fig. R11.1.3—Free body diagrams of the end of a beam

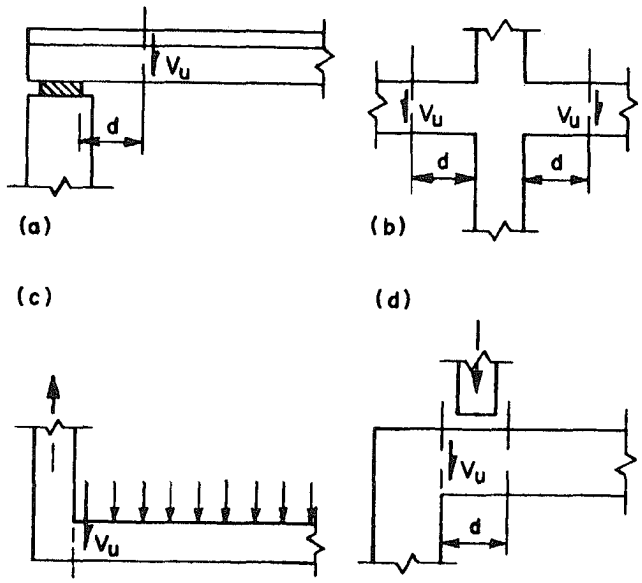

Fig. R11.1.3.1—Typical support conditions for locating factored shear force V_u

Support conditions where this provision should not be applied include: (1) Members framing into a supporting member in tension, such as shown in Fig. R11.1.3.1(c). For this case, the critical section for shear should be taken at the face of the support, shear within the connection should also be investigated, and special corner reinforcement should be provided. (2) Members loaded such that the shear at sections between the support and a distance ***d*** differs radically from the shear at distance ***d***. This commonly occurs in brackets and in beams where a concentrated load is located close to the support, as shown in Fig. R11.1.3.1(d) or in footings supported on piles. In this case the shear at the face of the support should be used.

CODE

11.1.3.2 — For prestressed members, sections located less than a distance ***h*/2** from face of support shall be permitted to be designed for the same shear V_u as that computed at a distance ***h*/2**.

11.1.4 — For deep flexural members, brackets and corbels, walls, and slabs and footings, the special provisions of 11.8 through 11.12 shall apply.

11.2 — Lightweight concrete

11.2.1 — Provisions for shear strength V_c apply to normal weight concrete. When lightweight aggregate concrete is used, one of the following modifications shall apply:

11.2.1.1 — When f_{ct} is specified and concrete is proportioned in accordance with 5.2, provisions for V_c shall be modified by substituting $f_{ct}/6.7$ for $\sqrt{f_c'}$, but the value of $f_{ct}/6.7$ shall not exceed $\sqrt{f_c'}$.

11.2.1.2 — When f_{ct} is not specified, all values of $\sqrt{f_c'}$ affecting V_c and M_{cr} shall be multiplied by 0.75 for "all-lightweight" concrete, and 0.85 for "sand-lightweight" concrete. Linear interpolation shall be permitted when partial sand replacement is used.

11.3 — Shear strength provided by concrete for nonprestressed members

11.3.1 — Shear strength V_c shall be computed by provisions of 11.3.1.1 through 11.3.1.3, unless a more detailed calculation is made in accordance with 11.3.2.

11.3.1.1 — For members subject to shear and flexure only,

$$V_c = 2\sqrt{f_c'}\, b_w d \qquad (11\text{-}3)$$

11.3.1.2 — For members subject to axial compression,

$$V_c = 2\left(1 + \frac{N_u}{2000A_g}\right)\sqrt{f_c'}\, b_w d \qquad (11\text{-}4)$$

Quantity N_u/A_g shall be expressed in psi.

11.3.1.3 — For members subject to significant axial tension, shear reinforcement shall be designed to

COMMENTARY

R11.1.3.2 — Because ***d*** frequently varies in prestressed members the location of the critical section has arbitrarily been taken as ***h*/2** from the face of the support.

R11.2 — Lightweight concrete

Two alternate procedures are provided to modify the provisions for shear when lightweight aggregate concrete is used. The lightweight concrete modification applies only to the terms containing $\sqrt{f_c'}$ in the equations of Chapter 11.

R11.2.1.1 — The first alternate bases the modification on laboratory tests to determine the relationship between splitting tensile strength f_{ct} and the compressive strength f_c' for the lightweight concrete being used. For normal weight concrete, the splitting tensile strength f_{ct} is approximately equal to $6.7\sqrt{f_c'}$.[11.9,11.10]

R11.2.1.2 — The modification may also be based on the assumption that the tensile strength of lightweight concrete is a fixed fraction of the tensile strength of normal weight concrete.[11.10] The multipliers are based on data from tests on many types of structural lightweight aggregate concrete.

R11.3 — Shear strength provided by concrete for nonprestressed members

R11.3.1.1 — See R11.3.2.1.

R11.3.1.2 and R11.3.1.3 — See R11.3.2.2.

CODE

carry total shear unless a more detailed analysis is made using 11.3.2.3.

11.3.2 — Shear strength V_c shall be permitted to be computed by the more detailed calculation of 11.3.2.1 through 11.3.2.3.

11.3.2.1 — For members subject to shear and flexure only,

$$V_c = \left(1.9\sqrt{f_c'} + 2500\rho_w \frac{V_u d}{M_u}\right) b_w d \qquad (11\text{-}5)$$

but not greater than $3.5\sqrt{f_c'}\, b_w d$. Quantity $V_u d/M_u$ shall not be taken greater than 1.0 in computing V_c by Eq. (11-5), where M_u is factored moment occurring simultaneously with V_u at section considered.

11.3.2.2 — For members subject to axial compression, it shall be permitted to compute V_c using Eq. (11-5) with M_m substituted for M_u and $V_u d/M_u$ not then limited to 1.0, where

$$M_m = M_u - N_u \frac{(4h - d)}{8} \qquad (11\text{-}6)$$

However, V_c shall not be taken greater than

$$V_c = 3.5\sqrt{f_c'} b_w d \sqrt{1 + \frac{N_u}{500 A_g}} \qquad (11\text{-}7)$$

Quantity N_u/A_g shall be expressed in psi. When M_m as computed by Eq. (11-6) is negative, V_c shall be computed by Eq. (11-7).

11.3.2.3 — For members subject to significant axial tension, up to designer's judgement.

$$V_c = 2\left(1 + \frac{N_u}{500 A_g}\right)\sqrt{f_c'} b_w d \qquad (11\text{-}8)$$

but not less than zero, where N_u is negative for tension. Quantity N_u/A_g shall be expressed in psi.

COMMENTARY

R11.3.2.1 — Eq. (11-5) is the basic expression for shear strength of members without shear reinforcement.[11.3] Designers should recognize that the three variables in Eq. (11-5), $\sqrt{f_c'}$ (as a measure of concrete tensile strength), ρ_w, and $V_u d/M_u$, are known to affect shear strength, although some research data[11.1,11.11] indicate that Eq. (11-5) overestimates the influence of f_c' and underestimates the influence of ρ_w and $V_u d/M_u$. Further information[11.12] has indicated that shear strength decreases as the overall depth of the member increases.

The minimum value of M_u equal to $V_u d$ in Eq. (11-5) is to limit V_c near points of inflection.

For most designs, it is convenient to assume that the second term of Eq. (11-5) equals $0.1\sqrt{f_c'}$ and use V_c equal to $2\sqrt{f_c'}\, b_w d$ as permitted in 11.3.1.1.

R11.3.2.2 — Eq. (11-6) and (11-7) for members subject to axial compression in addition to shear and flexure, are derived in the ACI-ASCE Committee 326 report.[11.3] As N_u is increased, the value of V_c computed from Eq. (11-5) and (11-6) will exceed the upper limit given by Eq. (11-7) before the value of M_m given by Eq. (11-6) becomes negative. The value of V_c obtained from Eq. (11-5) has no physical significance if a negative value of M_m is substituted. For this condition, Eq. (11-7) or Eq. (11-4) should be used to calculate V_c. Values of V_c for members subject to shear and axial load are illustrated in Fig. R11.3. The background for these equations is discussed and comparisons are made with test data in Reference 11.2.

Because of the complexity of Eq. (11-5) and (11-6), an alternative design provision, Eq. (11-4), is permitted.

R11.3.2.3 — Eq. (11-8) may be used to compute V_c for members subject to significant axial tension. Shear reinforcement may then be designed for $V_n - V_c$. The term "significant" is used to recognize that a designer must use judgment in deciding whether axial tension needs to be considered. Low levels of axial tension often occur due to volume changes, but are not important in structures with adequate expansion joints and minimum reinforcement. It may be desirable to design shear reinforcement to carry total shear if there is uncertainty about the magnitude of axial tension.

CODE

11.4 — Shear strength provided by concrete for prestressed members

11.4.1 — For members with effective prestress force not less than 40 percent of the tensile strength of flexural reinforcement, unless a more detailed calculation is made in accordance with 11.4.2,

$$V_c = \left(0.6\sqrt{f_c'} + 700\frac{V_u d}{M_u} \right) b_w d \qquad (11\text{-}9)$$

but V_c need not be taken less than $2\sqrt{f_c'}\, b_w d$ nor shall V_c be taken greater than $5\sqrt{f_c'}\, b_w d$ nor the value given in 11.4.3 or 11.4.4. The quantity $V_u d/M_u$ shall not be taken greater than 1.0, where M_u is factored moment occurring simultaneously with V_u at section considered. When applying Eq. (11-9), d in the term $V_u d/M_u$ shall be the distance from extreme compression fiber to centroid of prestressed reinforcement.

COMMENTARY

R11.4 — Shear strength provided by concrete for prestressed members

R11.4.1 — Eq. (11-9) offers a simple means of computing V_c for prestressed concrete beams.[11.2] It may be applied to beams having prestressed reinforcement only, or to members reinforced with a combination of prestressed reinforcement and nonprestressed deformed bars. Eq. (11-9) is most applicable to members subject to uniform loading and may give conservative results when applied to composite girders for bridges.

In applying Eq. (11-9) to simply supported members subject to uniform loads $V_u d/M_u$ can be expressed as

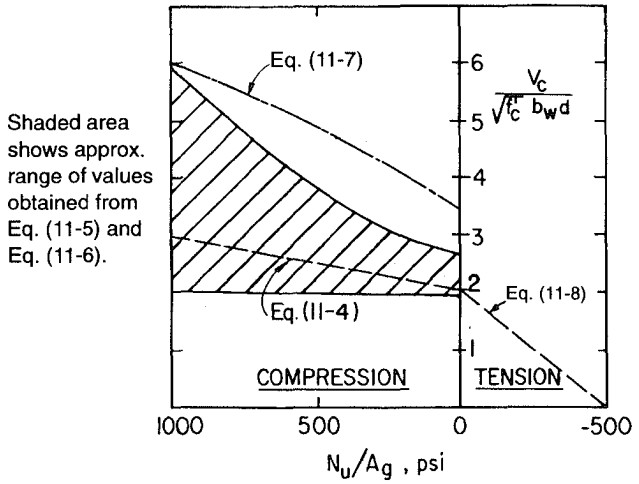

Fig. R11.3—Comparison of shear strength equations for members subject to axial load

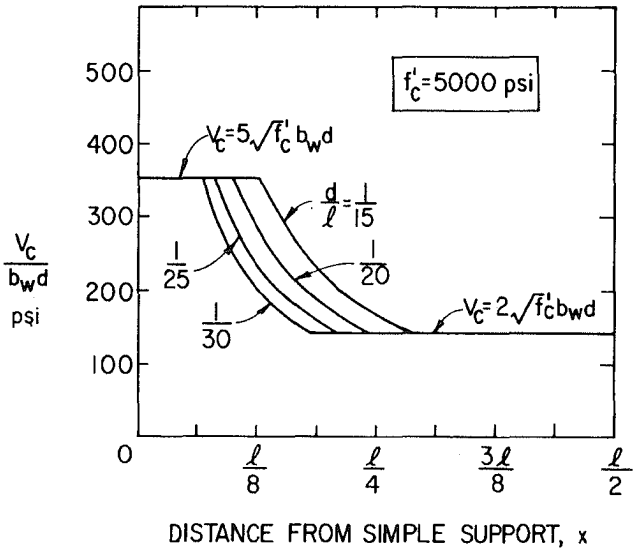

Fig. R11.4.1—Application of Eq. (11-9) to uniformly loaded prestressed members

CODE

COMMENTARY

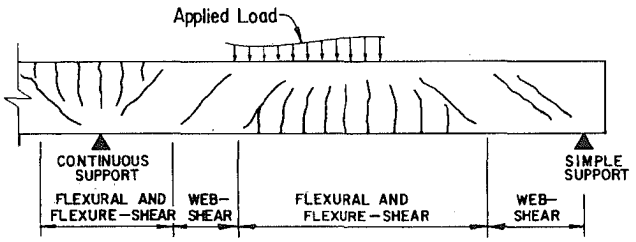

Fig. R11.4.2—Types of cracking in concrete beams

$$\frac{V_u x}{M_u} = \frac{d(\ell - 2x)}{x(\ell - x)}$$

where ℓ is the span length and x is the distance from the section being investigated to the support. For concrete with f_c' equal to 5000 psi, V_c from 11.4.1 varies as shown in Fig. R11.4.1. Design aids based on this equation are given in Reference 11.13.

11.4.2 — Shear strength V_c shall be permitted to be computed in accordance with 11.4.2.1 and 11.4.2.2, where V_c shall be the lesser of V_{ci} or V_{cw}.

11.4.2.1—Shear strength V_{ci} shall be computed by

$$V_{ci} = 0.6\sqrt{f_c'}\,b_w d + V_d + \frac{V_i M_{cr}}{M_{max}} \quad (11\text{-}10)$$

but V_{ci} need not be taken less than $1.7\sqrt{f_c'}\,b_w d$, where

$$M_{cr} = (I/y_t)(6\sqrt{f_c'} + f_{pe} - f_d) \quad (11\text{-}11)$$

and values of M_{max} and V_i shall be computed from the load combination causing maximum moment to occur at the section.

11.4.2.2—Shear strength V_{cw} shall be computed by

$$V_{cw} = (3.5\sqrt{f_c'} + 0.3f_{pc})b_w d + V_p \quad (11\text{-}12)$$

Alternatively, V_{cw} shall be computed as the shear force corresponding to dead load plus live load that results in a principal tensile stress of $4\sqrt{f_c'}$ at the centroidal axis of member, or at the intersection of flange and web when the centroidal axis is in the flange. In composite members, the principal tensile stress shall be computed using the cross section that resists live load.

11.4.2.3 — In Eq. (11-10) and (11-12), d shall be the distance from extreme compression fiber to centroid of prestressed reinforcement or $0.8h$, whichever is greater.

R11.4.2 — Two types of inclined cracking occur in concrete beams: web-shear cracking and flexure-shear cracking. These two types of inclined cracking are illustrated in Fig. R11.4.2.

Web-shear cracking begins from an interior point in a member when the principal tensile stresses exceed the tensile strength of the concrete. Flexure-shear cracking is initiated by flexural cracking. When flexural cracking occurs, the shear stresses in the concrete above the crack are increased. The flexure-shear crack develops when the combined shear and tensile stress exceeds the tensile strength of the concrete.

Eq. (11-10) and (11-12) may be used to determine the shear forces causing flexure-shear and web-shear cracking, respectively. The shear strength provided by the concrete V_c is assumed equal to the lesser of V_{ci} and V_{cw}. The derivations of Eq. (11-10) and (11-12) are summarized in Reference 11.14.

In deriving Eq. (11-10) it was assumed that V_{ci} is the sum of the shear required to cause a flexural crack at the point in question given by:

$$V = \frac{V_i M_{cr}}{M_{max}}$$

plus an additional increment of shear required to change the flexural crack to a flexure-shear crack. The externally applied factored loads, from which V_i and M_{max} are determined, include superimposed dead load, earth pressure, live load, etc. In computing M_{cr} for substitution into Eq. (11-10), I and y_t are the properties of the section resisting the externally applied loads.

CODE

COMMENTARY

For a composite member, where part of the dead load is resisted by only a part of the section, appropriate section properties should be used to compute f_d. The shear due to dead loads V_d and that due to other loads V_i are separated in this case. V_d is then the total shear force due to unfactored dead load acting on that part of the section carrying the dead loads acting prior to composite action plus the unfactored superimposed dead load acting on the composite member. The terms V_i and M_{max} may be taken as:

$$V_i = V_u - V_d$$

$$M_{max} = M_u - M_d$$

where V_u and M_u are the factored shear and moment due to the total factored loads, and M_d is the moment due to unfactored dead load (i.e., the moment corresponding to f_d).

For noncomposite uniformly loaded beams, the total cross section resists all the shear and the live and dead load shear force diagrams are similar. In this case Eq. (11-10) reduces to:

$$V_{ci} = 0.6\sqrt{f_c'}\,b_w d + \frac{V_u M_{ct}}{M_u}$$

where

$$M_{ct} = (I/y_t)\left(6\sqrt{f_c'} + f_{pe}\right)$$

The symbol M_{ct} in the two preceding equations represents the total moment, including dead load, required to cause cracking at the extreme fiber in tension. This is not the same as M_{cr} in code Eq. (11-10) where the cracking moment is that due to all loads except the dead load. In Eq. (11-10) the dead load shear is added as a separate term.

M_u is the factored moment on the beam at the section under consideration, and V_u is the factored shear force occurring simultaneously with M_u. Since the same section properties apply to both dead and live load stresses, there is no need to compute dead load stresses and shears separately, and the cracking moment M_{ct} reflects the total stress change from effective prestress to a tension of $6\sqrt{f_c'}$, assumed to cause flexural cracking.

Eq. (11-12) is based on the assumption that web-shear cracking occurs due to the shear causing a principal tensile stress of approximately $4\sqrt{f_c'}$ at the centroidal axis of the cross section. V_p is calculated from the effective prestress force without load factors.

CODE

11.4.3 — In a pretensioned member in which the section at a distance $h/2$ from face of support is closer to the end of member than the transfer length of the prestressing tendons, the reduced prestress shall be considered when computing V_{cw}. This value of V_{cw} shall also be taken as the maximum limit for Eq. (11-9). The prestress force shall be assumed to vary linearly from zero at end of tendon to a maximum at a distance from end of tendon equal to the transfer length, assumed to be 50 diameters for strand and 100 diameters for single wire.

11.4.4—In a pretensioned member where bonding of some tendons does not extend to the end of member, a reduced prestress shall be considered when computing V_c in accordance with 11.4.1 or 11.4.2. The value of V_{cw} calculated using the reduced prestress shall also be taken as the maximum limit for Eq. (11-9). The prestress force due to tendons for which bonding does not extend to the end of member, shall be assumed to vary linearly from zero at the point at which bonding commences to a maximum at a distance from this point equal to the transfer length, assumed to be 50 diameters for strand and 100 diameters for single wire.

11.5 — Shear strength provided by shear reinforcement

11.5.1 — Types of shear reinforcement

11.5.1.1 — Shear reinforcement consisting of the following shall be permitted:

(a) Stirrups perpendicular to axis of member.

(b) Welded wire fabric with wires located perpendicular to axis of member.

11.5.1.2 — For nonprestressed members, shear reinforcement shall be permitted to also consist of:

(a) Stirrups making an angle of 45 deg or more with longitudinal tension reinforcement.

(b) Longitudinal reinforcement with bent portion making an angle of 30 deg or more with the longitudinal tension reinforcement.

(c) Combinations of stirrups and bent longitudinal reinforcement.

(d) Spirals.

COMMENTARY

R11.4.3 and R11.4.4 — The effect of the reduced prestress near the ends of pretensioned beams on the shear strength must be taken into account. Section 11.4.3 relates to the shear strength at sections within the transfer length of tendons when bonding of tendons extends to the end of the member.

Section 11.4.4 relates to the shear strength at sections within the length over which some tendons are not bonded to the concrete, or within the transfer length of those tendons for which bonding does not extend to the end of the beam.

R11.5 — Shear strength provided by shear reinforcement

CODE

11.5.2 — Design yield strength of shear reinforcement shall not exceed 60,000 psi, except that the design yield strength of welded deformed wire fabric shall not exceed 80,000 psi.

11.5.3 — Stirrups and other bars or wires used as shear reinforcement shall extend to a distance d from extreme compression fiber and shall be anchored at both ends according to 12.13 to develop the design yield strength of reinforcement.

11.5.4 — Spacing limits for shear reinforcement

11.5.4.1 — Spacing of shear reinforcement placed perpendicular to axis of member shall not exceed $d/2$ in nonprestressed members and $(3/4)h$ in prestressed members, nor 24 in.

11.5.4.2 — Inclined stirrups and bent longitudinal reinforcement shall be so spaced that every 45 deg line, extending toward the reaction from middepth of member $d/2$ to longitudinal tension reinforcement, shall be crossed by at least one line of shear reinforcement.

11.5.4.3 — When V_s exceeds $4\sqrt{f_c'}\,b_w d$, maximum spacings given in 11.5.4.1 and 11.5.4.2 shall be reduced by one-half.

11.5.5 — Minimum shear reinforcement

11.5.5.1 — A minimum area of shear reinforcement shall be provided in all reinforced concrete flexural members (prestressed and nonprestressed) where factored shear force V_u exceeds one-half the shear strength provided by concrete ϕV_c, except:

(a) Slabs and footings

(b) Concrete joist construction defined by 8.11

(c) Beams with total depth not greater than 10 in., $2\frac{1}{2}$ times thickness of flange, or $\frac{1}{2}$ the width of web, whichever is greatest.

COMMENTARY

R11.5.2 — Limiting the design yield strength of shear reinforcement to 60,000 psi provides a control on diagonal crack width. However, in the 1995 code, the limitation on design yield strength of 60,000 psi for shear reinforcement was raised to 80,000 psi for welded deformed wire fabric. Recent research[11.15,11.16,11.17] has indicated that the performance of higher strength steels as shear reinforcement has been satisfactory. In particular, full scale beam tests described in Reference 11.16 indicated that the widths of inclined shear cracks at service load levels were less for beams reinforced with smaller diameter deformed welded wire fabric cages designed on the basis of a yield strength of 75 ksi than beams reinforced with deformed Grade 60 stirrups.

R11.5.3 — It is essential that shear (and torsion) reinforcement be adequately anchored at both ends, to be fully effective on either side of any potential inclined crack. This generally requires a hook or bend at the end of the reinforcement as provided by 12.13.

R11.5. 5 — Minimum shear reinforcement

R11.5.5.1 — Shear reinforcement restrains the growth of inclined cracking. Ductility is increased and a warning of failure is provided. In an unreinforced web, the sudden formation of inclined cracking might lead directly to failure without warning. Such reinforcement is of great value if a member is subjected to an unexpected tensile force or an overload. Accordingly, a minimum area of shear reinforcement not less than that given by Eq. (11-13) or (11-14) is required wherever the total factored shear force V_u is greater than one-half the shear strength provided by concrete ϕV_c. Slabs, footings and joists are excluded from the minimum shear reinforcement requirement because there is a possibility of load sharing between weak and strong areas.

CODE

COMMENTARY

Even when the total factored shear strength V_u is less than one-half of the shear strength provided by the concrete ϕV_c, the use of some web reinforcement is recommended in all thin-web post-tensioned prestressed concrete members (joists, waffle slabs, beams, and T-beams) to reinforce against tensile forces in webs resulting from local deviations from the design tendon profile, and to provide a means of supporting the tendons in the design profile during construction. If sufficient support is not provided, lateral wobble and local deviations from the smooth parabolic tendon profile assumed in design may result during placement of the concrete. In such cases, the deviations in the tendons tend to straighten out when the tendons are stressed. This process may impose large tensile stresses in webs, and severe cracking may develop if no web reinforcement is provided. Unintended curvature of the tendons, and the resulting tensile stresses in webs, may be minimized by securely tying tendons to stirrups that are rigidly held in place by other elements of the reinforcing cage and held down in the forms. The maximum spacing of stirrups used for this purpose should not exceed the smaller of $1\frac{1}{2}h$ or 4 ft. When applicable, the shear reinforcement provisions of 11.5.4 and 11.5.5 will require closer stirrup spacings.

For repeated loading of flexural members, the possibility of inclined diagonal tension cracks forming at stresses appreciably smaller than under static loading should be taken into account in the design. In these instances, it would be prudent to use at least the minimum shear reinforcement expressed by Eq. (11-13) or (11-14), even though tests or calculations based on static loads show that shear reinforcement is not required.

11.5.5.2 — Minimum shear reinforcement requirements of 11.5.5.1 shall be permitted to be waived if shown by test that required nominal flexural and shear strengths can be developed when shear reinforcement is omitted. Such tests shall simulate effects of differential settlement, creep, shrinkage, and temperature change, based on a realistic assessment of such effects occurring in service.

R11.5.5.2 — When a member is tested to demonstrate that its shear and flexural strengths are adequate, the actual member dimensions and material strengths are known. The strength used as a basis for comparison should therefore be that corresponding to a strength reduction factor of unity (ϕ = **1.0**), i.e. the required nominal strength V_n and M_n. This ensures that if the actual material strengths in the field were less than specified, or the member dimensions were in error such as to result in a reduced member strength, a satisfactory margin of safety will be retained.

11.5.5.3 — Where shear reinforcement is required by 11.5.5.1 or for strength and where 11.6.1 allows torsion to be neglected, the minimum area of shear reinforcement for prestressed (except as provided in 11.5.5.4) and nonprestressed members shall be computed by

$$A_v = 50\frac{b_w s}{f_y} \qquad (11\text{-}13)$$

where b_w and s are in inches.

CODE

11.5.5.4 — For prestressed members with an effective prestress force not less than 40 percent of the tensile strength of the flexural reinforcement, the area of shear reinforcement shall not be less than the smaller A_v from Eq. (11-13) and (11-14).

$$A_v = \frac{A_{ps} f_{pu} s}{80 f_y d} \sqrt{\frac{d}{b_w}} \qquad (11\text{-}14)$$

11.5.6 — Design of shear reinforcement

11.5.6.1 — Where factored shear force V_u exceeds shear strength ϕV_c, shear reinforcement shall be provided to satisfy Eq. (11-1) and (11-2), where shear strength V_s shall be computed in accordance with 11.5.6.2 through 11.5.6.8.

11.5.6.2 — When shear reinforcement perpendicular to axis of member is used,

$$V_s = \frac{A_v f_y d}{s} \qquad (11\text{-}15)$$

where A_v is the area of shear reinforcement within a distance s.

11.5.6.3 — When inclined stirrups are used as shear reinforcement,

$$V_s = \frac{A_v f_y (\sin\alpha + \cos\alpha)\, d}{s} \qquad (11\text{-}16)$$

11.5.6.4 — When shear reinforcement consists of a single bar or a single group of parallel bars, all bent up at the same distance from the support,

$$V_s = A_v f_y \sin\alpha \qquad (11\text{-}17)$$

but not greater than $3\sqrt{f_c'}\, b_w d$.

11.5.6.5 — When shear reinforcement consists of a series of parallel bent-up bars or groups of parallel bent-up bars at different distances from the support, shear strength V_s shall be computed by Eq. (11-16).

11.5.6.6 — Only the center three-fourths of the inclined portion of any longitudinal bent bar shall be considered effective for shear reinforcement.

11.5.6.7 — Where more than one type of shear reinforcement is used to reinforce the same portion of a member, shear strength V_s shall be computed as the sum of the V_s values computed for the various types.

COMMENTARY

R11.5.5.4 — Tests of prestressed beams with minimum web reinforcement based on Eq. (11-13) and (11-14) indicated that the smaller A_v from these two equations was sufficient to develop ductile behavior.

Eq. (11-14) may be used only for prestressed members meeting the minimum prestress force requirements given in 11.5.5.4. This equation is discussed in Reference 11.18.

R11.5.6 — Design of shear reinforcement

Design of shear reinforcement is based on a modified truss analogy. The truss analogy assumes that the total shear is carried by shear reinforcement. However, considerable research on both nonprestressed and prestressed members has indicated that shear reinforcement need be designed to carry only the shear exceeding that which causes inclined cracking, provided the diagonal members in the truss are assumed to be inclined at 45 deg.

Eq. (11-15), (11-16), and (11-17) are presented in terms of shear strength V_s attributed to the shear reinforcement. When shear reinforcement perpendicular to axis of member is used, the required area of shear reinforcement A_v and its spacing s are computed by

$$\frac{A_v}{s} = \frac{(V_u - \phi V_c)}{\phi f_y d}$$

Research[11.19,11.20] has shown that shear behavior of wide beams with substantial flexural reinforcement is improved if the transverse spacing of stirrup legs across the section is reduced.

CODE

11.5.6.8 — Shear strength V_s shall not be taken greater than $8\sqrt{f'_c}\, b_w d$.

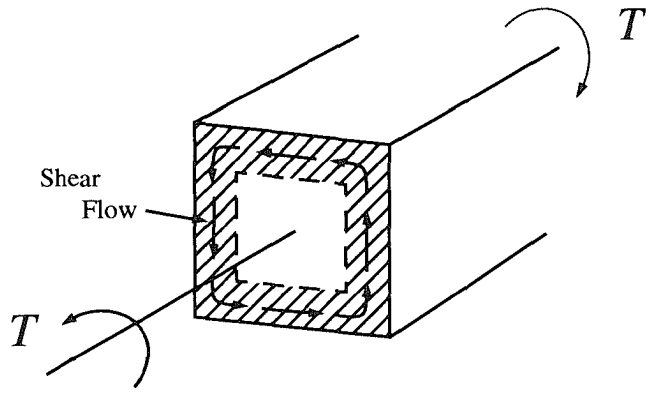
11.6 — Design for torsion

COMMENTARY

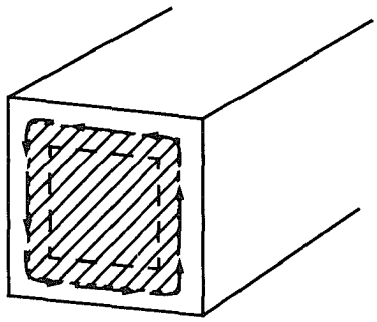
R11.6 — Design for torsion

In the 1995 code the design for torsion is based on a thin-walled tube, space truss analogy. A beam subjected to torsion is idealized as a thin-walled tube with the core concrete cross section in a solid beam neglected as shown in Fig. R11.6(a). Once a reinforced concrete beam has cracked in torsion its torsional resistance is provided primarily by closed stirrups and longitudinal bars located near the surface of the member. In the thin-walled tube analogy the resistance is assumed to be provided by the outer skin of the cross section roughly centered on the closed stirrups. Both hollow and solid sections are idealized as thin-walled tubes both before and after cracking.

In a closed thin-walled tube the shear stresses τ due to torsion act as shown in Fig. R11.6(a). The product of the shear stress τ and the wall thickness t at any point in the perimeter is known as the shear flow, $q = \tau t$. The shear flow q due to



(a) Thin-walled tube



(b) Area enclosed by shear flow path

Fig. R11.6—(a) Thin-walled tube; (b) area enclosed by shear flow path

CODE

11.6.1 — It shall be permitted to neglect torsion effects when the factored torsional moment T_u is less than:

(a) for nonprestressed members:

$$\phi\sqrt{f_c'}\left(\frac{A_{cp}^2}{p_{cp}}\right)$$

(b) for prestressed members:

$$\phi\sqrt{f_c'}\left(\frac{A_{cp}^2}{p_{cp}}\right)\sqrt{1+\frac{f_{pc}}{4\sqrt{f_c'}}}$$

For members cast monolithically with a slab, the overhanging flange width used in computing A_{cp} and p_{cp} shall conform to 13.2.4.

COMMENTARY

torsion is constant at all points around the perimeter of the tube. The path along which it acts extends around the tube at midthickness of the walls of the tube. At any point along the perimeter of the tube the shear stress due to torsion is $\tau = T/(2A_o t)$ where A_o is the gross area enclosed by the shear flow path, shown shaded in Fig. R11.6(b), and t is the thickness of the wall at the point where τ is being computed. The shear flow path follows the midplane of the walls of the tube and A_o is the area enclosed by the midplane of the walls of the tube. For a hollow member with continuous walls, A_o includes the area of the hole.

In the 1995 code, the former elliptical interaction between the shear carried by the concrete, V_c, and the torsion carried by the concrete has been eliminated. V_c remains constant at the value it has when there is no torsion, and the torsion carried by the concrete is always taken as zero.

The design procedure is derived and compared to tests in Reference 11.21.

R11.6.1 — Torques that do not exceed approximately one-quarter of the cracking torque T_{cr} will not cause a structurally significant reduction in either the flexural or shear strength and hence can be ignored. The cracking torsion under pure torsion T_{cr} is derived by replacing the actual section with an equivalent thin-walled tube with a wall thickness t prior to cracking of $0.75A_{cp}/p_{cp}$ and an area enclosed by the wall centerline A_o equal to $2A_{cp}/3$. Cracking is assumed to occur when the principal tensile stress reaches $4\sqrt{f_c'}$. In a nonprestressed beam loaded with torsion alone, the principal tensile stress is equal to the torsional shear stress, $\tau = T/(2A_o t)$. Thus, cracking occurs when τ reaches $4\sqrt{f_c'}$, giving the cracking torque T_{cr} as:

$$T_{cr} = 4\sqrt{f_c'}\left(\frac{A_{cp}^2}{p_{cp}}\right)$$

The limit set in 11.6.1 is one-quarter of this value. The stress at cracking $4\sqrt{f_c'}$ has purposely been taken as a lower bound value.

For prestressed members the torsional cracking load is increased by the prestress. A Mohr's Circle analysis based on average stresses indicates the torque required to cause a principle tensile stress equal to $4\sqrt{f_c'}$ is $\sqrt{1+f_{pc}/(4\sqrt{f_c'})}$ times the corresponding torque in a nonprestressed beam.

For an isolated member with or without flanges, A_{cp} is the area of the entire cross section including the area of voids in hollow cross sections, and p_{cp} is the perimeter of the entire cross section. For a T-beam cast monolithically with a slab, A_{cp} and p_{cp} can include portions of the adjacent slabs conforming to 13.2.4.

CODE

COMMENTARY

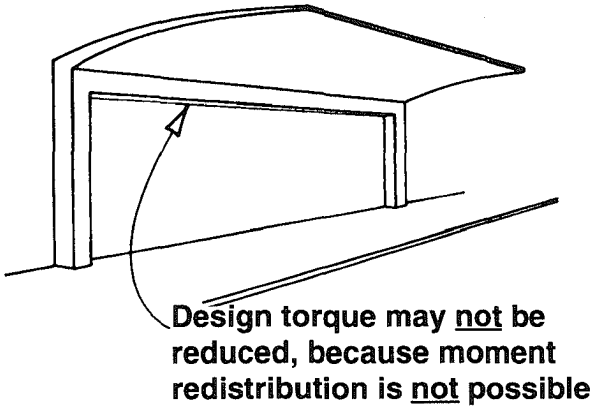


Fig. R11.6.2.1—Design torque may not be reduced (11.6.2.1)

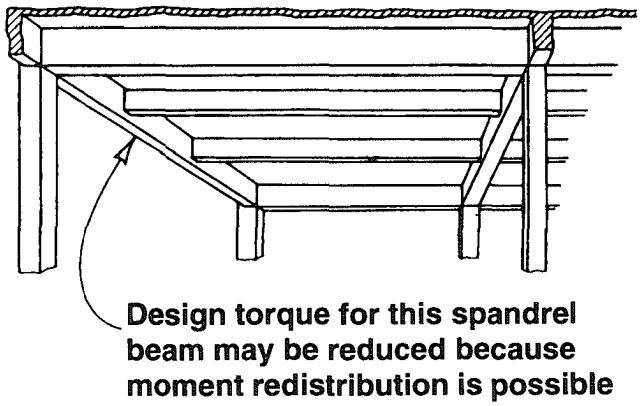

Fig. R11.6.2.2—Design torque may be reduced (11.6.2.2)

11.6.2 — Calculation of factored torsional moment T_u

11.6.2.1 — If the factored torsional moment T_u in a member is required to maintain equilibrium and exceeds the minimum value given in 11.6.1, the member shall be designed to carry that torsional moment in accordance with 11.6.3 through 11.6.6.

11.6.2.2 — In a statically indeterminate structure where reduction of the torsional moment in a member can occur due to redistribution of internal forces upon cracking, the maximum factored torsional moment T_u shall be permitted to be reduced to

(a) for nonprestressed members, at the sections described in 11.6.2.4:

R11.6.2 — Calculation of factored torsional moment T_u

R11.6.2.1 and R11.6.2.2 — In designing for torsion in reinforced concrete structures, two conditions may be identified:[11.22,11.23]

(a) The torsional moment cannot be reduced by redistribution of internal forces (11.6.2.1). This is referred to as "equilibrium torsion," since the torsional moment is required for the structure to be in equilibrium.

For this condition, illustrated in Fig. R11.6.2.1, torsion reinforcement designed according to 11.6.3 through 11.6.6 must be provided to resist the total design torsional moments.

(b) The torsional moment can be reduced by redistribution of internal forces after cracking (11.6.2.2) if the tor-

CODE

$$\phi 4\sqrt{f_c'}\left(\frac{A_{cp}^2}{p_{cp}}\right)$$

(b) for prestressed members, at the sections described in 11.6.2.5:

$$\phi 4\sqrt{f_c'}\left(\frac{A_{cp}^2}{p_{cp}}\right)\sqrt{1+\frac{f_{pc}}{4\sqrt{f_c'}}}$$

In such a case, the correspondingly redistributed bending moments and shears in the adjoining members shall be used in the design of these members.

11.6.2.3 — Unless determined by a more exact analysis, it shall be permitted to take the torsional loading from a slab as uniformly distributed along the member.

11.6.2.4 — In nonprestressed members, sections located less than a distance ***d*** from the face of a support shall be designed for not less than the torsion T_u computed at a distance ***d***. If a concentrated torque occurs within this distance, the critical section for design shall be at the face of the support.

11.6.2.5 — In prestressed members, sections located less than a distance ***h/2*** from the face of a support shall be designed for not less than the torsion T_u computed at a distance ***h/2***. If a concentrated torque occurs within this distance, the critical section for design shall be at the face of the support.

11.6.3 — Torsional moment strength

11.6.3.1 — The cross-sectional dimensions shall be such that:

COMMENTARY

sion arises from the member twisting in order to maintain compatibility of deformations. This type of torsion is referred to as "compatibility torsion."

For this condition, illustrated in Fig. R11.6.2.2, the torsional stiffness before cracking corresponds to that of the uncracked section according to St. Venant's theory. At torsional cracking, however, a large twist occurs under an essentially constant torque, resulting in a large redistribution of forces in the structure.[11.22,11.23] The cracking torque under combined shear, flexure, and torsion corresponds to a principle tensile stress somewhat less than the $4\sqrt{f_c'}$ quoted in R11.6.1.

When the torsional moment exceeds the cracking torque, a maximum factored torsional moment equal to the cracking torque may be assumed to occur at the critical sections near the faces of the supports. This limit has been established to control the width of torsional cracks.

Section 11.6.2.2 applies to typical and regular framing conditions. With layouts that impose significant torsional rotations within a limited length of the member, such as a heavy torque loading located close to a stiff column, or a column that rotates in the reverse directions because of other loading, a more exact analysis is advisable.

When the factored torsional moment from an elastic analysis based on uncracked section properties is between the values in 11.6.1 and the values given in this section, torsion reinforcement should be designed to resist the computed torsional moments.

R11.6.2.4 and R11.6.2.5 — It is not uncommon for a beam to frame into one side of a girder near the support of the girder. In such a case a concentrated shear and torque are applied to the girder.

R11.6.3 — Torsional moment strength

R11.6.3.1 —The size of a cross section is limited for two reasons, first to reduce unsightly cracking and second to

CODE

(a) for solid sections:

(b) for hollow sections:

$$\left(\frac{V_u}{b_w d}\right) + \left(\frac{T_u p_h}{1.7 A_{oh}^2}\right) \le \phi\left(\frac{V_c}{b_w d} + 8\sqrt{f_c'}\right) \qquad (11\text{-}19)$$

Shear caused by SHEAR + SHEAR caused BY TORSION ≤ ϕ

COMMENTARY

prevent crushing of the surface concrete due to inclined compressive stresses due to shear and torsion. In Eq. (11-18) and (11-19), the two terms on the left hand side are the shear stresses due to shear and torsion. The sum of these stresses may not exceed the stress causing shear cracking plus $8\sqrt{f_c'}$, similar to the limiting strength given in 11.5.6.8 for shear without torsion. The limit is expressed in terms of V_c to allow its use for nonprestressed or prestressed concrete. It was originally derived on the basis of crack control. It is not necessary to check against crushing of the web since this happens at higher shear stresses.

In a hollow section, the shear stresses due to shear and torsion both occur in the walls of the box as shown in Fig. 11.6.3.1(a) and hence are directly additive at point A as given in Eq. (11-19). In a solid section the shear stresses due to torsion act in the "tubular" outside section while the shear stresses due to V_u are spread across the width of the section

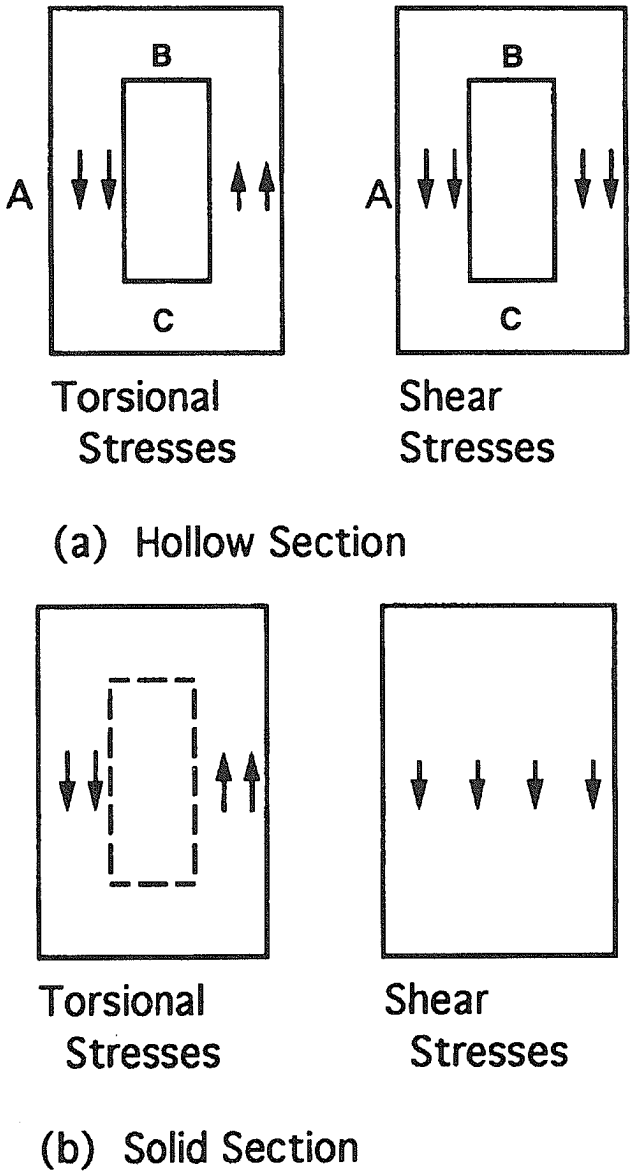

Fig. R11.6.3.1—Addition of torsional and shear stresses

CODE

11.6.3.2—If the wall thickness varies around the perimeter of a hollow section, Eq. (11-19) shall be evaluated at the location where the left-hand side of Eq. (11-19) is a maximum.

11.6.3.3 — If the wall thickness is less than A_{oh}/p_h, the second term in Eq. (11-19) shall be taken as:

$$\left(\frac{T_u}{1.7A_{oh}t}\right)$$

where t is the thickness of the wall of the hollow section at the location where the stresses are being checked.

11.6.3.4 — Design yield strength of nonprestressed torsion reinforcement shall not exceed 60,000 psi.

11.6.3.5 — The reinforcement required for torsion shall be determined from:

$$\phi T_n \geq T_u \qquad (11\text{-}20)$$

COMMENTARY

as shown in Fig. R11.6.3.1(b). For this reason stresses are combined in Eq. (11-18) using the square root of the sum of the squares rather than by direct addition.

R11.6.3.2 — If the wall thickness varies around the perimeter of a hollow section, 11.6.3.2 requires that Eq. (11-19) be evaluated at the point in the cross section where the left side of Eq. (11-19) is a maximum. Generally, this will be on the wall where the torsional and shearing stresses are additive [Point A in Fig. R11.6.3.1(a)]. If the top or bottom flanges are thinner than the vertical webs, it may be necessary to evaluate Eq. (11-19) at points B and C in Fig. R11.6.3.1(a). At these points the stresses due to the shear force are usually negligible.

R11.6.3.4 — Limiting the design yield strength of torsion reinforcement to 60,000 psi provides a control on diagonal crack width.

R11.6.3.5 — The factored torsional resistance ϕT_n must equal or exceed the torsion T_u due to the factored loads. In the calculation of T_n, all the torque is assumed to be resisted by stirrups and longitudinal steel with $T_c = 0$. At the same time, the shear resisted by concrete V_c is assumed to be unchanged by the presence of torsion. For beams with V_u greater than about $0.8\phi V_c$ the resulting amount of combined shear and torsional reinforcement is essentially the same as required by the 1989 Code. For smaller values of V_u, more shear and torsion reinforcement will be required.

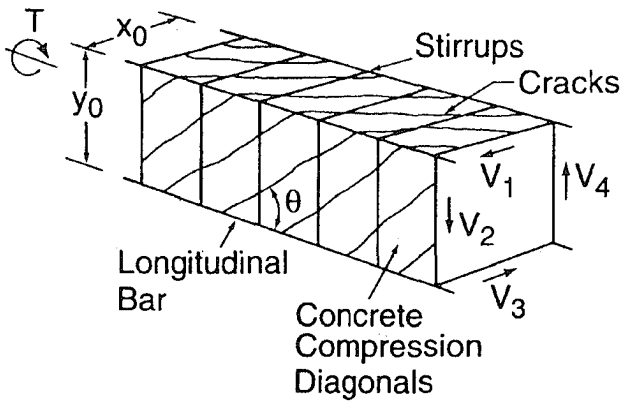

Fig. R11.6.3.6(a)—Space truss analogy

CODE

11.6.3.6 — The transverse reinforcement for torsion shall be designed using:

$$T_n = \frac{2A_oA_tf_{yv}}{s}\cot\theta \qquad (11\text{-}21)$$

where A_o shall be determined by analysis except that it shall be permitted to take A_o equal to $0.85A_{oh}$; θ shall not be taken smaller than 30 deg nor larger than 60 deg. It shall be permitted to take θ equal to:

(a) 45 deg for nonprestressed members or members with less prestress than in (b),

(b) 37.5 deg for prestressed members with an effective prestress force not less than 40 percent of the tensile strength of the longitudinal reinforcement.

11.6.3.7 — The additional longitudinal reinforcement required for torsion shall not be less than:

$$A_\ell = \frac{A_t}{s}p_h\left(\frac{f_{yv}}{f_{y\ell}}\right)\cot^2\theta \qquad (11\text{-}22)$$

where θ shall be the same value used in Eq. (11-21) and A_t/s shall be taken as the amount computed from Eq. (11-21) not modified in accordance with 11.6.5.2 or 11.6.5.3.

COMMENTARY

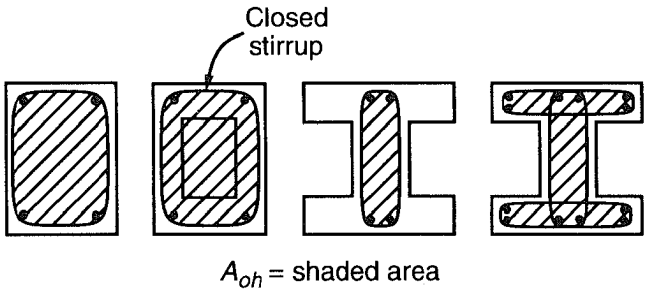

Fig. R11.6.3.6(b)—Definition of A_{oh}

R11.6.3.6 — Eq. (11-21) is based on the space truss analogy shown in Fig. R11.6.3.6(a) with compression diagonals at an angle θ, assuming the concrete carries no tension and the reinforcement yields. After torsional cracking develops, the torsional resistance is provided mainly by closed stirrups, longitudinal bars, and compression diagonals. The concrete outside these stirrups is relatively ineffective. For this reason A_o, the area enclosed by the shear flow path around the perimeter of the tube, is defined after cracking in terms of A_{oh}, the area enclosed by the centerline of the outermost closed hoops. The area A_{oh} is shown in Fig. R11.6.3.6(b) for various cross sections. In an I-, T-, or L-shaped section A_{oh} is taken as that area enclosed by the outermost legs of interlocking stirrups as shown in Fig. R11.6.3.6(b). The expression for A_o given by Hsu[11.24] may be used if greater accuracy is desired.

The shear flow q in the walls of the tube, discussed in R11.6, can be resolved into the shear forces V_1 to V_4 acting in the individual sides of the tube or space truss, as shown in Fig. R11.6.3.6(a).

The angle θ can be obtained by analysis[11.24] or may be taken to be equal to the values given in subsections (a) and (b). The same value of θ must be used in both Eq. (11-21) and (11-22). As θ gets smaller, the amount of stirrups required by Eq. (11-21) decreases. At the same time the amount of longitudinal steel required by Eq. (11-22) increases.

R11.6.3.7 — Fig. R11.6.3.7 shows one side of the equivalent tube assumed to resist torsion. The torsional cracks

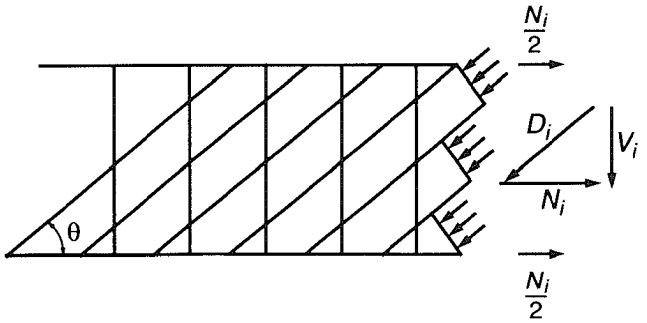

Fig. R11.6.3.7—resolution of shear force into diagonal compression and axial tension

CODE

COMMENTARY

have formed a series of inclined concrete struts crossed by stirrups. The component of the shear flow resisting the torque and acting on this side of the tube is V_i. This can be resolved into a diagonal compressive force D_i parallel to the concrete diagonals, and an axial tension force N_i. The force D_i causes diagonal compressive stresses in the walls of the tube. Longitudinal reinforcement with a capacity of $A_\ell f_{y\ell}$ must be provided to resist the sum ΣN_i of the axial forces N_i acting on all of the walls of the tube.

Frequently, the maximum allowable stirrup spacing governs the amount of stirrups provided. Furthermore, when combined shear and torsion act, the total stirrup area is the sum of the amounts provided for shear and torsion. To avoid the need to provide excessive amounts of longitudinal reinforcement, 11.6.3.7 states that the A_t/s used in calculating A_ℓ at any given section shall be taken as the A_t/s calculated at that section using Eq. (11-21).

11.6.3.8 — Reinforcement required for torsion shall be added to that required for the shear, moment and axial force that act in combination with the torsion. The most restrictive requirements for reinforcement spacing and placement must be met.

R11.6.3.8 — The stirrup requirements for torsion and shear are added and stirrups are provided to supply at least the total amount required. Since the stirrup area A_v for shear is defined in terms of all the legs of a given stirrup while the stirrup area A_t for torsion is defined in terms of one leg only, the addition of stirrups is carried out as follows:

$$\text{Total}\left(\frac{A_{v+t}}{s}\right) = \frac{A_v}{s} + 2\frac{A_t}{s}$$

If a stirrup group had four legs for shear, only the legs adjacent to the sides of the beam would be included in this summation since the inner legs would be ineffective for torsion.

The longitudinal reinforcement required for torsion is added at each section to the longitudinal reinforcement required for bending moment that acts at the same time as the torsion. The longitudinal reinforcement is then chosen for this sum, but should not be less than the amount required for the maximum bending moment at that section if this exceeds the moment acting at the same time as the torsion. If the maximum bending moment occurs at one section, say midspan, while the maximum torsional moment occurs at another, such as the support, the total longitudinal steel required may be less than that obtained by adding the maximum flexural steel plus the maximum torsional steel. In such a case the required longitudinal steel is evaluated at several locations.

The most restrictive requirements for spacing, cut-off points, and placement for flexural, shear, and torsional steel must be satisfied. The flexural steel must be extended a distance d, but not less than $12d_b$, past where it is no longer needed for flexure as required in 12.10.3.

CODE

11.6.3.9 — It shall be permitted to reduce the area of longitudinal torsion reinforcement in the flexural compression zone by an amount equal to $M_u/(0.9df_{y\ell})$, where M_u is the factored moment acting at the section in combination with T_u, except that the reinforcement provided shall not be less than that required by 11.6.5.3 or 11.6.6.2.

11.6.3.10 — In prestressed beams:

(a) the total longitudinal reinforcement including tendons at each section shall resist the factored bending moment at that section plus an additional concentric longitudinal tensile force equal to $A_\ell f_{y\ell}$, based on the factored torsion at that section, and

(b) the spacing of the longitudinal reinforcement including tendons shall satisfy the requirements in 11.6.6.2.

11.6.3.11 — In prestressed beams, it shall be permitted to reduce the area of longitudinal torsional reinforcement on the side of the member in compression due to flexure below that required by 11.6.3.10 in accordance with 11.6.3.9.

11.6.4 — Details of torsional reinforcement

11.6.4.1 — Torsion reinforcement shall consist of longitudinal bars or tendons and one or more of the following:

(a) closed stirrups or closed ties, perpendicular to the axis of the member, or

(b) a closed cage of welded wire fabric with transverse wires perpendicular to the axis of the member, or

(c) in nonprestressed beams, spiral reinforcement.

COMMENTARY

R11.6.3.9 — The longitudinal tension due to torsion is offset in part by the compression in the flexural compression zone, allowing a reduction in the longitudinal torsion steel required in the compression zone.

R11.6.3.10 — As explained in R11.6.3.7, torsion causes an axial tension force. In a nonprestressed beam this force is resisted by longitudinal reinforcement having an axial tensile capacity of $A_\ell f_{y\ell}$. This steel is in addition to the flexural reinforcement and is distributed uniformly around the sides of the perimeter so that the resultant of $A_\ell f_{y\ell}$ acts along the axis of the member.

In a prestressed beam the same technique (providing additional reinforcing bars with capacity $A_\ell f_{y\ell}$) can be followed, or the designer can use any overcapacity of the tendons to resist some of the axial force $A_\ell f_{y\ell}$ as outlined in the next paragraph.

In a prestressed beam the tendon stress at ultimate at the section of the maximum moment is f_{ps}. At other sections the tendon stress at ultimate will be between f_{se} and f_{ps}. A portion of the $A_\ell f_{y\ell}$ force acting on the sides of the perimeter where the tendons are located can be resisted by a force $A_{ps}\Delta f_p$ in the tendons where Δf_p is f_{ps} minus the tendon stress due to flexure at the ultimate load at the section in question. This can be taken as M_u at the section, divided by $(\phi 0.9 d_p A_{ps})$, but Δf_p should not be more than 60 ksi. Longitudinal reinforcing bars will be required on the other sides of the member to provide the remainder of the $A_\ell f_{y\ell}$ force, or to satisfy the spacing requirements given in 11.6.6.2, or both.

R11.6.4 — Details of torsional reinforcement

R11.6.4.1 — Both longitudinal and closed transverse reinforcement are required to resist the diagonal tension stresses due to torsion. The stirrups must be closed, since inclined cracking due to torsion may occur on all faces of a member.

In the case of sections subjected primarily to torsion, the concrete side cover over the stirrups spalls off at high torques.[11.25] This renders lapped-spliced stirrups ineffective, leading to a premature torsional failure.[11.26] In such cases, closed stirrups should not be made up of pairs of U-stirrups lapping one another.

CODE

COMMENTARY

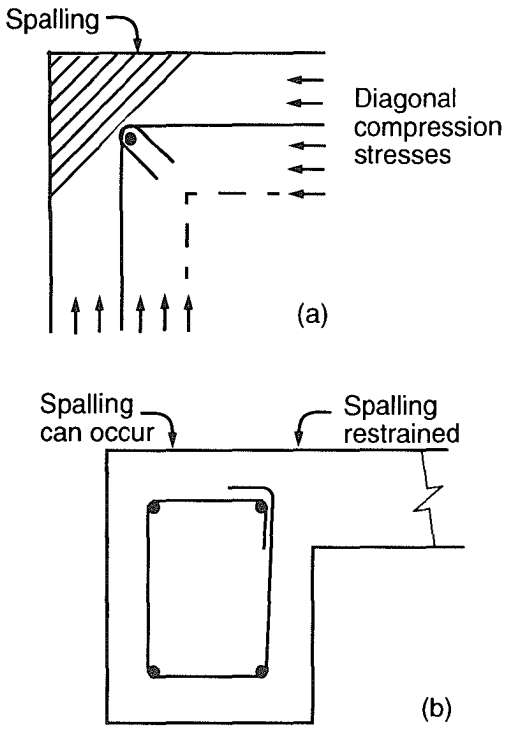

Fig. R11.6.4.2—Spalling of corners of beams loaded in torsion

11.6.4.2 — Transverse torsional reinforcement shall be anchored by one of the following:

(a) a 135 deg standard hook around a longitudinal bar, or

(b) according to 12.13.2.1, 12.13.2.2, or 12.13.2.3 in regions where the concrete surrounding the anchorage is restrained against spalling by a flange or slab or similar member.

R11.6.4.2 — When a rectangular beam fails in torsion, the corners of the beam tend to spall off due to the inclined compressive stresses in the concrete diagonals of the space truss changing direction at the corner as shown in Fig. 11.6.4.2(a). In tests, closed stirrups anchored by 90 deg hooks failed when this occurred.[11.25] For this reason, 135 deg hooks are preferable for torsional stirrups in all cases. In regions where this spalling is prevented by an adjacent slab or flange, 11.6.4.2(b) relaxes this and allows 90 deg hooks.

11.6.4.3 — Longitudinal torsion reinforcement shall be developed at both ends.

R.11.6.4.3 — If high torsion acts near the end of a beam, the longitudinal torsion reinforcement must be adequately anchored. Sufficient development length must be provided outside the inner face of the support to develop the needed tension force in the bars or tendons. In the case of bars this may require hooks or horizontal U-shaped bars lapped with the longitudinal torsion reinforcement.

11.6.4.4 — For hollow sections in torsion, the distance from the centerline of the transverse torsional reinforcement to the inside face of the wall of the hollow section shall not be less than $0.5A_{oh}/p_h$.

R11.6.4.4 — The closed stirrups provided for torsion in a hollow section should be located in the outer half of the wall thickness effective for torsion where the wall thickness can be taken as A_{oh}/p_h.

11.6.5 — Minimum torsion reinforcement

R11.6.5 — Minimum torsion reinforcement

11.6.5.1 — A minimum area of torsion reinforcement shall be provided in all regions where the factored tor-

R11.6.5.1 and R11.6.5.2 — If a member is subject to a factored torsional moment T_u greater than the values speci-

CODE

sional moment T_u exceeds the values specified in 11.6.1.

11.6.5.2 — Where torsional reinforcement is required by 11.6.5.1, the minimum area of transverse closed stirrups shall be computed by:

$$(A_v + 2A_t) = \frac{50 b_w s}{f_{yv}} \qquad (11\text{-}23)$$

11.6.5.3 — Where torsional reinforcement is required by 11.6.5.1, the minimum total area of longitudinal torsional reinforcement shall be computed by:

$$A_{\ell,min} = \frac{5\sqrt{f'_c} A_{cp}}{f_{y\ell}} - \left(\frac{A_t}{s}\right) p_h \frac{f_{yv}}{f_{y\ell}} \qquad (11\text{-}24)$$

where A_t/s shall not be taken less than $25 b_w/f_{yv}$.

11.6.6 — Spacing of torsion reinforcement

11.6.6.1 — The spacing of transverse torsion reinforcement shall not exceed the smaller of $p_h/8$ or 12 in.

11.6.6.2 — The longitudinal reinforcement required for torsion shall be distributed around the perimeter of the closed stirrups with a maximum spacing of 12 in. The longitudinal bars or tendons shall be inside the stirrups. There shall be at least one longitudinal bar or tendon in each corner of the stirrups. Bars shall have a diameter at least $^1/_{24}$ of the stirrup spacing, but not less than a No. 3 bar.

11.6.6.3 — Torsion reinforcement shall be provided for a distance of at least $(b_t + d)$ beyond the point theoretically required.

11.7 — Shear-friction

11.7.1 — Provisions of 11.7 are to be applied where it is appropriate to consider shear transfer across a given plane, such as: an existing or potential crack, an

COMMENTARY

fied in 11.6.1, the minimum amount of transverse web reinforcement for combined shear and torsion is $50 b_w s/f_{yv}$. The differences in the definition of A_v and the symbol A_t should be noted; A_v is the area of two legs of a closed stirrup while A_t is the area of only one leg of a closed stirrup.

R11.6.5.3 — Reinforced concrete beam specimens with less than 1 percent torsional reinforcement by volume have failed in pure torsion at torsional cracking.[11.21] In the 1989 and prior codes, a relationship was presented which required about 1 percent torsional reinforcement in beams loaded in pure torsion and less in beams with combined shear and torsion, as a function of the ratio of shear stresses due to torsion and shear. Eq. (11-24) was simplified by assuming a single value of this reduction factor and results in a volumetric ratio of about 0.5 percent.

R11.6.6 — Spacing of torsion reinforcement

R11.6.6.1 — The spacing of the stirrups is limited to ensure the development of the ultimate torsional strength of the beam, to prevent excessive loss of torsional stiffness after cracking, and to control crack widths. For a square cross section the $p_h/8$ limitation requires stirrups at $d/2$, which corresponds to 11.5.4.1.

R11.6.6.2 — In R11.6.3.7 it was shown that longitudinal reinforcement is needed to resist the sum of the longitudinal tensile forces due to torsion in the walls of the thin-walled tube. Since the force acts along the centroidal axis of the section, the centroid of the additional longitudinal reinforcement for torsion should approximately coincide with the centroid of the section. The code accomplishes this by requiring the longitudinal torsional reinforcement to be distributed around the perimeter of the closed stirrups. Longitudinal bars or tendons are required in each corner of the stirrups to provide anchorage for the legs of the stirrups. Corner bars have also been found to be very effective in developing torsional strength and in controlling cracks.

R11.6.6.3 — The distance $(b_t + d)$ beyond the point theoretically required for torsional reinforcement is larger than that used for shear and flexural reinforcement because torsional diagonal tension cracks develop in a helical form.

R11.7 — Shear-friction

R11.7.1 — With the exception of 11.7, virtually all provisions regarding shear are intended to prevent diagonal tension failures rather than direct shear transfer failures. The

CODE

interface between dissimilar materials, or an interface between two concretes cast at different times.

11.7.2 — Design of cross sections subject to shear transfer as described in 11.7.1 shall be based on Eq. (11-1), where V_n is calculated in accordance with provisions of 11.7.3 or 11.7.4.

11.7.3 — A crack shall be assumed to occur along the shear plane considered. The required area of shear-friction reinforcement A_{vf} across the shear plane shall be designed using either 11.7.4 or any other shear transfer design methods that result in prediction of strength in substantial agreement with results of comprehensive tests.

11.7.3.1 — Provisions of 11.7.5 through 11.7.10 shall apply for all calculations of shear transfer strength.

COMMENTARY

purpose of 11.7 is to provide design methods for conditions where shear transfer should be considered: an interface between concretes cast at different times, an interface between concrete and steel, reinforcement details for precast concrete structures, and other situations where it is considered appropriate to investigate shear transfer across a plane in structural concrete. (See References 11.27 and 11.28).

R11.7.3 — Although uncracked concrete is relatively strong in direct shear there is always the possibility that a crack will form in an unfavorable location. The shear-friction concept assumes that such a crack will form, and that reinforcement must be provided across the crack to resist relative displacement along it. When shear acts along a crack, one crack face slips relative to the other. If the crack faces are rough and irregular, this slip is accompanied by separation of the crack faces. At ultimate, the separation is sufficient to stress the reinforcement crossing the crack to its yield point. The reinforcement provides a clamping force $A_{vf}f_y$ across the crack faces. The applied shear is then resisted by friction between the crack faces, by resistance to the shearing off of protrusions on the crack faces, and by dowel action of the reinforcement crossing the crack. Successful application of 11.7 depends on proper selection of the location of an assumed crack.[11.13,11.27]

The relationship between shear-transfer strength and the reinforcement crossing the shear plane can be expressed in various ways. Eq. (11-25) and (11-26) of 11.7.4 are based on the shear-friction model. This gives a conservative prediction of shear-transfer strength. Other relationships which give a closer estimate of shear-transfer strength[11.13,11.29,11.30] can be used under the provisions of 11.7.3. For example, when the shear-friction reinforcement is perpendicular to the shear plane, the shear strength V_n is given by[11.29,11.30]

$$V_n = 0.8A_{vf}f_y + A_cK_1$$

where A_c is the area of concrete section resisting shear transfer (sq in.) and K_1 = **400 psi** for normal weight concrete, 200 psi for "all-lightweight" concrete, and 250 psi for "sand-lightweight" concrete. These values of K_1 apply to both monolithically cast concrete and to concrete cast against hardened concrete with a rough surface, as defined in 11.7.9.

In this equation, the first term represents the contribution of friction to shear-transfer resistance (0.8 representing the coefficient of friction). The second term represents the sum

CODE

11.7.4 — Shear-friction design method

11.7.4.1 — When shear-friction reinforcement is perpendicular to shear plane, shear strength V_n shall be computed by

$$V_n = A_{vf} f_y \mu \qquad (11\text{-}25)$$

where μ is coefficient of friction in accordance with 11.7.4.3.

11.7.4.2 — When shear-friction reinforcement is inclined to shear plane, such that the shear force produces tension in shear-friction reinforcement, shear strength V_n shall be computed by

$$V_n = A_{vf} f_y(\mu \sin\alpha_f + \cos\alpha_f) \qquad (11\text{-}26)$$

where α_f is angle between shear-friction reinforcement and shear plane.

COMMENTARY

of: (1) the resistance to shearing of protrusions on the crack faces, and (2) the dowel action of the reinforcement.

When the shear-friction reinforcement is inclined to the shear plane, such that the shear force produces tension in that reinforcement, the shear strength V_n is given by

$$V_n = A_{vf} f_y (0.8 \sin\alpha_f + \cos\alpha_f) + A_c K_1 \sin^2\alpha_f$$

where α_f is the angle between the shear-friction reinforcement and the shear plane, (i.e. $\mathbf{0 < \alpha_f < 90}$ **deg**).

When using the modified shear-friction method, the terms $(A_{vf} f_y / A_c)$ or $(A_{vf} f_y \sin\alpha_f / A_c)$ must not be less than 200 psi for the design equations to be valid.

R11.7.4 — Shear-friction design method

R11.7.4.1 — The required area of shear-transfer reinforcement A_{vf} is computed using

$$A_{vf} = \frac{V_u}{\phi f_y \mu}$$

The specified upper limit on shear strength must also be observed.

R11.7.4.2 — When the shear-friction reinforcement is inclined to the shear plane, such that the component of the shear force parallel to the reinforcement tends to produce tension in the reinforcement, as shown in Fig. R11.7.4, part of the shear is resisted by the component parallel to the shear plane of the tension force in the reinforcement.[11.30] Eq. (11-26) must be used only when the shear force component parallel to the reinforcement produces tension in the reinforcement, as shown in Fig. R11.7.4. When α_f is greater than 90 deg, the relative movement of the surfaces tends to compress the bar and Eq. (11-26) is not valid.

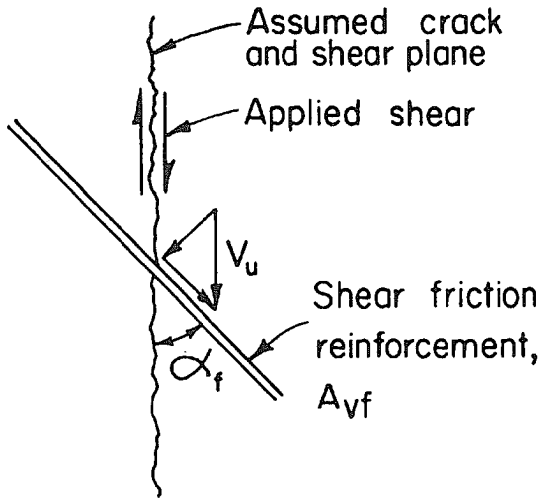

Fig. R11.7.4—Shear-friction reinforcement at an angle to assumed crack

CODE

11.7.4.3 — The coefficient of friction μ in Eq. (11-25) and Eq. (11-26) shall be

Concrete placed monolithically	1.4λ
Concrete placed against hardened concrete with surface intentionally roughened as specified in 11.7.9	1.0λ
Concrete placed against hardened concrete not intentionally roughened	0.6λ
Concrete anchored to as-rolled structural steel by headed studs or by reinforcing bars (see 11.7.10)	0.7λ

where λ = 1.0 for normal weight concrete, 0.85 for "sand-lightweight" concrete and 0.75 for "all lightweight" concrete. Linear interpolation shall be permitted when partial sand replacement is used.

11.7.5 — Shear strength V_n shall not be taken greater than $0.2f_c'A_c$ nor 800 A_c in pounds, where A_c is area of concrete section resisting shear transfer.

11.7.6 — Design yield strength of shear-friction reinforcement shall not exceed 60,000 psi.

11.7.7 — Net tension across shear plane shall be resisted by additional reinforcement. Permanent net compression across shear plane shall be permited to be taken as additive to the force in the shear-friction reinforcement $A_{vf}f_y$ when calculating required A_{vf}.

COMMENTARY

R11.7.4.3 — In the shear-friction method of calculation, it is assumed that all the shear resistance is due to the friction between the crack faces. It is, therefore, necessary to use artificially high values of the coefficient of friction in the shear-friction equations, so that the calculated shear strength will be in reasonable agreement with test results. For the case of concrete cast against hardened concrete not roughened in accordance with 11.7.9, shear resistance is primarily due to dowel action of the reinforcement and tests[11.31] indicate that reduced value of $\mu = 0.6\lambda$ specified for this case is appropriate.

The value of μ specified for concrete placed against as-rolled structural steel relates to the design of connections between precast concrete members, or between structural steel members and structural concrete members. The shear-transfer reinforcement may be either reinforcing bars or headed stud shear connectors; also, field welding to steel plates after casting of concrete is common. The design of shear connectors for composite action of concrete slabs and steel beams is not covered by these provisions, but should be in accordance with Reference 11.32.

R11.7.5 — This upper limit on shear strength is specified because Eq. (11-25) and (11-26) become unconservative if V_n has a greater value.

R11.7.7 — If a resultant tensile force acts across a shear plane, reinforcement to carry that tension must be provided in addition to that provided for shear transfer. Tension may be caused by restraint of deformations due to temperature change, creep, and shrinkage. Such tensile forces have caused failures, particularly in beam bearings.

When moment acts on a shear plane, the flexural tension stresses and flexural compression stresses are in equilibrium. There is no change in the resultant compression $A_{vf}f_y$ acting across the shear plane and the shear-transfer strength is not changed. It is therefore not necessary to provide additional reinforcement to resist the flexural tension stresses, unless the required flexural tension reinforcement exceeds the amount of shear-transfer reinforcement provided in the flexural tension zone. This has been demonstrated experimentally.[11.33]

It has also been demonstrated experimentally[11.28] that if a resultant compressive force acts across a shear plane, the shear-transfer strength is a function of the sum of the resultant compressive force and the force $A_{vf}f_y$ in the shear-friction reinforcement. In design, advantage should be taken of the existence of a compressive force across the shear plane to reduce the amount of shear-friction reinforcement

CODE

11.7.8 — Shear-friction reinforcement shall be appropriately placed along the shear plane and shall be anchored to develop the specified yield strength on both sides by embedment, hooks, or welding to special devices.

11.7.9 — For the purpose of 11.7, when concrete is placed against previously hardened concrete, the interface for shear transfer shall be clean and free of laitance. If μ is assumed equal to **1.0**λ, interface shall be roughened to a full amplitude of approximately $^1/_4$ in.

11.7.10 — When shear is transferred between as-rolled steel and concrete using headed studs or welded reinforcing bars, steel shall be clean and free of paint.

11.8 — Special provisions for deep flexural members

11.8.1 — The provisions of 11.8 shall apply to members with ℓ_n/d less than 5 that are loaded on one face and supported on the opposite face so that compression struts can develop between the loads and the supports. See also 12.10.6.

11.8.2 — The design of simply supported deep flexural members for shear shall be based on Eq. (11-1) and (11-2), where the shear strength V_c shall be in accordance with 11.8.6 or 11.8.7 and the shear strength V_s shall be in accordance with 11.8.8.

COMMENTARY

required, only if it is absolutely certain that the compressive force is permanent.

R11.7.8 — If no moment acts across the shear plane, reinforcement should be uniformly distributed along the shear plane to minimize crack widths. If a moment acts across the shear plane, it is desirable to distribute the shear-transfer reinforcement primarily in the flexural tension zone.

Since the shear-friction reinforcement acts in tension, it must have full tensile anchorage on both sides of the shear plane. Further, the shear-friction reinforcement anchorage must engage the primary reinforcement, otherwise a potential crack may pass between the shear-friction reinforcement and the body of the concrete. This requirement applies particularly to welded headed studs used with steel inserts for connections in precast and cast-in-place concrete. Anchorage may be developed by bond, by a welded mechanical anchorage, or by threaded dowels and screw inserts. Space limitations often require a welded mechanical anchorage. For anchorage of headed studs in concrete see Reference 11.13.

R11.8 — Special provisions for deep flexural members

R11.8.1—The behavior of a deep beam is discussed in References 11.5 and 11.34. For a normal deep beam supporting gravity loads, this section applies if the loads are applied on the top of the beam and the beam is supported on its bottom face. If the loads are applied through the sides or bottom of such a member, the design for shear should be the same as for ordinary beams.

The longitudinal tension reinforcement in deep flexural members should be extended to the supports and adequately anchored by embedment, hooks, or welding to special devices. Truss bars are not recommended.

CODE

11.8.3 — The design of continuous deep flexural members for shear shall be based on 11.1 through 11.5 with 11.8.5 substituted for 11.1.3, or on methods satisfying equilibrium and strength requirements. In either case the design shall also satisfy 11.8.4, 11.8.9, and 11.8.10.

11.8.4 — Shear strength V_n for deep flexural members shall not be taken greater than $8\sqrt{f_c'}\,b_w d$ when ℓ_n/d is less than 2. When ℓ_n/d is between 2 and 5,

$$V_n = \frac{2}{3}\left(10 + \frac{\ell_n}{d}\right)\sqrt{f_c'}\,b_w d \qquad (11\text{-}27)$$

11.8.5 — Critical section for shear measured from face of support shall be taken at a distance $0.15\ell_n$ for uniformly loaded beams and $0.50a$ for beams with concentrated loads, but not greater than d.

11.8.6 — Unless a more detailed calculation is made in accordance with 11.8.7,

$$V_c = 2\sqrt{f_c'}\,b_w d \qquad (11\text{-}28)$$

11.8.7 — Shear strength V_c shall be permitted to be computed by

$$V_c = \left(3.5 - 2.5\frac{M_u}{V_u d}\right)\left(1.9\sqrt{f_c'} + 2500\rho_w\frac{V_u d}{M_u}\right)b_w d \qquad (11\text{-}29)$$

except that the term

$$\left(3.5 - 2.5\frac{M_u}{V_u d}\right)$$

shall not exceed 2.5, and V_c shall not be taken greater than $6\sqrt{f_c'}\,b_w d$. M_u is factored moment occurring simultaneously with V_u at the critical section defined in 11.8.5.

11.8.8 — Where factored shear force V_u exceeds shear strength ϕV_c, shear reinforcement shall be provided to satisfy Eq. (11-1) and (11-2), where shear strength V_s shall be computed by

COMMENTARY

R11.8.3 — In a continuous beam, the critical section for shear defined in 11.8.5 occurs at a point where M_u approaches zero. As a result, the second term in Eq. (11-29) becomes large. For this reason, 11.8.3 requires continuous deep beams to be designed for shear according to the regular beam design procedures except that 11.8.5 is used to define the critical section for shear rather than 11.1.3. For a uniformly loaded beam, 11.1.3 allows one to design for the shear at d away from the support. This will frequently approach zero in a deep beam.

As an alternative to the regular beam design procedures, design methods satisfying equilibrium and strength requirements are allowed. Such methods are presented in References 11.34 and 11.35.

R11.8.7 — As the span-depth ratio of a member without web reinforcement decreases, its shear strength increases above the shear causing diagonal tension cracking. In Eq. (11-29) it is assumed that diagonal cracking occurs at the same shear strength as for ordinary beams, but that the shear strength carried by the concrete will be greater than the shear strength causing diagonal cracking.

Designers should note that shear in excess of the shear causing diagonal cracking may result in unsightly cracking unless shear reinforcement is provided.

R11.8.8 — The inclination of diagonal cracking may be greater than 45 deg, therefore, both horizontal and vertical shear reinforcement is required in deep flexural members.[11.36] The relative amounts of horizontal and vertical

CODE

$$V_s = \left[\frac{A_v}{s}\left(\frac{1+\frac{\ell_n}{d}}{12}\right) + \frac{A_{vh}}{s_2}\left(\frac{11-\frac{\ell_n}{d}}{12}\right)\right] f_y d \qquad (11\text{-}30)$$

where A_v is area of shear reinforcement perpendicular to flexural tension reinforcement within a distance s, and A_{vh} is area of shear reinforcement parallel to flexural reinforcement within a distance s_2.

11.8.9 — Area of shear reinforcement A_v shall not be less than $0.0015 b_w s$, and s shall not exceed $d/5$, nor 18 in.

11.8.10 — The area of horizontal shear reinforcement A_{vh} shall not be less than $0.0025 b_w s_2$ and s_2 shall not exceed $d/3$ nor 18 in.

11.8.11 — Shear reinforcement required at the critical section defined in 11.8.5 shall be used throughout the span.

11.9 — Special provisions for brackets and corbels

11.9.1 — Provisions of 11.9 shall apply to brackets and corbels with a shear span-to-depth ratio a/d not greater than unity, and subject to a horizontal tensile force N_{uc} not larger than V_u. Distance d shall be measured at face of support.

11.9.2 — Depth at outside edge of bearing area shall not be less than $0.5d$.

COMMENTARY

shear reinforcement that are selected from Eq. (11-30) may vary, as long as limits on the minimum amount and spacing are observed.

Special attention is directed to the importance of adequate anchorage for the shear reinforcement. Horizontal web reinforcement should be extended to the supports and anchored in the same manner as the tension reinforcement.

R11.8.11 — Based on the analysis carried out at the critical sections specified in 11.8.5, it may be determined that the member either does not need shear reinforcement, or that shear reinforcement is required, in which case it must be used throughout the span.

R11.9 — Special provisions for brackets and corbels

Brackets and corbels are cantilevers having shear span-to-depth ratios not greater than unity, which tend to act as simple trusses or deep beams rather than flexural members designed for shear according to 11.3.

The corbel shown in Fig. R11.9.1 may fail by shearing along the interface between the column and the corbel, by yielding of the tension tie, by crushing or splitting of the compression strut, or by localized bearing or shearing failure under the loading plate. These failure modes are illustrated and are discussed more fully in Reference 11.1. The notation used in 11.9 is illustrated in Fig. R11.9.2.

R11.9.1 — An upper limit of unity for a/d is specified for two reasons. First, for shear span-to-depth ratios exceeding unity, the diagonal tension cracks are less steeply inclined and the use of horizontal stirrups alone as specified in 11.9.4 is not appropriate. Second, the specified method of design has only been validated experimentally for a/d of unity or less. An upper limit is specified for N_{uc} because this method of design has only been validated experimentally for N_{uc} less than or equal to V_u, including N_{uc} equal to zero.

R11.9.2 — A minimum depth is specified at the outside edge of the bearing area so that a premature failure will not occur due to a major diagonal tension crack propagating

CODE

COMMENTARY

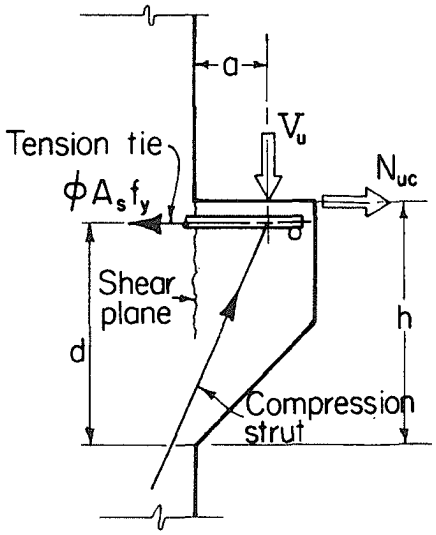

Fig. R11.9.1—Structural action of a corbel

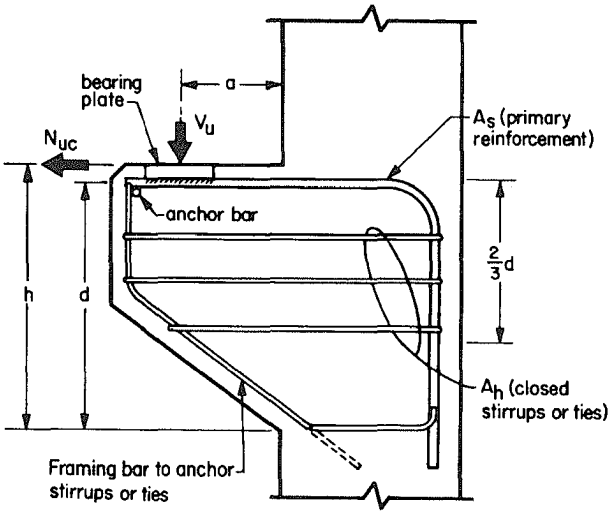

Fig. R11.9.2—Notation used in Section 11.9

from below the bearing area to the outer sloping face of the corbel or bracket. Failures of this type have been observed[11.37] in corbels having depths at the outside edge of the bearing area less than specified in this section of the code.

11.9.3 — Section at face of support shall be designed to resist simultaneously a shear V_u, a moment $[V_u a + N_{uc}(h - d)]$, and a horizontal tensile force N_{uc}.

11.9.3.1 — In all design calculations in accordance with 11.9, strength reduction factor ϕ shall be taken equal to 0.85.

R11.9.3.1 — Corbel and bracket behavior is predominantly controlled by shear; therefore, a single value of ϕ = **0.85** is specified for all design conditions.

11.9.3.2 — Design of shear-friction reinforcement A_{vf} to resist shear V_u shall be in accordance with 11.7.

CODE

11.9.3.2.1 — For normal weight concrete, shear strength V_n shall not be taken greater than $0.2f_c'b_wd$ nor $800b_wd$ in pounds.

11.9.3.2.2 — For "all-lightweight" or "sand-lightweight" concrete, shear strength V_n shall not be taken greater than $(0.2 - 0.07a/d)f_c'b_wd$ nor $(800 - 280a/d)b_wd$ in pounds.

11.9.3.3 — Reinforcement A_f to resist moment $[V_ua + N_{uc}(h - d)]$ shall be computed in accordance with 10.2 and 10.3.

11.9.3.4 — Reinforcement A_n to resist tensile force N_{uc} shall be determined from $N_{uc} \leq \phi A_n f_y$. Tensile force N_{uc} shall not be taken less than $0.2V_u$ unless special provisions are made to avoid tensile forces. Tensile force N_{uc} shall be regarded as a live load even when tension results from creep, shrinkage, or temperature change.

11.9.3.5 — Area of primary tension reinforcement A_s shall be made equal to the greater of $(A_f + A_n)$ or $(2A_{vf}/3 + A_n)$.

11.9.4 — Closed stirrups or ties parallel to A_s, with a total area A_h not less than $0.5(A_s - A_n)$, shall be uniformly distributed within two-thirds of the effective depth adjacent to A_s.

COMMENTARY

R11.9.3.2.2 — Tests[11.38] have shown that the maximum shear strength of lightweight concrete corbels or brackets is a function of both f_c' and a/d. No data are available for corbels or brackets made of sand-lightweight concrete. As a result, the same limitations have been placed on both all-lightweight and sand-lightweight brackets and corbels.

R11.9.3.3 — Reinforcement required to resist moment can be calculated using ordinary flexural theory. The factored moment is calculated by summing moments about the flexural reinforcement at the face of support.

R11.9.3.4 — Because the magnitude of horizontal forces acting on corbels or brackets cannot usually be determined with great accuracy, it is specified that N_{uc} be regarded as a live load.

R11.9.3.5 — Tests[11.38] suggest that the total amount of reinforcement $(A_s + A_h)$ required to cross the face of support must be the greater of:

(a) The sum of A_{vf} calculated according to 11.9.3.2 and A_n calculated according to 11.9.3.4, or

(b) The sum of $^3/_2$ times A_f calculated according to 11.9.3.3 and A_n calculated according to 11.9.3.4.

If (a) controls, $A_s = (2A_{vf}/3 + A_n)$ is required as primary tensile reinforcement, and the remaining $A_{vf}/3$ must be provided as closed stirrups parallel to A_s and distributed within $(^2/_3)d$, adjacent to A_s. Section 11.9.4 satisfies this by requiring $A_h = 0.5(2A_{vf}/3)$.

If (b) controls, $A_s = (A_f + A_n)$ is required as primary tension reinforcement, and the remaining $A_f/2$ must be provided as closed stirrups parallel to A_s and distributed within $(^2/_3)d$, adjacent to A_s. Again 11.9.4 satisfies this requirement.

R11.9.4 — Closed stirrups parallel to the primary tension reinforcement are necessary to prevent a premature diagonal tension failure of the corbel or bracket. The required area of closed stirrups $A_h = 0.5(A_s - A_n)$ automatically yields the appropriate amounts, as discussed in R11.9.3.5 above.

CODE

COMMENTARY

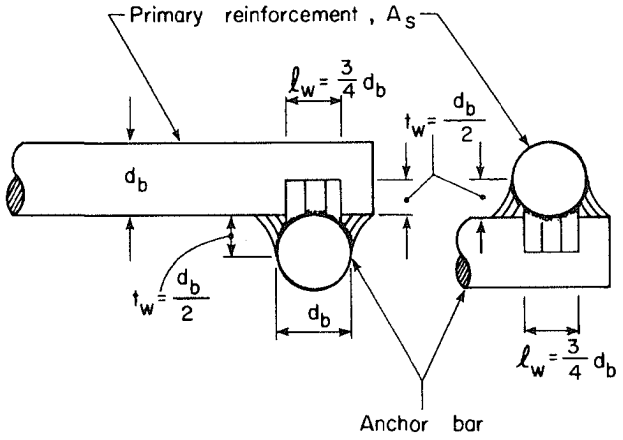

Fig. R11.9.6—Weld details used in tests of Reference 11.38

11.9.5 — Ratio $\rho = A_s/bd$ shall not be less than $0.04 (f_c'/f_y)$.

R11.9.5 — A minimum amount of reinforcement is specified to prevent the possibility of sudden failure should the bracket or corbel concrete crack under the action of flexural moment and outward tensile force N_{uc}.

11.9.6 — At front face of bracket or corbel, primary tension reinforcement A_s shall be anchored by one of the following: (a) by a structural weld to a transverse bar of at least equal size; weld to be designed to develop specified yield strength f_y of A_s bars; (b) by bending primary tension bars A_s back to form a horizontal loop; or (c) by some other means of positive anchorage.

R11.9.6 — Because the horizontal component of the inclined concrete compression strut (see Fig. R11.9.1) is transferred to the primary tension reinforcement at the location of the vertical load, the reinforcement A_s is essentially uniformly stressed from the face of the support to the point where the vertical load is applied. It must, therefore, be anchored at its outer end and in the supporting column, so as to be able to develop its yield strength from the face of support to the vertical load. Satisfactory anchorage at the outer end can be obtained by bending the A_s bars in a horizontal loop as specified in (b), or by welding a bar of equal diameter or a suitably sized angle across the ends of the A_s bars. The welds must be designed to develop the yield strength of the reinforcement A_s. The weld detail used successfully in the corbel tests reported in Reference 11.38 is shown in Fig. R11.9.6. The reinforcement A_s must be anchored within the supporting column in accordance with the requirements of Chapter 12. See additional discussion on end anchorage in R12.10.6.

11.9.7 — Bearing area of load on bracket or corbel shall not project beyond straight portion of primary tension bars A_s, nor project beyond interior face of transverse anchor bar (if one is provided).

R11.9.7 — The restriction on the location of the bearing area is necessary to ensure development of the yield strength of the reinforcement A_s near the load. When corbels are designed to resist horizontal forces, the bearing plate should be welded to the tension reinforcement A_s.

11.10 — Special provisions for walls

R11.10 — Special provisions for walls

11.10.1 — Design for shear forces perpendicular to face of wall shall be in accordance with provisions for slabs in 11.12. Design for horizontal shear forces in plane of wall shall be in accordance with 11.10.2 through 11.10.8.

R11.10.1 — Shear in the plane of the wall is primarily of importance for shearwalls with a small height-to-length ratio. The design of higher walls, particularly walls with uniformly distributed reinforcement, will probably be controlled by flexural considerations.

CODE

11.10.2 — Design of horizontal section for shear in plane of wall shall be based on Eq. (11-1) and (11-2), where shear strength V_c shall be in accordance with 11.10.5 or 11.10.6 and shear strength V_s shall be in accordance with 11.10.9.

11.10.3 — Shear strength V_n at any horizontal section for shear in plane of wall shall not be taken greater than $10\sqrt{f_c'}\,hd$.

11.10.4 — For design for horizontal shear forces in plane of wall, d shall be taken equal to $0.8\ell_w$. A larger value of d, equal to the distance from extreme compression fiber to center of force of all reinforcement in tension, shall be permitted to be used when determined by a strain compatibility analysis.

11.10.5 — Unless a more detailed calculation is made in accordance with 11.10.6, shear strength V_c shall not be taken greater than $2\sqrt{f_c'}\,hd$ for walls subject to N_u in compression, or V_c shall not be taken greater than the value given in 11.3.2.3 for walls subject to N_u in tension.

11.10.6 — Shear strength V_c shall be permitted to be computed by Eq. (11-31) and (11-32), where V_c shall be the lesser of Eq. (11-31) or (11-32).

$$V_c = 3.3\sqrt{f_c'}hd + \frac{N_u d}{4\ell_w} \qquad (11\text{-}31)$$

or

$$V_c = \left[0.6\sqrt{f_c'} + \frac{\ell_w\left(1.25\sqrt{f_c'} + 0.2\dfrac{N_u}{\ell_w h}\right)}{\dfrac{M_u}{V_u} - \dfrac{\ell_w}{2}}\right] hd \qquad (11\text{-}32)$$

where N_u is negative for tension. When $(M_u/V_u - \ell_w/2)$ is negative, Eq. (11-32) shall not apply.

11.10.7 — Sections located closer to wall base than a distance $\ell_w/2$ or one-half the wall height, whichever is less, shall be permitted to be designed for the same V_c as that computed at a distance $\ell_w/2$ or one-half the height.

11.10.8 — When factored shear force V_u is less than $\phi V_c/2$, reinforcement shall be provided in accordance with 11.10.9 or in accordance with Chapter 14. When V_u exceeds $\phi V_c/2$, wall reinforcement for resisting shear shall be provided in accordance with 11.10.9.

COMMENTARY

R11.10.3 — Although the width-to-depth ratio of shearwalls is less than that for ordinary beams, tests[11.39] on shearwalls with a thickness equal to $\ell_w/25$ have indicated that ultimate shear stresses in excess of $10\sqrt{f_c'}$ can be obtained.

R11.10.5 and R11.10.6 — Eq. (11-31) and (11-32) may be used to determine the inclined cracking strength at any section through a shearwall. Eq. (11-31) corresponds to the occurrence of a principal tensile stress of approximately $4\sqrt{f_c'}$ at the centroid of the shearwall cross section. Eq. (11-32) corresponds approximately to the occurrence of a flexural tensile stress of $6\sqrt{f_c'}$ at a section $\ell_w/2$ above the section being investigated. As the term

$$\left(\frac{M_u}{V_u} - \frac{\ell_w}{2}\right)$$

decreases, Eq. (11-31) will control before this term becomes negative. When this term becomes negative Eq. (11-31) should be used.

R11.10.7 — The values of V_c computed from Eq. (11-31) and (11-32) at a section located a distance $\ell_w/2$ or $h_w/2$ (whichever is less) above the base apply to that and all sections between this section and the base. However, the maximum factored shear force V_u at any section, including the base of the wall, is limited to ϕV_n in accordance with 11.10.3.

CODE

11.10.9 — Design of shear reinforcement for walls

11.10.9.1 — Where factored shear force V_u exceeds shear strength ϕV_c, horizontal shear reinforcement shall be provided to satisfy Eq. (11-1) and (11-2), where shear strength V_s shall be computed by

$$V_s = \frac{A_v f_y d}{s_2} \qquad (11\text{-}33)$$

where A_v is area of horizontal shear reinforcement within a distance s_2 and distance d is in accordance with 11.10.4. Vertical shear reinforcement shall be provided in accordance with 11.10.9.4.

11.10.9.2 — Ratio ρ_h of horizontal shear reinforcement area to gross concrete area of vertical section shall not be less than 0.0025.

11.10.9.3 — Spacing of horizontal shear reinforcement s_2 shall not exceed $\ell_w/5$, $3h$, nor 18 in.

11.10.9.4 — Ratio ρ_n of vertical shear reinforcement area to gross concrete area of horizontal section shall not be less than

$$\rho_n = 0.0025 + 0.5\left(2.5 - \frac{h_w}{\ell_w}\right)(\rho_h - 0.0025) \qquad (11\text{-}34)$$

nor 0.0025, but need not be greater than the required horizontal shear reinforcement.

11.10.9.5 — Spacing of vertical shear reinforcement s_1 shall not exceed $\ell_w/3$, $3h$, nor 18 in.

11.11 — Transfer of moments to columns

11.11.1 — When gravity load, wind, earthquake, or other lateral forces cause transfer of moment at connections of framing elements to columns, the shear resulting from moment transfer shall be considered in the design of lateral reinforcement in the columns.

11.11.2 — Except for connections not part of a primary seismic load-resisting system that are restrained on four sides by beams or slabs of approximately equal depth, connections shall have lateral reinforcement

COMMENTARY

R11.10.9 — Design of shear reinforcement for walls

Both horizontal and vertical shear reinforcement are required for all walls. For low walls, test data[11.40] indicate that horizontal shear reinforcement becomes less effective with vertical reinforcement becoming more effective. This change in effectiveness of the horizontal versus vertical reinforcement is recognized in Eq. (11-34); when h_w/ℓ_w is less than 0.5, the amount of vertical reinforcement is equal to the amount of horizontal reinforcement. When h_w/ℓ_w is greater than 2.5, only a minimum amount of vertical reinforcement is required ($0.0025\, s_1 h$).

Eq. (11-33) is presented in terms of shear strength V_s provided by the horizontal shear reinforcement for direct application in Eq. (11-1) and (11-2).

Vertical shear reinforcement also must be provided in accordance with 11.10.9.4 within the spacing limitation of 11.10.9.5.

R11.11 — Transfer of moments to columns

R11.11.1 — Tests[11.41] have shown that the joint region of a beam to column connection in the interior of a building does not require shear reinforcement if the joint is confined on four sides by beams of approximately equal depth. However, joints without lateral confinement, such as at the exterior of a building, need shear reinforcement to prevent deterioration due to shear cracking.[11.42]

For regions where strong earthquakes may occur, joints may be required to withstand several reversals of loading that develop the flexural capacity of the adjoining beams. See Chapter 21 for special provisions for seismic design.

CODE

not less than that required by Eq. (11-13) within the column for a depth not less than that of the deepest connection of framing elements to the columns. See also 7.9.

11.12 — Special provisions for slabs and footings

11.12.1 — The shear strength of slabs and footings in the vicinity of columns, concentrated loads, or reactions is governed by the more severe of two conditions:

11.12.1.1 — Beam action where each critical section to be investigated extends in a plane across the entire width. For beam action the slab or footing shall be designed in accordance with 11.1 through 11.5.

11.12.1.2 — Two-way action where each of the critical sections to be investigated shall be located so that its perimeter b_o is a minimum but need not approach closer than $d/2$ to

(a) edges or corners of columns, concentrated loads, or reaction areas, or

(b) changes in slab thickness such as edges of capitals or drop panels.

For two-way action the slab or footing shall be designed in accordance with 11.12.2 through 11.12.6.

11.12.1.3 — For square or rectangular columns, concentrated loads, or reaction areas, the critical sections with four straight sides shall be permitted.

11.12.2 — The design of a slab or footing for two-way action is based on Eq. (11-1) and (11-2). V_c shall be computed in accordance with 11.12.2.1, 11.12.2.2, or 11.12.3.1. V_s shall be computed in accordance with 11.12.3. For slabs with shearheads, V_n shall be in accordance with 11.12.4. When moment is transferred between a slab and a column, 11.12.6 shall apply.

COMMENTARY

R11.12 — Special provisions for slabs and footings

R11.12.1 — Differentiation must be made between a long and narrow slab or footing acting as a beam, and a slab or footing subject to two-way action where failure may occur by "punching" along a truncated cone or pyramid around a concentrated load or reaction area.

R11.12.1.2 — The critical section for shear in slabs subjected to bending in two directions follows the perimeter at the edge of the loaded area.[11.3] The shear stress acting on this section at factored loads is a function of $\sqrt{f_c'}$ and the ratio of the side dimension of the column to the effective slab depth. A much simpler design equation results by assuming a pseudocritical section located at a distance $d/2$ from the periphery of the concentrated load. When this is done, the shear strength is almost independent of the ratio of column size to slab depth. For rectangular columns, this critical section was originally defined by straight lines drawn parallel to and at a distance $d/2$ from the edges of the loaded area. Section 11.12.1.3 allows the use of a rectangular critical section.

For slabs of uniform thickness it is sufficient to check shear on one section. For slabs with changes in thickness as happens, for example at the edge of drop panels, it is necessary to check shear at several sections.

For edge columns at points where the slab cantilevers beyond the column, the critical perimeter will either be three-sided or four-sided.

CODE

COMMENTARY

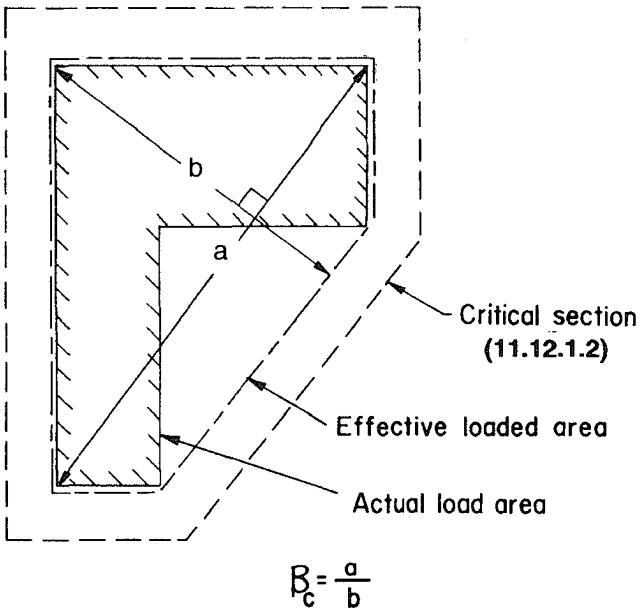

Fig. R11.12.2—Value of β_c for a nonrectangular loaded area

11.12.2.1 — For nonprestressed slabs and footings, V_c shall be the smallest of:

(a) $$V_c = \left(2 + \frac{4}{\beta_c}\right)\sqrt{f_c'}\,b_o d \qquad (11\text{-}35)$$

where β_c is the ratio of long side to short side of the column, concentrated load or reaction area

(b) $$V_c = \left(\frac{\alpha_s d}{b_o} + 2\right)\sqrt{f_c'}\,b_o d \qquad (11\text{-}36)$$

where α_s is 40 for interior columns, 30 for edge columns, 20 for corner columns, and

(c) $$V_c = 4\sqrt{f_c'}\,b_o d \qquad (11\text{-}37)$$

11.12.2.2 — At columns of two-way prestressed slabs and footings that meet the requirements of 18.9.3

$$V_c = \left(\beta_p\sqrt{f_c'} + 0.3 f_{pc}\right)b_o d + V_p \qquad (11\text{-}38)$$

where β_p is the smaller of 3.5 or $(\alpha_s d/b_o + 1.5)$, α_s is 40 for interior columns, 30 for edge columns, and 20

R11.12.2.1 — For square columns, the shear stress due to ultimate loads in slabs subjected to bending in two directions is limited to $4\sqrt{f_c'}$. However, tests[11.43] have indicated that the value of $4\sqrt{f_c'}$ is unconservative when the ratio β_c of the lengths of the long and short sides of a rectangular column or loaded area is larger than 2.0. In such cases, the actual shear stress on the critical section at punching shear failure varies from a maximum of about $4\sqrt{f_c'}$ around the corners of the column or loaded area, down to $2\sqrt{f_c'}$ or less along the long sides between the two end sections. Other tests[11.44] indicate that v_c decreases as the ratio b_o/d increases. Eq. (11-35) and (11-36) were developed to account for these two effects. The words "interior, edge, and corner columns" in 11.12.2.1(b) refer to critical sections with 4, 3, or 2 sides, respectively.

For shapes other than rectangular, β_c is taken to be the ratio of the longest overall dimension of the effective loaded area to the largest overall dimension of the effective loaded area measured perpendicular thereto, as illustrated for an L-shaped reaction area in Fig. R11.12.2. The effective loaded area is that area totally enclosing the actual loaded area, for which the perimeter is a minimum.

R11.12.2.2 — For prestressed slabs and footings, a modified form of code Eq. (11-35) and (11-36) is specified for two-way action shear strength. Research[11.45,11.46] indicates that the shear strength of two-way prestressed slabs around interior columns is conservatively predicted by Eq. (11-38). V_c from Eq. (11-36) corresponds to a diagonal tension failure of the concrete initiating at the critical section defined in 11.12.1.2. The mode of failure differs from a punching shear failure of the concrete compression zone around the perimeter of the loaded area predicted by Eq.

CODE

for corner columns, b_o is perimeter of critical section defined in 11.12.1.2, f_{pc} is the average value of f_{pc} for the two directions, and V_p is the vertical component of all effective prestress forces crossing the critical section. V_c shall be permitted to be computed by Eq. (11-38) if the following are satisfied; otherwise, 11.12.2.1 shall apply:

(a) no portion of the column cross section shall be closer to a discontinuous edge than 4 times the slab thickness, and

(b) f_c' in Eq. (11-38) shall not be taken greater than 5000 psi, and

(c) f_{pc} in each direction shall not be less than 125 psi, nor be taken greater than 500 psi.

11.12.3 — Shear reinforcement consisting of bars or wires shall be permitted in slabs and footings in accordance with the following:

11.12.3.1 — V_n shall be computed by Eq. (11-2), where V_c shall not be taken greater than $2\sqrt{f_c'}\,b_o d$, and the required area of shear reinforcement A_v and V_s shall be calculated in accordance with 11.5 and anchored in accordance with 12.13.

11.12.3.2 — V_n shall not be taken greater than $6\sqrt{f_c'}\,b_o d$.

COMMENTARY

(11-35). Consequently, the term β_c does not enter into Eq. (11-38). Design values for f_c' and f_{pc} are restricted due to limited test data available for higher values. When computing f_{pc}, loss of prestress due to restraint of the slab by shearwalls and other structural elements must be taken into account.

In a prestressed slab with distributed tendons, the V_p term in Eq. (11-38) contributes only a small amount to the shear strength; therefore, it may be conservatively taken as zero. If V_p is to be included, the tendon profile assumed in the calculations must be specified.

For an exterior column support where the distance from the outside of the column to the edge of the slab is less than four times the slab thickness, the prestress is not fully effective around the total perimeter b_o of the critical section. Shear strength in this case is therefore conservatively taken the same as for a nonprestressed slab.

R11.12.3 — Research has shown that shear reinforcement consisting of bars or wires can be used in slabs provided that it is well anchored. The anchorage detail used in the tests is shown in Fig. R11.12.3(a). Anchorage of stirrups according to the requirements of 12.13 may be difficult in slabs thinner than 10 in. For such thin slabs, stirrups should only be used if they are closed and enclose a longitudinal bar at each corner. Shear reinforcement consisting of vertical bars mechanically anchored at each end by a plate or head capable of developing the yield strength of the bars have been used successfully.

In a slab-column joint in which the moment transfer is negligible, the shear reinforcement should be symmetrical about the centroid of the critical section in location, number and spacing of stirrups as shown in Fig. R11.12.3(b). At edge columns or in the case of interior columns transferring moment, the shear reinforcement should be as symmetrical as possible. Although the average shear stresses on faces *AD* and *BC* of the exterior column in Fig. R11.12.3(c) are

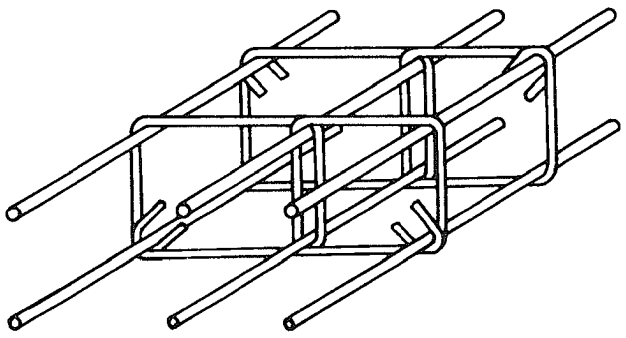

Fig. R11.12.3(a)—Slab stirrups

CODE

COMMENTARY

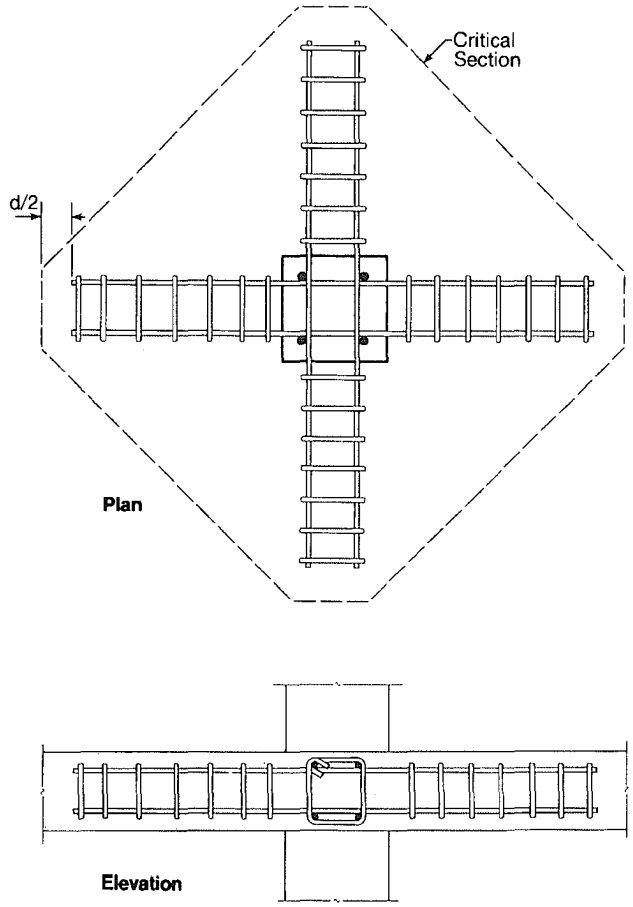

Fig. R11.12.3(b)—Arrangement of stirrup shear reinforcement, interior column

lower than on face *AB*, the stirrups extending from faces *AD* and *BC* reinforce against torsional stresses in the strip of slab along the edge.

When bars or wires are provided as shear reinforcement, the shear strength may be increased to a maximum shear stress of $6\sqrt{f_c'}$. However, shear reinforcement must be designed to carry all shear in excess of a stress of $2\sqrt{f_c'}$.[11.47]

11.12.4—Shear reinforcement consisting of steel I- or channel-shaped sections (shearheads) shall be permitted in slabs. The provisions of 11.12.4.1 through 11.12.4.9 shall apply where shear due to gravity load is transferred at interior column supports. Where moment is transferred to columns, 11.12.6.3 shall apply.

11.12.4.1 — Each shearhead shall consist of steel shapes fabricated by welding with a full penetration weld into identical arms at right angles. Shearhead arms shall not be interrupted within the column section.

11.12.4.2 — A shearhead shall not be deeper than 70 times the web thickness of the steel shape.

R11.12.4—Based on reported test data,[11.48] design procedures are presented for shearhead reinforcement consisting of structural steel shapes. For a column connection transferring moment, the design of shearheads is given in 11.12.6.3.

Three basic criteria must be considered in the design of shearhead reinforcement for connections transferring shear due to gravity load. First, a minimum flexural strength must be provided to assure that the required shear strength of the slab is reached before the flexural strength of the shearhead is exceeded. Second, the shear stress in the slab at the end of the shearhead reinforcement must be limited. Third, after these two requirements are satisfied, the designer can reduce the negative slab reinforcement in proportion to the moment contribution of the shearhead at the design section.

CODE

11.12.4.3 — The ends of each shearhead arm shall be permitted to be cut at angles not less than 30 deg with the horizontal, provided the plastic moment strength of the remaining tapered section is adequate to resist the shear force attributed to that arm of the shearhead.

11.12.4.4 — All compression flanges of steel shapes shall be located within **0.3*d*** of compression surface of slab.

COMMENTARY

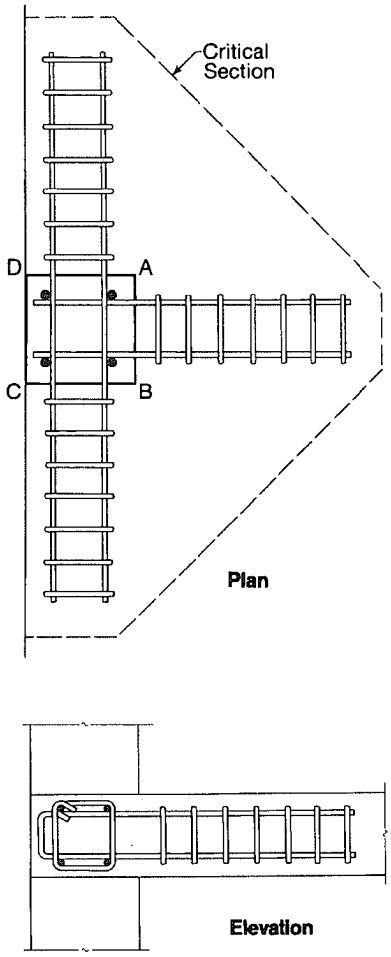

Fig. R11.12.3(c)—Arrangement of stirrup shear reinforcement, edge column

11.12.4.5 — The ratio α_v between the stiffness of each shearhead arm and that of the surrounding composite cracked slab section of width $(c_2 + d)$ shall not be less than 0.15.

11.12.4.6 — The plastic moment strength M_p required for each arm of the shearhead shall be computed by

$$\phi M_p = \frac{V_u}{2\eta}\left[h_v + \alpha_v\left(\ell_v - \frac{c_1}{2}\right)\right] \qquad (11\text{-}39)$$

where ϕ is the strength reduction factor for flexure, η is the number of arms, and ℓ_v is the minimum length of each shearhead arm required to comply with requirements of 11.12.4.7 and 11.12.4.8.

R11.12.4.5 and R11.12.4.6 — The assumed idealized shear distribution along an arm of a shearhead at an interior column is shown in Fig. R11.12.4.5. The shear along each of the arms is taken as $\alpha_v V_c/\eta$, where α_v and η are defined in 11.12.4.5 and 11.12.4.6, and V_c is defined in 11.12.2.1. However, the peak shear at the face of the column is taken as the total shear considered per arm $V_u/\phi\eta$ minus the shear considered carried to the column by the concrete compression zone of the slab. The latter term is expressed as

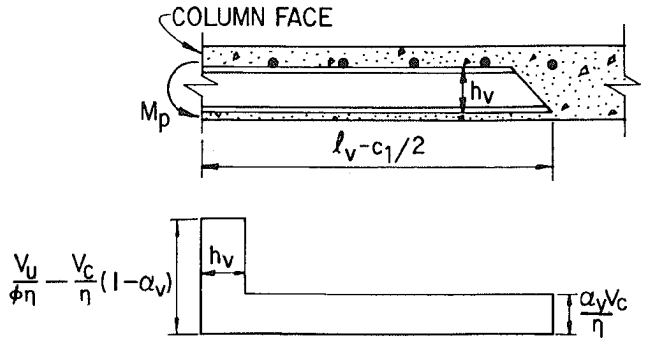

Fig. R11.12.4.5—Idealized shear acting on shearhead

CODE

COMMENTARY

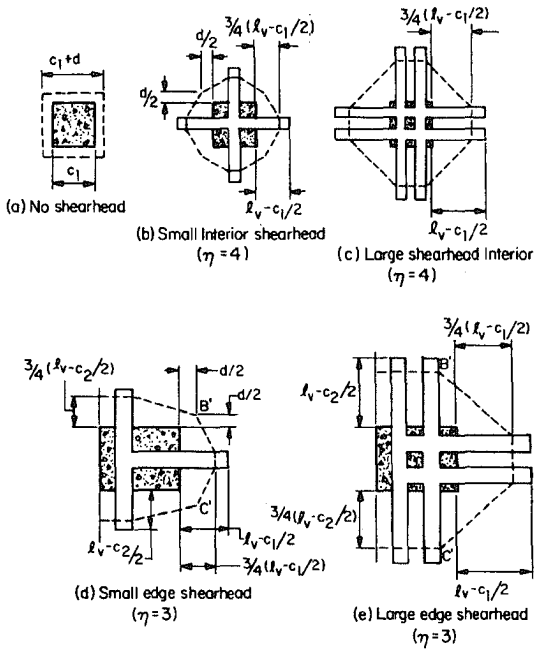

Fig. R11.12.4.7—Location of critical section defined in 11.12.4.7

$(V_c/\eta)(1 - \alpha_v)$, so that it approaches zero for a heavy shearhead and approaches $V_u/\phi\eta$ when a light shearhead is used. Eq. (11-39) then follows from the assumption that the inclined cracking shear force V_c is about one-half the shear force V_u. In this equation, M_p is the required plastic moment strength of each shearhead arm necessary to assure that ultimate shear is attained as the moment strength of the shearhead is reached. The quantity ℓ_v is the length from the center of the column to the point at which the shearhead is no longer required, and the distance $c_1/2$ is one-half the dimension of the column in the direction considered.

11.12.4.7 — The critical slab section for shear shall be perpendicular to the plane of the slab and shall cross each shearhead arm at three-quarters the distance $[\ell_v - (c_1/2)]$ from the column face to the end of the shearhead arm. The critical section shall be located so that its perimeter b_o is a minimum, but need not be closer than the perimeter defined in 11.12.1.2(a).

R11.12.4.7 — The test results indicated that slabs containing "underreinforcing" shearheads failed at a shear stress on a critical section at the end of the shearhead reinforcement less than $4\sqrt{f_c'}$. Although the use of "overreinforcing" shearheads brought the shear strength back to about the equivalent of $4\sqrt{f_c'}$, the limited test data suggest that a conservative design is desirable. Therefore, the shear strength is calculated as $4\sqrt{f_c'}$ on an assumed critical section located inside the end of the shearhead reinforcement.

The critical section is taken through the shearhead arms three-fourths of the distance $[\ell_v - (c_1/2)]$ from the face of the column to the end of the shearhead. However, this assumed critical section need not be taken closer than $d/2$ to the column. See Fig. R11.12.4.7.

11.12.4.8 — V_n shall not be taken greater than $4\sqrt{f_c'}\,b_o d$ on the critical section defined in 11.12.4.7. When shearhead reinforcement is provided, V_n shall not be

CODE

taken greater than $7\sqrt{f_c'}\,b_o d$ on the critical section defined in 11.12.1.2(a).

11.12.4.9 — The moment resistance M_v contributed to each slab column strip by a shearhead shall not be taken greater than

$$M_v = \frac{\phi\alpha_v V_u\left(\ell_v - \frac{c_1}{2}\right)}{2\eta} \qquad (11\text{-}40)$$

where ϕ is the strength reduction factor for flexure, η is the number of arms, and ℓ_v is the length of each shearhead arm actually provided. However, M_v shall not be taken larger than the smaller of:

(a) 30 percent of the total factored moment required for each slab column strip,

(b) the change in column strip moment over the length ℓ_v,

(c) the value of M_p computed by Eq. (11-39)

11.12.4.10 — When unbalanced moments are considered, the shearhead must have adequate anchorage to transmit M_p to column.

11.12.5 — Openings in slabs

When openings in slabs are located at a distance less than 10 times the slab thickness from a concentrated load or reaction area, or when openings in flat slabs are located within column strips as defined in Chapter 13, the critical slab sections for shear defined in 11.12.1.2 and 11.12.4.7 shall be modified as follows:

11.12.5.1 — For slabs without shearheads, that part of the perimeter of the critical section that is enclosed by straight lines projecting from the centroid of the column, concentrated load, or reaction area and tangent to the boundaries of the openings shall be considered ineffective.

11.12.5.2 — For slabs with shearheads, the ineffective portion of the perimeter shall be one-half of that defined in 11.12.5.1.

COMMENTARY

R11.12.4.9 — If the peak shear at the face of the column is neglected, and the cracking load V_c is again assumed to be about one-half of V_u, the moment contribution of the shearhead M_v can be conservatively computed from Eq. (11-40), in which ϕ is the factor for flexure (0.9).

R11.12.4.10 — See R11.12.6.3.

R11.12.5 — Openings in slabs

Provisions for design of openings in slabs (and footings) were developed in Reference 11.3. The locations of the

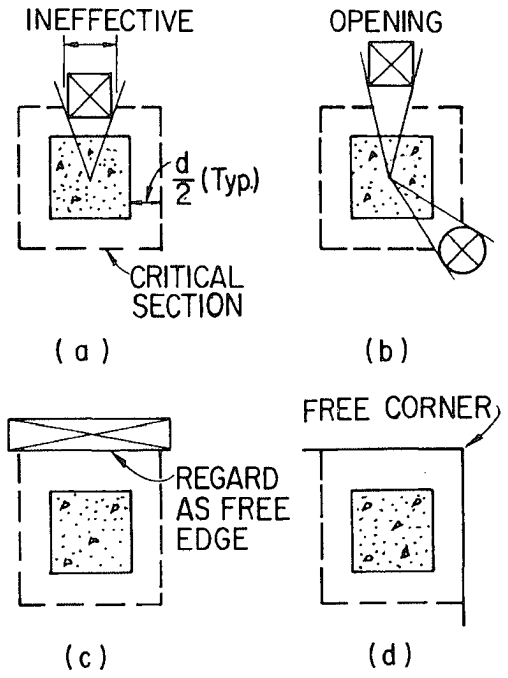

Fig. R11.12.5—Effect of openings and free edges (effective perimeter shown with dashed lines)

CODE

11.12.6 — Transfer of moment in slab-column connections

11.12.6.1 — When gravity load, wind, earthquake, or other lateral forces cause transfer of unbalanced moment M_u between a slab and a column, a fraction $\gamma_f M_u$ of the unbalanced moment shall be transferred by flexure in accordance with 13.5.3. The remainder of the unbalanced moment given by $\gamma_v M_u$ shall be considered to be transferred by eccentricity of shear about the centroid of the critical section defined in 11.12.1.2 where

$$\gamma_v = (1 - \gamma_f) \quad (11\text{-}41)$$

11.12.6.2 — The shear stress resulting from moment transfer by eccentricity of shear shall be assumed to vary linearly about the centroid of the critical sections defined in 11.12.1.2. The maximum shear stress due to the factored shear force and moment shall not exceed ϕv_n:

For members without shear reinforcement

$$\phi v_n = \phi V_c / (b_o d) \quad (11\text{-}42)$$

where V_c is as defined in 11.12.2.1 or 11.12.2.2.

For members with shear reinforcement other than shearheads:

$$\phi v_n = \phi (V_c + V_s) / (b_o d) \quad (11\text{-}43)$$

where V_c and V_s are defined in 11.12.3. If shear reinforcement is provided, the design shall take into account the variation of shear stress around the column.

COMMENTARY

effective portions of the critical section near typical openings and free edges are shown by the dashed lines in Fig. R11.12.5. Additional research[11.43] has confirmed that these provisions are conservative.

R11.12.6 — Transfer of moment in slab-column connections

R11.12.6.1 — In Reference 11.49 it was found that where moment is transferred between a column and a slab, 60 percent of the moment should be considered transferred by flexure across the perimeter of the critical section defined in 11.12.1.2, and 40 percent by eccentricity of the shear about the centroid of the critical section. For rectangular columns, it has been assumed that the portion of the moment transferred by flexure increases as the width of the face of the critical section resisting the moment increases as given by Eq. (13-1).

Most of the data in Reference 11.49 were obtained from tests of square columns, and little information is available for round columns. These can be approximated as square columns. Fig. R13.6.2.5 shows square supports having the same area as some nonrectangular members.

R11.12.6.2 — The stress distribution is assumed as illustrated in Fig. R11.12.6.2 for an interior or exterior column. The perimeter of the critical section, *ABCD*, is determined in accordance with 11.12.1.2. The factored shear force V_u and unbalanced moment M_u are determined at the centroi-

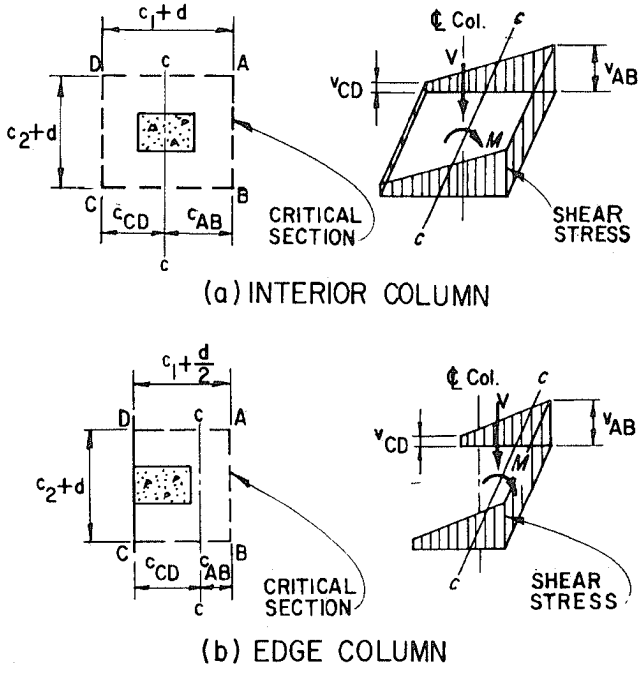

Fig. R11.12.6.2—Assumed distribution of shear stress

CODE

COMMENTARY

dal axis *c-c* of the critical section. The maximum factored shear stress may be calculated from:

$$v_{u(AB)} = \frac{V_u}{A_c} + \frac{\gamma_v M_u c_{AB}}{J_c}$$

or

$$v_{u(CD)} = \frac{V_u}{A_c} - \frac{\gamma_v M_u c_{CD}}{J_c}$$

where γ_v is given by Eq. (11-41). For an interior column, A_c and J_c may be calculated by

A_c = area of concrete of assumed critical section
$= 2d\,(c_1 + c_2 + 2d)$

J_c = property of assumed critical section analogous to polar moment of inertia

$$= \frac{d(c_1 + d)^3}{6} + \frac{(c_1 + d)\,d^3}{6} + \frac{d(c_2 + d)\,(c_1 + d)^2}{2}$$

Similar equations may be developed for A_c and J_c for columns located at the edge or corner of a slab.

The fraction of the unbalanced moment between slab and column not transferred by eccentricity of the shear must be transferred by flexure in accordance with 13.5.3. A conservative method assigns the fraction transferred by flexure over an effective slab width defined in 13.5.3.2. Often designers concentrate column strip reinforcement near the column to accommodate this unbalanced moment. Available test data seem to indicate that this practice does not increase shear strength but may be desirable to increase the stiffness of the slab-column junction.

Test data[11.50] indicate that the moment transfer capacity of a prestressed slab to column connection can be calculated using the procedures of 11.12.6 and 13.5.3.

11.12.6.3 — When shear reinforcement consisting of steel I- or channel-shaped sections (shearheads) is provided, the sum of the shear stresses due to vertical load acting on the critical section defined by 11.12.4.7 and the shear stresses resulting from moment transferred by eccentricity of shear about the centroid of the critical section defined in 11.12.1.2 shall not exceed $\phi 4\sqrt{f_c'}$.

R11.12.6.3 — Tests[11.51] indicate that the critical section defined in 11.12.1.2 is appropriate for calculations of shear stresses caused by transfer of moments even when shearheads are used. Then, even though the critical sections for direct shear and shear due to moment transfer differ, they coincide or are in close proximity at the column corners where the failures initiate. Because a shearhead attracts most of the shear as it funnels toward the column, it is conservative to take the maximum shear stress as the sum of the two components.

Section 11.12.4.10 requires the moment M_p transferred to the column in shearhead connections transferring unbalanced moments. This may be done by bearing within the column or positive mechanical anchorage.

CHAPTER 12 — DEVELOPMENT AND SPLICES OF REINFORCEMENT

CODE

12.0 — Notation

a = depth of equivalent rectangular stress block as defined in 10.2.7.1
A_b = area of an individual bar, in.^{2}
A_s = area of nonprestressed tension reinforcement, in.^{2}
A_{tr} = total cross-sectional area of all transverse reinforcement which is within the spacing s and which crosses the potential plane of splitting through the reinforcement being developed, in.^{2}
A_v = area of shear reinforcement within a distance s, in.^{2}
A_w = area of an individual wire to be developed or spliced, in.^{2}
b_w = web width, or diameter of circular section, in.
c = spacing or cover dimension, in. See 12.2.4
d = distance from extreme compression fiber to centroid of tension reinforcement, in.
d_b = nominal diameter of bar, wire, or prestressing strand, in.
f_c' = specified compressive strength of concrete, psi
$\sqrt{f_c'}$ = square root of specified compressive strength of concrete, psi
f_{ct} = average splitting tensile strength of lightweight aggregate concrete, psi
f_{ps} = stress in prestressed reinforcement at nominal strength, ksi
f_{se} = effective stress in prestressed reinforcement (after allowance for all prestress losses), ksi
f_y = specified yield strength of nonprestressed reinforcement, psi
f_{yt} = specified yield strength of transverse reinforcement, psi
h = overall thickness of member, in.
K_{tr} = transverse reinforcement index
$= \frac{A_{tr} f_{yt}}{1500sn}$ (constant 1500 carries the unit lb/in.^{2})
ℓ_a = additional embedment length at support or at point of inflection, in.
ℓ_d = development length, in.
$= \ell_{db}$ x applicable modification factors
ℓ_{db} = basic development length, in.
ℓ_{dh} = development length of standard hook in tension, measured from critical section to outside end of hook (straight embedment length between critical section and start of hook

COMMENTARY

The development length concept for anchorage of reinforcement was first introduced in the 1971 ACI Building Code, to replace the dual requirements for flexural bond and anchorage bond contained in earlier editions of the ACI Building Code. It is no longer necessary to consider the flexural bond concept which placed emphasis on the computation of nominal peak bond stresses. Consideration of an average bond resistance over a full development length of the reinforcement is more meaningful, partially because all bond tests consider an average bond resistance over a length of embedment of the reinforcement, and partially because uncalculated extreme variations in local bond stresses exist near flexural cracks.[12.1]

The development length concept is based on the attainable average bond stress over the length of embedment of the reinforcement. The specified development lengths are required because of the tendency of highly stressed bars to split relatively thin sections of restraining concrete. A single bar embedded in a mass of concrete should not require as great a development length; although a row of bars, even in mass concrete, can create a weakened plane, with longitudinal splitting along the plane of the bars.

In application, the development length concept requires the specified minimum lengths or extensions of reinforcement beyond all points of peak stress in the reinforcement. Such peak stresses generally occur at the points specified in 12.10.2.

The strength reduction factor ϕ is not used in this chapter. The basic development lengths ℓ_{db} already include an allowance for understrength. The required lengths are the same for either the strength design method or the alternate design method of Appendix A, since ℓ_{db} is based on f_y in either case.

CODE

[point of tangency] plus radius of bend and one bar diameter), in.

= ℓ_{hb} x applicable modification factors

ℓ_{hb} = basic development length of standard hook in tension, in.

M_n = nominal moment strength at section, in.-lb
= $A_s f_y(d - a/2)$

n = number of bars or wires being spliced or developed along the plane of splitting

s = maximum spacing of transverse reinforcement within ℓ_d center-to-center, in.

s_w = spacing of wire to be developed or spliced, in.

V_u = factored shear force at section

α = reinforcement location factor. See 12.2.4

β = coating factor. See 12.2.4

λ = lightweight aggregate concrete factor. See 12.2.4

12.1 — Development of reinforcement — General

12.1.1 — Calculated tension or compression in reinforcement at each section of structural concrete members shall be developed on each side of that section by embedment length, hook or mechanical device, or a combination thereof. Hooks shall not be used to develop bars in compression.

12.1.2 — The values of $\sqrt{f_c'}$ used in this chapter shall not exceed 100 psi.

12.2 — Development of deformed bars and deformed wire in tension

12.2.1 — Development length ℓ_d, in terms of diameter d_b for deformed bars and deformed wire in tension shall be determined from either 12.2.2 or 12.2.3, but ℓ_d shall not be less than 12 in.

12.2.2 — For deformed bars or deformed wire, ℓ_d/d_b shall be as follows:

COMMENTARY

R12.1 — Development of reinforcement — General

From a point of peak stress in reinforcement, some length of reinforcement or anchorage is necessary through which to develop the stress. This development length or anchorage is necessary on both sides of such peak stress points. Often the reinforcement continues for a considerable distance on one side of a critical stress point so that calculations need involve only the other side, e.g., the negative moment reinforcement continuing through a support to the middle of the next span.

R12.2 — Development of deformed bars and deformed wire in tension

In the 1989 Building Code, major changes were made in the procedures for calculating development lengths for deformed bars and deformed wires in tension. While the 1989 revisions were based on extensive research and professional judgment, many of those applying the 1989 provisions in design, detailing, and fabrication found them to be overly complex in application. Also, in some circumstances, the provisions required longer development lengths than prior experience indicated necessary. Committee 318 reexamined the basic tension development length procedures with a view of formulating a more "user friendly" format while maintaining general agreement with research results and professional judgment. In the 1995 code, the format for determining the development lengths for deformed bars and deformed wires in tension has been extensively revised. The revision, however, is still based on the same general

CODE

	No. 6 and smaller bars and deformed wires	No. 7 and larger bars
Clear spacing of bars being developed or spliced not less than d_b, clear cover not less than d_b, and stirrups or ties throughout ℓ_d not less than the code minimum or Clear spacing of bars being developed or spliced not less than $2d_b$ and clear cover not less than d_b	$\frac{\ell_d}{d_b} = \frac{f_y \alpha\beta\lambda}{25\sqrt{f_c'}}$	$\frac{\ell_d}{d_b} = \frac{f_y \alpha\beta\lambda}{20\sqrt{f_c'}}$
Other cases	$\frac{\ell_d}{d_b} = \frac{3f_y \alpha\beta\lambda}{50\sqrt{f_c'}}$	$\frac{\ell_d}{d_b} = \frac{3f_y \alpha\beta\lambda}{40\sqrt{f_c'}}$

12.2.3 — For deformed bars or deformed wire, ℓ_d/d_b shall be:

$$\frac{\ell_d}{d_b} = \frac{3}{40}\frac{f_y}{\sqrt{f_c'}}\left(\frac{\alpha\beta\gamma\lambda}{\frac{c + K_{tr}}{d_b}}\right) \qquad (12\text{-}1)$$

in which the term $(c + K_{tr})/d_b$ shall not be taken greater than 2.5.

COMMENTARY

equation[12.9] for development length previously endorsed by Committee 408.[12.2,12.3]

After extensive discussion, the committee decided to show as many of the previous multipliers as possible in the basic equation, as well as to rearrange terms and to eliminate compounding ϕ-factors. This results in the development length equation (expressed in terms of bar or wire diameter) given in 12.2.3:

$$\frac{\ell_d}{d_b} = \frac{3}{40}\frac{f_y}{\sqrt{f_c'}}\left(\frac{\alpha\beta\gamma\lambda}{\frac{c + K_{tr}}{d_b}}\right)$$

c is a factor which represents the smallest of the side cover, cover over the bar or wire (in both cases measured to the center of the bar or wire) or one-half the center-to-center spacing of the bars or wires. K_{tr} is a factor which represents the contribution of confining reinforcement across potential splitting planes. α is the traditional reinforcement location factor to reflect the adverse effects of the top reinforcement casting position. β is a coating factor reflecting the effects of epoxy coating for some applications. These factors have been revised to reflect recent research findings and there is a limit on the product $\alpha\beta$. γ is a reinforcement size factor which reflects the more favorable performance of smaller diameter reinforcement. λ is a lightweight concrete factor which reflects the generally lower tensile strength of lightweight concrete and the resulting reduction of splitting resistance which is important in the development of deformed reinforcement. A limit on the term $(c + K_{tr})/d_b$ of 2.5 is included to safeguard against pullout type failures. Provision of this limit eliminated the need for the check of $0.03 d_b f_y/\sqrt{f_c'}$ previously required under ACI 318-89, Section 12.2.3.6.

The general Eq. (12-1) allows the designer to see the effect of all variables controlling the development length. The designer is permitted to disregard terms when such omission results in longer and hence more conservative development lengths. Evaluation of Eq. (12-1) for certain design conditions, and for given concrete strengths and reinforcing steel grades gives the basic development length in bar diameter multiples. This format was judged by designers and reinforcing bar suppliers to be a much more practical formulation.

However, practical implementation requires that either the user calculate ℓ_d based on the actual $(c + K_{tr})/d_b$ for each case or that a range of $(c + K_{tr})/d_b$ values be preselected for common cases. Committee 318 chose a final format which allows the user to choose between either of two approaches:

(1) Section 12.2.2 presents a "simpler" approach which recognizes that many current practical construction cases

CODE

COMMENTARY

utilize spacing and cover values along with confining reinforcement such as stirrups or ties which result in a value of $(c + K_{tr})/d_b$ of at least 1.5. Typical examples would be minimum clear cover of $\mathbf{1.0}d_b$ along with either minimum clear spacing of $\mathbf{2}d_b$ or a combination of minimum clear spacing of $\mathbf{1.0}d_b$ and minimum ties or stirrups. For these frequently occurring cases, the development length for larger bars can be taken as $\ell_d/d_b = {}^1/_{20}(f_y\,\alpha\beta\lambda/\sqrt{f_c'})$. Comparison with past provisions and a check of massive data bank of experimental results maintained by Committee 408 indicated that for No. 6 deformed bars and smaller, as well as for deformed wire, these values could be reduced 20 percent using $\gamma = 0.80$. This became the basis for the first row of the table in 12.2.2. With lesser cover and in the absence of minimum ties or stirrups, the minimum clear spacing limits of 7.6.1 and the minimum concrete cover requirements of 7.7 result in minimum values of c of $\mathbf{1.0}d_b$. Thus, for "other cases," the values are multiplied by 1.5 to restore them to equivalence with Eq. (12.1).

While the equations in the table may initially look complex, they are readily evaluated and for the generally occurring conditions, the user may easily construct very simple, quite useful expressions. For example, in all structures with normal weight concrete ($\lambda = \mathbf{1.0}$), uncoated reinforcement ($\beta = \mathbf{1.0}$), No. 6 or smaller bottom bars ($\alpha = \mathbf{1.0}$) with $f_c' = \mathbf{4}$ ksi and Grade 60 reinforcement, the equations reduce to

$$\frac{\ell_d}{d_b} = \frac{(60,000)\ (1.0)\ (1.0)\ (1.0)}{25\sqrt{4000}} = 38$$

or

$$\frac{\ell_d}{d_b} = \frac{3\ (60,000)\ (1.0)\ (1.0)\ (1.0)}{50\sqrt{4000}} = 57$$

Thus, a designer or detailer knows that for these widely occurring cases as long as minimum cover of d_b, and either minimum clear spacing of $\mathbf{2}d_b$ or minimum clear spacing of d_b along with minimum ties or stirrups are provided, $\ell_d = \mathbf{38}d_b$. The penalty for spacing bars closer or providing less cover is the requirement that $\ell_d = \mathbf{57}d_b$.

(2) A "more general" approach, which is basically quite similar in many respects to the original 408 proposal,[12.2,12.3] is included in 12.2.3. This allows the user to evaluate $(c + K_{tr})/d_b$ for each particular combination of cover, spacing, and transverse reinforcement. This allows one to more rigorously calculate development lengths where critical or in special investigations. A limit on $(c + K_{tr})/d_b$ of 2.5 is imposed to maintain the 1989 Section 12.2.3.6 limit of $\ell_{db} \geq \mathbf{0.03}\,d_b f_y/\sqrt{f_c'}$ based on the pullout failure mode controlling.

CODE

12.2.4 — The factors for use in the expressions for development of deformed bars and deformed wires in tension in Chapter 12 are as follows:

α = reinforcement location factor

Horizontal reinforcement so placed that more than 12 in. of fresh concrete is cast in the member below the development length or splice 1.3

Other reinforcement 1.0

β = coating factor

Epoxy-coated bars or wires with cover less than $3d_b$, or clear spacing less than $6d_b$ 1.5

All other epoxy-coated bars or wires 1.2

Uncoated reinforcement 1.0

However, the product of $\alpha\beta$ need not be taken greater than 1.7.

γ = reinforcement size factor

No. 6 and smaller bars and deformed wires 0.8

No. 7 and larger bars 1.0

λ = lightweight aggregate concrete factor

When lightweight aggregate concrete is used 1.3

However, when f_{ct} is specified, λ shall be permitted to be taken as $6.7\sqrt{f_c'}/f_{ct}$ but not less than 1.0

When normal weight concrete is used 1.0

c = spacing or cover dimension, in.

Use the smaller of either the distance from the center of the bar or wire to the nearest concrete surface or one-half the center-to-center spacing of the bars or wires being developed.

COMMENTARY

There are many practical combinations of side cover, clear cover, and confining reinforcement which can be used with 12.2.3 to produce significantly shorter development lengths than allowed by 12.2.2. For example: Bars or wires with minimum clear cover not less than $2d_b$ and minimum clear spacing not less than $4d_b$ and without any confining reinforcement would have a $(c + K_{tr})/d_b$ value of 2.5 and hence would require only 0.6 times the values of 12.2.2.

The new provisions of 12.2.2 and 12.2.3 give a two-tier approach as provided in many other places in the code. They should result in simpler computations where approximations are acceptable while retaining the more general ACI 408 approach where special cases or many repetitions make the greater efficiency desirable.

The basis for determining tension development length in the 1995 code is the same as that in the 1989 code. Thus, design aids and computer programs based on Section 12.2 of ACI 318-89 can be used for complying with the 1995 ACI Building Code.

R12.2.4 — The reinforcement location factor α accounts for position of the reinforcement in freshly placed concrete. The factor had been reduced from 1.4 in the 1983 code to 1.3 in the 1989 code to reflect recent research.[12.4,12.5]

The factor λ for lightweight aggregate concrete was made the same for all types of aggregates in 1989. Research on hooked bar anchorages did not support the variations specified in previous codes for "all-lightweight and sand-lightweight" concrete and a single value, 1.3, was selected. Section 12.2.4 allows a lower factor to be used when the splitting tensile strength of the lightweight concrete is specified. See 5.1.4.

Studies[12.6,12.7,12.8] of the anchorage of epoxy-coated bars show that bond strength is reduced because the coating prevents adhesion and friction between the bar and the concrete. The various factors reflect the type of anchorage failure likely to occur. When the cover or spacing is small, a splitting failure can occur and the anchorage or bond strength is substantially reduced. If the cover and spacing between bars is large, a splitting failure is precluded and the effect of the epoxy coating on anchorage strength is not as large. Studies[12.9] have shown that although the cover or spacing may be small, the anchorage strength may be increased by adding transverse steel crossing the plane of splitting, and restraining the splitting crack.

Although no studies on the effect of coated transverse steel have been reported to date, the addition of transverse steel should improve the anchorage strength of epoxy-coated bars. Since the bond of epoxy-coated bars is already reduced due to the loss of adhesion between the bar and the concrete, an upper limit of 1.7 is established for the product

CODE

K_{tr} = transverse reinforcement index

$$= \frac{A_{tr} f_{yt}}{1500sn}$$

where

A_{tr} = total cross-sectional area of all transverse reinforcement which is within the spacing s and which crosses the potential plane of splitting through the reinforcement being developed, in.^{2}

f_{yt} = specified yield strength of transverse reinforcement, psi

s = maximum spacing of transverse reinforcement within ℓ_d, center-to-center, in.

n = number of bars or wires being developed along the plane of splitting

It shall be permitted to use $K_{tr} = 0$ as a design simplification even if transverse reinforcement is present.

12.2.5 — Excess reinforcement

Reduction in development length shall be permitted where reinforcement in a flexural member is in excess of that required by analysis except where anchorage or development for f_y is specifically required or the reinforcement is designed under provisions of 21.2.1.4 ..... (A_s required)/(A_s provided)

12.3 — Development of deformed bars in compression

12.3.1 — Development length ℓ_d, in inches, for deformed bars in compression shall be computed as the product of the basic development length ℓ_{db} of 12.3.2 and applicable modification factors of 12.3.3, but ℓ_d shall be not less than 8 in.

12.3.2 — Basic development length

ℓ_{db} shall be ..... $0.02 d_b f_y / \sqrt{f'_c}$

but not less than..... $0.0003 d_b f_y$*

12.3.3 — Basic development length ℓ_{db} shall be permitted to be multiplied by applicable factors for:

12.3.3.1 — Excess reinforcement
Reinforcement in excess of that required by analysis..... (A_s required)/(A_s provided)

*The constant carries the unit of in.^{2}/lb.

COMMENTARY

of the top reinforcement and epoxy-coated reinforcement factors.

R12.2.5 — Excess reinforcement

The reduction factor based on area is not to be used in those cases where anchorage development for full f_y is required. For example, the excess reinforcement factor does not apply for development of positive moment reinforcement at supports according to 12.11.2, for development of shrinkage and temperature reinforcement according to 7.12.2.3, or for development of reinforcement provided according to 7.13 and 13.3.8.5.

R12.3 — Development of deformed bars in compression

The weakening effect of flexural tension cracks is not present for bars in compression and usually end bearing of the bars on the concrete is beneficial. Therefore, shorter basic development lengths ℓ_{db} are specified for compression than for tension. The basic development length may be reduced 25 percent in 12.3.3.2 when the reinforcement is enclosed within a column type spiral or an individual spiral around each bar or group of bars.

CODE

12.3.3.2 — Spirals and ties
Reinforcement enclosed within spiral reinforcement not less than 1/4 in. diameter and not more than 4 in. pitch or within No. 4 ties in conformance with 7.10.5 and spaced at not more than 4 in. on center 0.75

12.4 — Development of bundled bars

12.4.1 — Development length of individual bars within a bundle, in tension or compression, shall be that for the individual bar, increased 20 percent for three-bar bundle, and 33 percent for four-bar bundle.

12.4.2 — For determining the appropriate factors in 12.2, a unit of bundled bars shall be treated as a single bar of a diameter derived from the equivalent total area.

12.5 — Development of standard hooks in tension

12.5.1 — Development length ℓ_{dh}, in inches, for deformed bars in tension terminating in a standard hook (see 7.1) shall be computed as the product of the basic development length ℓ_{hb} of 12.5.2 and the applicable modification factor or factors of 12.5.3, but ℓ_{dh} shall not be less than $8d_b$ nor less than 6 in.

12.5.2 — Basic development length ℓ_{hb} for a hooked bar with f_y equal to 60,000 psi shall be ..... $1200d_b/\sqrt{f_c'}$*

* Constant carries unit of lb/in.^{2}

COMMENTARY

R12.4 — Development of bundled bars

R12.4.1 — An increased development length for individual bars is required when three or four bars are bundled together. The extra extension is needed because the grouping makes it more difficult to mobilize bond resistance from the "core" between the bars.

The designer should also note 7.6.6.4 relating to the cutoff points of individual bars within a bundle and 12.14.2.2 relating to splices of bundled bars. The increases in development length of 12.4 do apply when computing splice lengths of bundled bars in accordance with 12.14.2.2. The development of bundled bars by a standard hook of the bundle is not covered by the provisions of 12.5.

R12.4.2 — Although splice and development lengths of bundled bars are based on the diameter of individual bars increased by 20 percent or 33 percent as appropriate, it is necessary to use an equivalent diameter of the entire bundle derived from the equivalent total area of bars when determining factors in 12.2 which considers cover and clear spacing and represent the tendency of concrete to split.

R12.5 — Development of standard hooks in tension

The provisions for hooked bar anchorage were extensively revised in the 1983 code. Study of failures of hooked bars indicate that splitting of the concrete cover in the plane of the hook is the primary cause of failure and that splitting originates at the inside of the hook where the local stress concentrations are very high. Thus, hook development is a direct function of bar diameter d_b which governs the magnitude of compressive stresses on the inside of the hook. Only standard hooks (see 7.1) are considered and the influence of larger radius of bend cannot be evaluated by 12.5.

The hooked bar anchorage provisions give the total hooked bar embedment length as shown in Fig. R12.5.1. The development length ℓ_{dh} is measured from the critical section to the outside end (or edge) of the hook.

The development length ℓ_{dh} is the product of the basic development length ℓ_{hb} of 12.5.2 and the applicable modifi-

CODE

12.5.3 — Basic development length ℓ_{hb} shall be multiplied by applicable factor or factors for:

12.5.3.1 — Bar yield strength
Bars with f_y other than 60,000 psi ..... $f_y/60{,}000$

12.5.3.2 — Concrete cover
For No. 11 bar and smaller, side cover (normal to plane of hook) not less than $2\frac{1}{2}$ in., and for 90 deg hook, cover on bar extension beyond hook not less than 2 in. 0.7

12.5.3.3 — Ties or stirrups
For No. 11 bar and smaller, hook enclosed vertically or horizontally within ties or stirrup-ties spaced along the full development length ℓ_{dh} not greater than $3d_b$, where d_b is diameter of hooked bar 0.8

12.5.3.4 — Excess reinforcement
Where anchorage or development for f_y is not specifically required, reinforcement in excess of that required by analysis ..... (A_s required)/(A_s provided)

12.5.3.5 — Lightweight aggregate concrete 1.3

12.5.3.6 — Epoxy-coated reinforcement
Hooked bars with epoxy coating 1.2

12.5.4 — For bars being developed by a standard hook at discontinuous ends of members with both side cover and top (or bottom) cover over hook less than $2\frac{1}{2}$ in., hooked bar shall be enclosed within ties or stir-

COMMENTARY

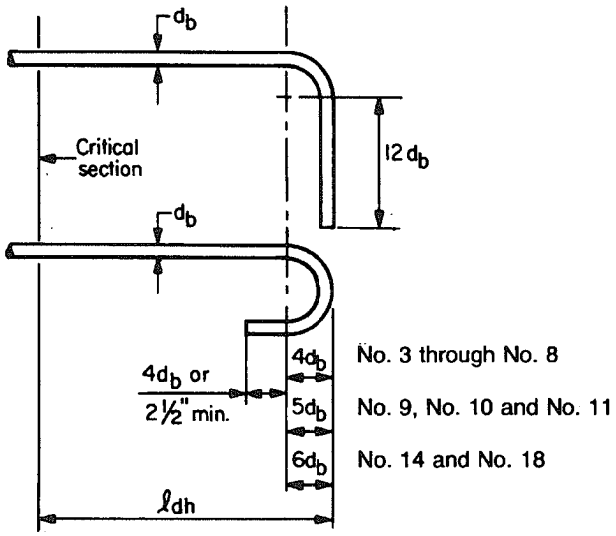

Fig. R12.5.1—Hooked bar details for development of standard hooks

cation factors of 12.5.3. If side cover is large so that splitting is effectively eliminated, and ties are provided, both factors of 12.5.3.2 and 12.5.3.3 may be applied: ($\ell_{dh} = \ell_{hb}$ **x 0.7 x 0.8**). If, for the same case, anchorage is in lightweight concrete: ($\ell_{dh} = \ell_{hb}$ **x 0.7 x 0.8 x 1.3**).

Modification factors are provided for bar yield strength, excess reinforcement, lightweight concrete, and factors to reflect the resistance to splitting provided from confinement by concrete and transverse ties or stirrups. The factors are based on recommendations from References 12.2 and 12.3.

The factor for excess reinforcement applies only where anchorage or development for full f_y is not specifically required. The factor for lightweight concrete is a simplification over the procedure in 12.2.3.3 of ACI 318-83 in which the increase varies from 18 percent to 33 percent, depending on the amount of lightweight aggregate used. Unlike straight bar development, no distinction is made between top bars and other bars; such a distinction is difficult for hook bars in any case. A minimum value of ℓ_{dh} is specified to prevent failure by direct pullout in cases where a hook may be located very near the critical section. Hooks cannot be considered effective in compression.

Recent tests[12.10] indicate that the development length for hooked bars should be increased by 20 percent to account for reduced bond when reinforcement is epoxy coated.

R12.5.4 — Bar hooks are especially susceptible to a concrete splitting failure if both side cover (normal to plane of hook) and top or bottom cover (in plane of hook) are small. See Fig. R12.5.4. With minimum confinement provided by

CODE

rup-ties spaced along the full development length ℓ_{dh} not greater than $3d_b$, where d_b is diameter of hooked bar. For this case, factor of 12.5.3.3 shall not apply.

COMMENTARY

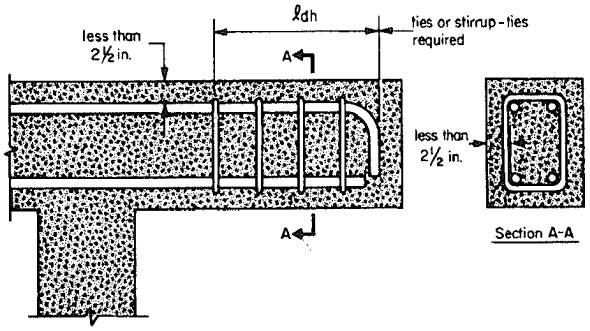

Fig. R12.5.4—Concrete cover per 12.5.4

concrete, confinement provided by ties or stirrups is essential, especially if full bar strength must be developed by a hooked bar with such small cover. Typical cases where hooks may require ties or stirrups for confinement are at ends of simply supported beams, at free end of cantilevers, and at ends of members framing into a joint where members do not extend beyond the joint. In contrast, if calculated bar stress is low so that the hook is not needed for bar anchorage, the ties or stirrups are not necessary. Also, for hooked bars at discontinuous ends of slabs with confinement provided by the slab continuous on both sides normal to the plane of the hook, provisions of 12.5.4 do not apply.

12.5.5 — Hooks shall not be considered effective in developing bars in compression.

R12.5.5 — In compression, hooks are ineffective and cannot be used as anchorage.

12.6 — Mechanical anchorage

R12.6 — Mechanical anchorage

12.6.1 — Any mechanical device capable of developing the strength of reinforcement without damage to concrete is allowed as anchorage.

R12.6.1 — Mechanical anchorage can be made adequate for strength both for prestressing tendons and for bar reinforcement.

12.6.2 — Test results showing adequacy of such mechanical devices shall be presented to the building official.

12.6.3 — Development of reinforcement shall be permitted to consist of a combination of mechanical anchorage plus additional embedment length of reinforcement between the point of maximum bar stress and the mechanical anchorage.

R12.6.3 — Total development of a bar simply consists of the sum of all the parts that contribute to anchorage. When a mechanical anchorage is not capable of developing the required design strength of the reinforcement, additional embedment length of reinforcement must be provided between the mechanical anchorage and the critical section.

12.7 — Development of welded deformed wire fabric in tension

R12.7 — Development of welded deformed wire fabric in tension

12.7.1 — Development length ℓ_d, in inches, of welded deformed wire fabric measured from the point of criti-

Fig. R12.7 shows the development requirements for deformed wire fabric with one cross wire within the devel-

CODE

cal section to the end of wire shall be computed as the product of the development length ℓ_d, from 12.2.2 or 12.2.3 times a wire fabric factor from 12.7.2 or 12.7.3. It shall be permitted to reduce the development length in accordance with 12.2.5 when applicable, but ℓ_d shall not be less than 8 in. except in computation of lap splices by 12.18. When using the wire fabric factor from 12.7.2, it shall be permitted to use an epoxy-coating factor β of 1.0 for epoxy-coated welded wire fabric in 12.2.2 and 12.2.3.

12.7.2 — For welded deformed wire fabric with at least one cross wire within the development length and not less than 2 in. from the point of the critical section, the wire fabric factor shall be the greater of:

$$\left(\frac{f_y - 35{,}000}{f_y}\right)$$

or

$$\left(\frac{5d_b}{s_w}\right)$$

but need not be taken greater than 1.

12.7.3 — For welded deformed wire fabric with no cross wires within the development length or with a single cross wire less than 2 in. from the point of the critical section, the wire fabric factor shall be taken as 1, and the development length shall be determined as for deformed wire.

12.7.4—When any plain wires are present in the deformed wire fabric in the direction of the development length, the fabric shall be developed in accordance with 12.8.

12.8—Development of welded plain wire fabric in tension

Yield strength of welded plain wire fabric shall be considered developed by embedment of two cross wires with the closer cross wire not less than 2 in. from the point of the critical section. However, the development length ℓ_d, in inches, measured from the point of the critical section to the outermost cross wire shall not be less than

$$0.27\frac{A_w}{s_w}\left(\frac{f_y}{\sqrt{f_c'}}\right)\lambda$$

except that when reinforcement provided is in excess of that required, this length may be reduced in accordance with 12.2.5. ℓ_d shall not be less than 6 in. except in computation of lap splices by 12.19.

COMMENTARY

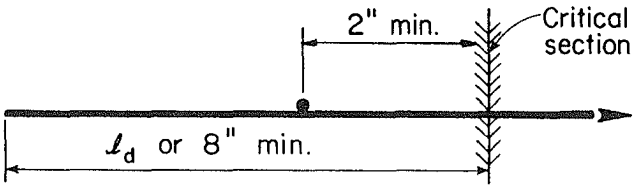

Fig. R12.7—Development of welded deformed wire fabric

opment length. ASTM A 497 for deformed wire fabric requires the same strength of the weld as required for plain wire fabric (ASTM A 185). Some of the development is assigned to welds and some assigned to the length of deformed wire. The development computations are simplified from earlier code provisions for wire development by assuming that only one cross wire is contained in the development length. The factors in 12.7.2 are applied to the deformed wire development length computed from 12.2 but with an absolute minimum of 8 in. The explicit statement that the mesh multiplier not be taken greater than 1 corrects an oversight in earlier codes. The multipliers were derived using the general relationships between deformed wire mesh and deformed wires in the ℓ_{db} values of ACI 318-83.

Tests[12.11] have indicated that epoxy-coated welded wire fabric has essentially the same development and splice strengths as uncoated fabric since the cross wires provide the primary anchorage for the wire. Therefore, an epoxy-coating factor of 1.0 is used for development and splice lengths of epoxy-coated welded wire fabric with cross wires within the splice or development length.

R12.8 — Development of welded smooth wire fabric in tension

Fig. R12.8 shows the development requirements for plain wire fabric with development primarily dependent on the location of cross wires. For fabrics made with the smaller wires, an embedment of at least two cross wires 2 in. or more beyond the point of critical section is adequate to develop the full yield strength of the anchored wires. However, for fabrics made with larger closely spaced wires a longer embedment is required and a minimum development length is provided for these fabrics.

CODE

COMMENTARY

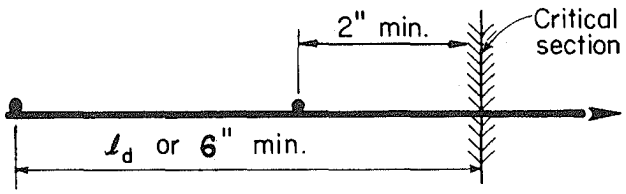

Fig. R12.8—Development of welded plain wire fabric

12.9 — Development of prestressing strand

12.9.1 — Three- or seven-wire pretensioning strand shall be bonded beyond the critical section for a development length, in inches, not less than

$$\left(f_{ps} - \frac{2}{3} f_{se}\right) d_b \text{*}$$

where d_b is strand diameter in inches, and f_{ps} and f_{se} are expressed in kips/in.^{2}

12.9.2 — Limiting the investigation to cross sections nearest each end of the member that are required to develop full design strength under specified factored loads shall be permitted.

* Expression in parenthesis used as a constant without units.

R12.9 — Development of prestressing strand

The development requirements for prestressing strand are intended to provide bond integrity for the strength of the member. The provisions are based on tests performed on normal weight concrete members with a minimum cover of 2 in. These tests may not represent the behavior of strand in low water-cementitious materials ratio, no-slump concrete. Fabrication methods should ensure consolidation of concrete around the strand with complete contact between the steel and concrete. Extra precautions should be exercised when low water-cementitious materials ratio, no-slump concrete is used. In general, this section will control only for the design of cantilever and short-span members.

The expression for development length ℓ_d may be rewritten as:

$$\ell_d = \frac{f_{se}}{3} d_b + (f_{ps} - f_{se}) d_b$$

where ℓ_d and d_b are in inches, and f_{ps} and f_{se} are in kips/in.^{2} The first term represents the transfer length of the strand, i.e., the distance over which the strand must be bonded to the concrete to develop the prestress f_{se} in the strand. The second term represents the additional length over which the strand must be bonded so that a stress f_{ps} may develop in the strand at nominal strength of the member.

The variation of strand stress along the development length of the strand is shown in Fig. R12.9. The expressions for transfer length, and for the additional bonded length necessary to develop an increase in stress of $(f_{ps} - f_{se})$ are based on tests of members prestressed with clean, $^1/_4$, $^3/_8$, and $^1/_2$ in. diameter strands for which the maximum value of f_{ps} was 275 kips/in.^{2} See References 12.12, 12.13, and 12.14.

The transfer length of strand is a function of the perimeter configuration area and surface condition of the steel, the stress in the steel, and the method used to transfer the steel force to the concrete. Strand with a slightly rusted surface can have an appreciably shorter transfer length than clean strand. Gentle release of the strand will permit a shorter

CODE

COMMENTARY

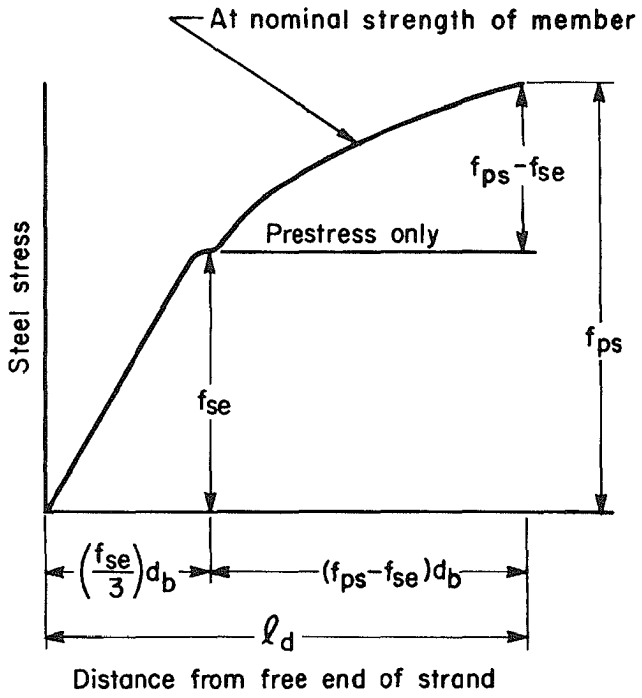

Fig. R12.9—Variation of steel stress with distance from free end of strand

transfer length than abruptly cutting the strands.

The provisions of 12.9 do not apply to plain wires nor to end anchored tendons. The length for smooth wire could be expected to be considerably greater due to the absence of mechanical interlock. Flexural bond failure would occur with plain wire when first slip occurred.

12.9.3 — Where bonding of a strand does not extend to end of member, and design includes tension at service load in precompressed tensile zone as permitted by 18.4.2, development length specified in 12.9.1 shall be doubled.

R12.9.3 — Exploratory tests conducted in 1965[12.12] to study the effect of debonded strand (bond not permitted to extend to the ends of members) on performance of pretensioned girders, indicated that the performance of these girders with embedment lengths twice those required by 12.9.1 closely matched the flexural performance of similar pretensioned girders with strand fully bonded to ends of girders. Accordingly, doubled development length is required for strand not bonded through to the end of a member. Subsequent tests[12.15] indicated that in pretensioned members designed for zero tension in the concrete under service load conditions (see 18.4.2), the development length for debonded strands need not be doubled.

12.10 — Development of flexural reinforcement — General

R12.10 — Development of flexural reinforcement — General

12.10.1 — Development of tension reinforcement by bending across the web to be anchored or made continuous with reinforcement on the opposite face of member shall be permitted.

CODE

COMMENTARY

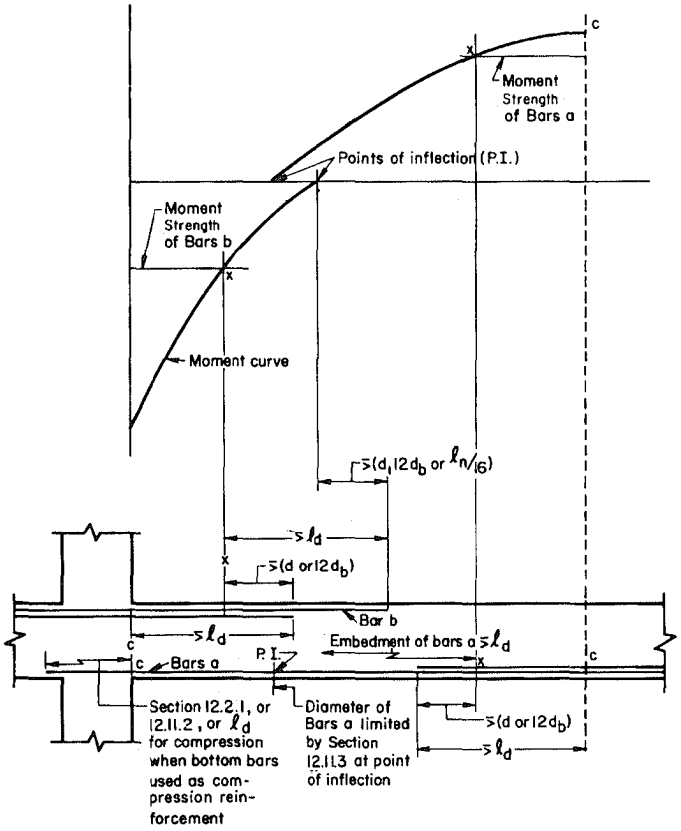

Fig. R12.10.2—Development of flexural reinforcement in a typical continuous beam

12.10.2 — Critical sections for development of reinforcement in flexural members are at points of maximum stress and at points within the span where adjacent reinforcement terminates, or is bent. Provisions of 12.11.3 must be satisfied.

R12.10.2 — Critical sections for a typical continuous beam are indicated with a "c" or an "x" in Fig. R12.10.2. For uniform loading, the positive reinforcement extending into the support is more apt to be governed by the requirements of 12.11.3 rather than by development length measured from a point of maximum moment or bar cutoff.

12.10.3 — Reinforcement shall extend beyond the point at which it is no longer required to resist flexure for a distance equal to the effective depth of member or $12d_b$, whichever is greater, except at supports of simple spans and at free end of cantilevers.

R12.10.3 — The moment diagrams customarily used in design are approximate; some shifting of the location of maximum moments may occur due to changes in loading, settlement of supports, lateral loads, or other causes. A diagonal tension crack in a flexural member without stirrups may shift the location of the calculated tensile stress approximately a distance d towards a point of zero moment. When stirrups are provided, this effect is less severe, although still present to some extent.

To provide for shifts in the location of maximum moments, the code requires the extension of reinforcement a distance d or $12d_b$ beyond the point at which it is theoretically no longer required to resist flexure, except as noted.

Cutoff points of bars to meet this requirement are illustrated in Fig. R12.10.2.

CODE

COMMENTARY

When bars of different sizes are used, the extension should be in accordance with the diameter of bar being terminated. A bar bent to the far face of a beam and continued there may logically be considered effective, in satisfying this section, to the point where the bar crosses the middepth of the member.

12.10.4 — Continuing reinforcement shall have an embedment length not less than the development length ℓ_d beyond the point where bent or terminated tension reinforcement is no longer required to resist flexure.

R12.10.4 — Peak stresses exist in the remaining bars wherever adjacent bars are cut off, or bent, in tension regions. In Fig. R12.10.2 an "x" mark is used to indicate the peak stress points remaining in continuing bars after part of the bars have been cut off. If bars are cut off as short as the moment diagrams allow, these peak stresses become the full f_y, which requires a full ℓ_d extension as indicated. This extension may exceed the length required for flexure.

12.10.5 — Flexural reinforcement shall not be terminated in a tension zone unless one of the following conditions is satisfied:

12.10.5.1 — Shear at the cutoff point does not exceed two-thirds that permitted, including shear strength of shear reinforcement provided.

12.10.5.2—Stirrup area in excess of that required for shear and torsion is provided along each terminated bar or wire over a distance from the termination point equal to three-fourths the effective depth of member. Excess stirrup area A_v shall be not less than $60b_w s/f_y$. Spacing s shall not exceed $d/8\beta_b$ where β_b is the ratio of area of reinforcement cut off to total area of tension reinforcement at the section.

12.10.5.3—For No. 11 bar and smaller, continuing reinforcement provides double the area required for flexure at the cutoff point and shear does not exceed three-fourths that permitted.

R12.10.5 — Reduced shear strength and loss of ductility when bars are cut off in a tension zone, as in Fig. R12.10.2, has been reported. The code does not permit flexural reinforcement to be terminated in a tension zone unless special conditions are satisfied. Flexure cracks tend to open early wherever any reinforcement is terminated in a tension zone. If the steel stress in the continuing reinforcement and the shear strength are each near their limiting values, diagonal tension cracking tends to develop prematurely from these flexure cracks. Diagonal cracks are less likely to form where shear stress is low (see 12.10.5.1). Diagonal cracks can be restrained by closely spaced stirrups (see 12.10.5.2). A lower steel stress reduces the probability of such diagonal cracking (see 12.10.5.3). These requirements are not intended to apply to tension splices which are covered by 12.15, 12.13.5, and the related 12.2.

12.10.6 — Adequate anchorage shall be provided for tension reinforcement in flexural members where reinforcement stress is not directly proportional to moment, such as: sloped, stepped, or tapered footings; brackets; deep flexural members; or members in which tension reinforcement is not parallel to compression face. See 12.11.4 and 12.12.4 for deep flexural members.

R12.10.6 — Brackets, members of variable depth, and other members where steel stress f_s does not decrease linearly in proportion to a decreasing moment require special consideration for proper development of the flexural reinforcement. For the bracket shown in Fig. R12.10.6, the stress at ultimate in the reinforcement is almost constant at approxi-

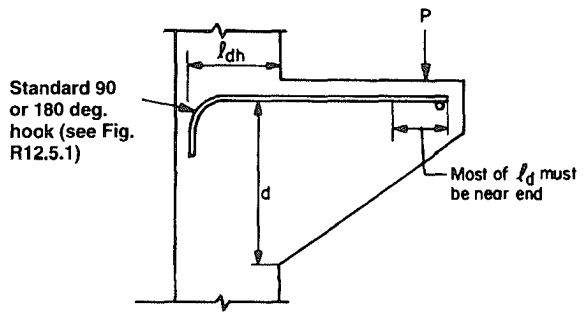

Fig. R12.10.6—Special member largely dependent on end anchorage

CODE

COMMENTARY

mately f_y from the face of support to the load point. In such a case, development of the flexural reinforcement depends largely on the end anchorage provided at the loaded end. Reference 12.1 suggests a welded cross bar of equal diameter as a means of providing effective end anchorage. An end hook in the vertical plane, with the minimum diameter bend, is not totally effective because an essentially plain concrete corner will exist near loads applied close to the corner. For wide brackets (perpendicular to the plane of the figure) and loads not applied close to the corners, U-shaped bars in a horizontal plane provide effective end hooks.

12.11 — Development of positive moment reinforcement

R12.11 — Development of positive moment reinforcement

12.11.1 — At least one-third the positive moment reinforcement in simple members and one-fourth the positive moment reinforcement in continuous members shall extend along the same face of member into the support. In beams, such reinforcement shall extend into the support at least 6 in.

R12.11.1 — Specified amounts of the positive moment reinforcement are required to be carried into the support to provide for some shifting of the moments due to changes in loading, settlement of supports, lateral loads, and other causes.

12.11.2 — When a flexural member is part of a primary lateral load resisting system, positive moment reinforcement required to be extended into the support by 12.11.1 shall be anchored to develop the specified yield strength f_y in tension at the face of support.

R12.11.2 — When a flexural member is part of a primary lateral load resisting system, loads greater than those anticipated in design may cause reversal of moment at supports; some positive reinforcement should be well anchored into the support. This anchorage is required to assure ductility of response in the event of serious overstress, such as from blast or earthquake. It is not sufficient to use more reinforcement at lower stresses.

12.11.3 — At simple supports and at points of inflection, positive moment tension reinforcement shall be limited to a diameter such that ℓ_d computed for f_y by 12.2 satisfies Eq. (12-2); except, Eq. (12-2) need not be satisfied for reinforcement terminating beyond centerline of simple supports by a standard hook, or a mechanical anchorage at least equivalent to a standard hook.

$$\ell_d \le \frac{M_n}{V_u} + \ell_a \qquad (12\text{-}2)$$

where:

M_n is nominal moment strength assuming all reinforcement at the section to be stressed to the specified yield strength f_y.

V_u is factored shear force at the section.

ℓ_a at a support shall be the embedment length beyond center of support.

R12.11.3 — At simple supports and points of inflection such as those marked "PI" in Fig. R12.10.2, the diameter of the positive reinforcement must be small enough so that computed development length of the bar ℓ_d does not exceed $M_n/V_u + \ell_a$, or under favorable support conditions, $1.3M_n/V_u + \ell_a$. Fig. R12.11.3(a) illustrates the use of the provision.

At the point of inflection the value of ℓ_a must not exceed the actual bar extension used beyond the point of zero moment. The M_n/V_u portion of the available length is a theoretical quantity not generally associated with an obvious maximum stress point. M_n is the nominal strength of the cross section without the ϕ-factor and is not the applied factored moment.

The length M_n/V_u corresponds to the development length for the maximum size bar obtained from the previously used flexural bond equation $\Sigma_o = V/ujd$, where u is bond stress, and the jd is moment arm. In the 1971 ACI Building Code, this anchorage requirement was relaxed from previous codes by crediting the available end anchorage length ℓ_a and by including a 30 percent increase for M_n/V_u when the ends of the reinforcement are confined by a compressive reaction.

CODE

ℓ_a at a point of inflection shall be limited to the effective depth of member or $12d_b$, whichever is greater.

An increase of 30 percent in the value of M_n/V_u shall be permitted when the ends of reinforcement are confined by a compressive reaction.

COMMENTARY

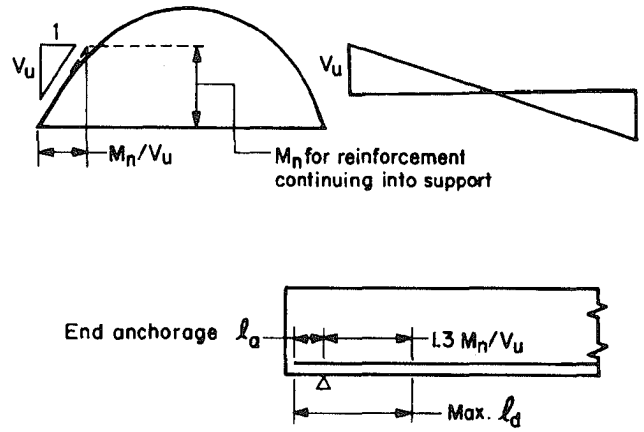

Fig. R12.11.3—Concept for determining maximum bar size per 12.11.3

As an example, consider a bar size is provided at a simple support such that ℓ_d as computed by 12.2 is equal to $0.04 A_b f_y/\sqrt{f_c'}$. The bar size provided is satisfactory only if $0.04 A_b f_y/\sqrt{f_c'}$ does not exceed $1.3M_n/V_u + \ell_a$.

The ℓ_a to be used at points of inflection is limited to the effective depth of the member d or 12 bar diameters ($12d_b$), whichever is greater. Fig. R12.11.3(b) illustrates this provision at points of inflection. The ℓ_a limitation is added since test data are not available to show that a long end anchorage length will be fully effective in developing a bar that has only a short length between a point of inflection and a point of maximum stress.

12.11.4 — At simple supports of deep flexural members, positive moment tension reinforcement shall be anchored to develop the specified yield strength f_y in tension at the face of support. At interior supports of

R12.11.4 — The use of the strut and tie model for the design of reinforced concrete deep flexural members clarifies that there is significant tension in the reinforcement at the face of the support. This requires the tension reinforce-

CODE

deep flexural members, positive moment tension reinforcement shall be continuous or be spliced with that of the adjacent spans.

12.12 — Development of negative moment reinforcement

12.12.1 — Negative moment reinforcement in a continuous, restrained, or cantilever member, or in any member of a rigid frame, shall be anchored in or through the supporting member by embedment length, hooks, or mechanical anchorage.

12.12.2 — Negative moment reinforcement shall have an embedment length into the span as required by 12.1 and 12.10.3.

12.12.3 — At least one-third the total tension reinforcement provided for negative moment at a support shall have an embedment length beyond the point of inflection not less than effective depth of member, $12d_b$, or one-sixteenth the clear span, whichever is greater.

12.12.4 — At interior supports of deep flexural members, negative moment tension reinforcement shall be continuous with that of the adjacent spans.

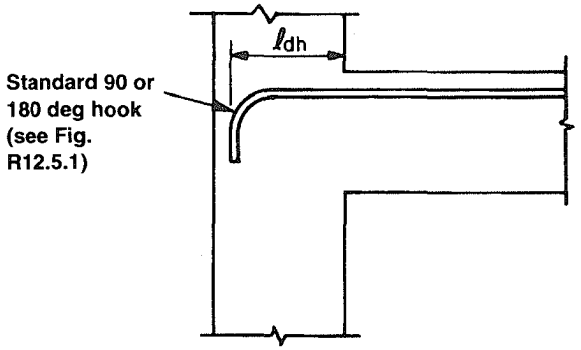
COMMENTARY

ment to be continuous or be developed through and beyond the support.[12.16]

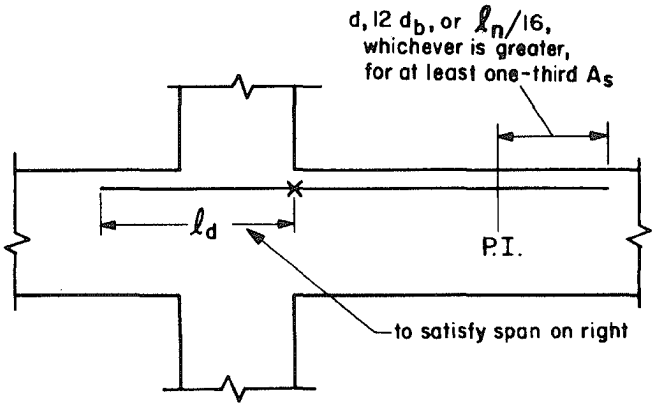
R12.12 — Development of negative moment reinforcement

Fig. R12.12 illustrates two methods of satisfying requirements for anchorage of tension reinforcement beyond the face of support. For anchorage of reinforcement with hooks, see R12.5.

Section 12.12.3 provides for possible shifting of the moment diagram at a point of inflection, as discussed under R12.10.3. This requirement may exceed that of 12.10.3, and the more restrictive of the two provisions governs.



(a) Anchorage into exterior column



Note: Usually such anchorage becomes part of the adjacent beam reinforcement.

(b) Anchorage into adjacent beam

Fig. R12.12—Development of negative moment reinforcement

CODE

12.13 — Development of web reinforcement

12.13.1 — Web reinforcement shall be carried as close to compression and tension surfaces of member as cover requirements and proximity of other reinforcement will permit.

12.13.2 — Ends of single leg, simple U-, or multiple U-stirrups shall be anchored by one of the following means:

12.13.2.1 — For No. 5 bar and D31 wire, and smaller, and for No. 6, No. 7, and No. 8 bars with f_y of 40,000 psi or less, a standard hook around longitudinal reinforcement.

12.13.2.2 — For No. 6, No. 7, and No. 8 stirrups with f_y greater than 40,000 psi, a standard stirrup hook around a longitudinal bar plus an embedment between midheight of the member and the outside end of the hook equal to or greater than $0.014 d_b f_y / \sqrt{f'_c}$.

12.13.2.3—For each leg of welded plain wire fabric forming simple U-stirrups, either:

(a) Two longitudinal wires spaced at a 2 in. spacing along the member at the top of the U.

(b) One longitudinal wire located not more than $d/4$ from the compression face and a second wire closer to the compression face and spaced not less than 2 in. from the first wire. The second wire shall be per-

COMMENTARY

R12.13 — Development of web reinforcement

R12.13.1 — Stirrups must be carried as close to the compression face of the member as possible because near ultimate load the flexural tension cracks penetrate deeply.

R12.13.2 — The anchorage or development requirements for stirrups composed of bars or deformed wire were changed in the 1989 code to simplify the requirements. The straight anchorage was deleted as this stirrup is difficult to hold in place during concrete placement and the lack of a hook may make the stirrup ineffective as it crosses shear cracks near the end of the stirrup.

R12.13.2.1 — For a No. 5 bar or smaller, anchorage is provided by a standard stirrup hook, as defined in 7.1.3, hooked around a longitudinal bar. The 1989 code eliminated the need for a calculated straight embedment length in addition to the hook for these small bars, but 12.13.1 requires a full depth stirrup. Likewise, larger stirrups with f_y equal to or less than 40,000 are sufficiently anchored with a standard stirrup hook around the longitudinal reinforcement.

R12.13.2.2—Since it is not possible to bend a No. 6, No. 7, or No. 8 stirrup tightly around a longitudinal bar and due to the force in a bar with a design stress greater than 40,000 psi, stirrup anchorage depends on both the value of the hook and whatever development length is provided. A longitudinal bar within a stirrup hook limits the width of any flexural cracks, even in a tensile zone. Since such a stirrup hook cannot fail by splitting parallel to the plane of the hooked bar, the hook strength as utilized in 12.5.2 has been adjusted to reflect cover and confinement around the stirrup hook.

For stirrups with f_y of only 40,000 psi, a standard stirrup hook provides sufficient anchorage and these bars are covered in 12.13.2.1. For bars with higher strength, the embedment must be checked. A 135-deg or 180-deg hook is preferred, but a 90-deg hook may be used provided the free end of the 90-deg hook is extended the full 12 bar diameters as required in 7.1.3.

R12.13.2.3—The requirements for anchorage of welded plain wire fabric stirrups are illustrated in Fig. R12.13.2.3.

CODE

mitted to be located on the stirrup leg beyond a bend, or on a bend with an inside diameter of bend not less than $8d_b$.

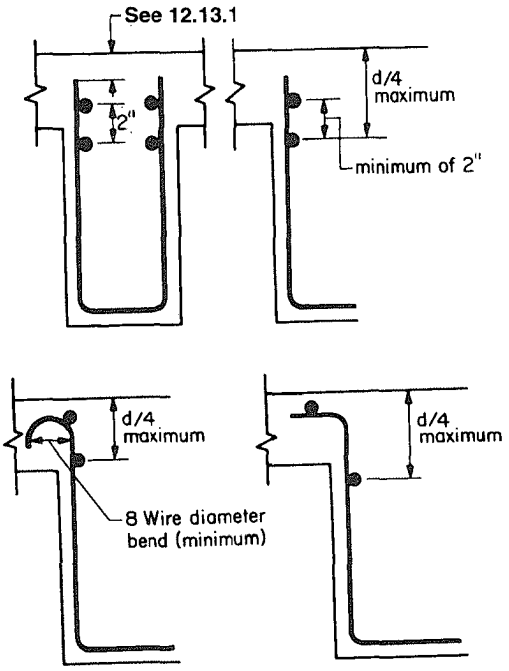


Fig. R12.13.2.3—Anchorage in compression zone of welded plain wire fabric U-stirrups

12.13.2.4 — For each end of a single leg stirrup of welded plain or deformed wire fabric, two longitudinal wires at a minimum spacing of 2 in. and with the inner wire at least the greater of ***d*/4** or 2 in. from middepth of member ***d*/2**. Outer longitudinal wire at tension face shall not be farther from the face than the portion of primary flexural reinforcement closest to the face.

COMMENTARY

R12.13.2.4 — Use of welded wire fabric for shear reinforcement has become commonplace in the precast, prestressed concrete industry. Rationale for acceptance of straight sheets of wire fabric as shear reinforcement is presented in a report by a joint PCI/WRI Ad Hoc Committee on Welded Wire Fabric for Shear Reinforcement.[12.17]

The provisions for anchorage of single leg welded wire fabric in the tension face emphasize the location of the longitudinal wire at the same depth as the primary flexural

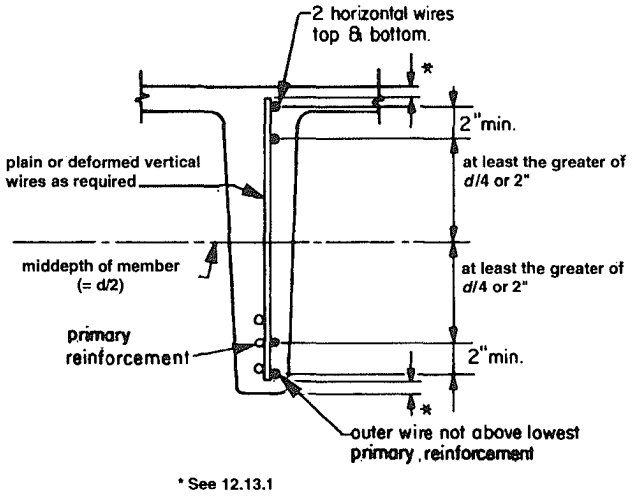

Fig. R12.13.2.4—Anchorage of single leg welded wire fabric shear reinforcement

CODE

COMMENTARY

reinforcement to avoid a splitting problem at the tension steel level. Fig. R12.13.2.4 illustrates the anchorage requirements for single leg welded wire fabric. For anchorage of single leg welded wire fabric, the code has permitted hooks and embedment length in the compression and tension faces of members (see 12.13.2.1 and 12.13.2.3), and embedment only in the compression face (see 12.13.2.2). Section 12.13.2.4 provides for anchorage of straight single leg welded wire fabric using longitudinal wire anchorage with adequate embedment length in compression and tension faces of members.

12.13.2.5 — In joist construction as defined in 8.11, for No. 4 bar and D20 wire and smaller, a standard hook.

R12.13.2.5 — In joists, a small bar or wire can be anchored by a standard hook not engaging longitudinal reinforcement, allowing a continuously bent bar to form a series of single leg stirrups in the joist.

12.13.3 — Between anchored ends, each bend in the continuous portion of a simple U-stirrup or multiple U-stirrup shall enclose a longitudinal bar.

12.13.4 — Longitudinal bars bent to act as shear reinforcement, if extended into a region of tension, shall be continuous with longitudinal reinforcement and, if extended into a region of compression, shall be anchored beyond middepth ***d/2*** as specified for development length in 12.2 for that part of f_y required to satisfy Eq. (11-17).

12.13.5 — Pairs of U-stirrups or ties so placed as to form a closed unit shall be considered properly spliced when length of laps are $1.3\ell_d$. In members at least 18 in. deep, such splices with $A_b f_y$ not more than 9000 lb per leg shall be considered adequate if stirrup legs extend the full available depth of member.

R12.13.5 — These requirements for lapping of double U-stirrups to form closed stirrups control over the provisions of 12.15.

12.14 — Splices of reinforcement — General

R12.14 — Splices of reinforcement — General

12.14.1 — Splices of reinforcement shall be made only as required or permitted on design drawings, or in specifications, or as authorized by the engineer.

Splices should, if possible, be located away from points of maximum tensile stress. The lap splice requirements of 12.15 encourage this practice.

12.14.2 — Lap splices

R12.14.2 — Lap splices

12.14.2.1 — Lap splices shall not be used for bars larger than No. 11 except as provided in 12.16.2 and 15.8.2.3.

R12.14.2.1 — Because of lack of adequate experimental data on lap splices of No. 14 and No. 18 bars in compression and in tension, lap splicing of these bar sizes is prohibited except as permitted in 12.16.2 and 15.8.2.3 for compression lap splices of No. 14 and No. 18 bars with smaller bars.

12.14.2.2 — Lap splices of bars in a bundle shall be based on the lap splice length required for individual bars within the bundle, increased in accordance with 12.4. Individual bar splices within a bundle shall

R12.14.2.2 — The increased length of lap required for bars in bundles is based on the reduction in the exposed perimeter of the bars. The ℓ_d to be used in computing splice length prescribed in 12.15.1 or 12.16.1 is for an individual

CODE

not overlap. Entire bundles shall not be lap spliced.

12.14.2.3 — Bars spliced by noncontact lap splices in flexural members shall not be spaced transversely farther apart than one-fifth the required lap splice length, nor 6 in.

12.14.3 — Welded splices and mechanical connections

12.14.3.1 — Welded splices and other mechanical connections are allowed.

12.14.3.2 — Except as provided in this code, all welding shall conform to "Structural Welding Code—Reinforcing Steel" (ANSI/AWS D1.4).

12.14.3.3—A full welded splice shall develop at least 125 percent of the specified yield strength f_y of the bar.

12.14.3.4—A full mechanical connection shall develop in tension or compression, as required, at least 125 percent of specified yield strength f_y of the bar.

12.14.3.5—Welded splices and mechanical connections not meeting requirements of 12.14.3.3 or 12.14.3.4 are allowed only for No. 5 bars and smaller and in accordance with 12.15.4.

COMMENTARY

bar. Bundled bars are lap spliced only by splicing individual bars along a length of the bundle. Two bundles should not be lap spliced as individual bars.

R12.14.2.3 — If individual bars in noncontact lap splices are too widely spaced, an unreinforced section is created. Forcing a potential crack to follow a zigzag line (5 to 1 slope) is considered a minimum precaution. The 6 in. maximum spacing is added because most research available on the lap splicing of deformed bars was conducted with reinforcement within this spacing.

R12.14.3 — Welded splices and mechanical connections

R12.14.3.2 — The code requires all welding of reinforcing steel to conform to the American Welding Society **"Structural Welding Code—Reinforcing Steel"** (ANSI/AWS D1.4). See R3.5.2 for discussion on welding.

R12.14.3.3—A full welded splice is primarily intended for large bars (No. 6 and larger) in main members. The tensile strength requirement of 125 percent of specified yield will ensure sound welding, adequate also for compression. The maximum reinforcement stress used in design under the code is the yield strength. To ensure sufficient strength in splices so that yielding can be achieved in a member and thus brittle failure avoided, the 25 percent increase above the specified yield strength was selected as both an adequate minimum for safety and a practicable maximum for economy. The 1995 edition eliminated a requirement that the bars be butted since indirect butt welds are permitted by ANSI/AWS D1.4, although ANSI/AWS D1.4 does indicate that wherever practical, direct butt splices are preferable for No. 7 bars and larger.

R12.14.3.4—Full mechanical connections are also required to develop 125 percent of the yield strength, in tension or compression as required, for the same reasons discussed for full welded splices in R12.14.3.3.

R12.14.3.5—The use of welded splices or mechanical connections of less strength than 125 percent of yield strength is permitted if the minimum design criteria of 12.15.4 are met. Therefore, lap welds of reinforcing bars, either with or without backup material, welds to plate connections, and end-bearing splices are allowed under certain conditions. The 1995 edition limited these lower strength welds and connections to No. 5 bars and smaller due to the potentially brittle nature of failure at these welds.

CODE

12.15 — Splices of deformed bars and deformed wire in tension

12.15.1 — Minimum length of lap for tension lap splices shall be as required for Class A or B splice, but not less than 12 in., where:

Class A splice ..... $1.0\ell_d$

Class B splice ..... $1.3\ell_d$

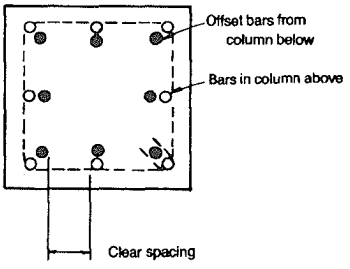
where ℓ_d is the tensile development length for the specified yield strength f_y in accordance with 12.2 without the modification factor of 12.2.5.

COMMENTARY

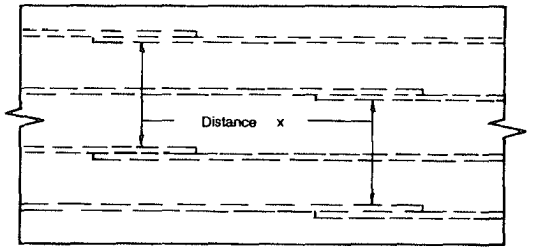
R12.15 — Splices of deformed bars and deformed wire in tension

R12.15.1 — Lap splices in tension are classified as Types A and B, with length of lap a multiple of the tensile development length ℓ_d. The development length $\ell_d = \ell_{db}$ times the applicable modification factors (see 12.2) used to obtain lap length must be based on full f_y because the splice classifications already reflect any excess reinforcement at the splice location; therefore, the factor from 12.2.5 for excess A_s must not be used. The increasing modification factors of 12.2.4 for top reinforcement, lightweight concrete, and epoxy-coated reinforcement must be applied where appropriate. A modifying factor must also be included to account for clear spacing, amount of cover, and transverse reinforcement. When multiple bars are spliced at the same section, the clear spacing is the minimum clear distance between the bars measured outside the splice length less one bar diameter. For splices in columns with offset bars, Fig. R12.15.1(a) illustrates the clear spacing to be used. For staggered splices, the clear spacing is the distance between adjacent spliced bars [distance x in Fig. R12.15.1(b)] less the diameters of any intermediate unspliced bars.

The 1989 code contained several changes in development length in tension which eliminated many of the concerns regarding tension splices due to closely spaced bars with minimal cover. Thus, the Class C splice was eliminated although development lengths, on which splice lengths are based, have in some cases increased. Committee 318 con-



a) Offset column bars



b) Staggered splices

Fig. R12.15.1—Clear spacing of spliced bars

CODE

COMMENTARY

sidered suggestions from many sources, including Committee 408, but has retained a two-level splice length primarily to encourage designers to splice bars at points of minimum stress and to stagger splices to improve behavior of critical details.

12.15.2 — Lap splices of deformed bars and deformed wire in tension shall be Class B splices except that Class A splices are allowed when: (a) the area of reinforcement provided is at least twice that required by analysis over the entire length of the splice, and (b) one-half or less of the total reinforcement is spliced within the required lap length.

R12.15.2 — The tension lap splice requirements of 12.15.1 encourage the location of splices away from regions of high tensile stress, to locations where the area of steel provided is at least twice that required by analysis. Table R12.15.2 presents the splice requirements in tabular form as presented in earlier code editions.

TABLE R12.15.2—TENSION LAP SPLICES

$\frac{A_s \text{ provided}^*}{A_s \text{ required}}$	Maximum percent of A_s spliced within required lap length	
	50	100
Equal to or greater than 2	Class A	Class B
Less than 2	Class B	Class B

* Ratio of area of reinforcement provided to area of reinforcement required by analysis at splice locations.

12.15.3 — Welded splices or mechanical connections used where area of reinforcement provided is less than twice that required by analysis shall meet requirements of 12.14.3.3 or 12.14.3.4.

R12.15.3 — A welded splice or mechanical connection must develop at least 125 percent of the specified yield strength when located in regions of high tensile stress in the reinforcement. Such splices or connections need not be staggered although such staggering is encouraged where the area of reinforcement provided is less than twice that required by the analysis.

12.15.4 — Welded splices and mechanical connections not meeting the requirements of 12.14.3.3 or 12.14.3.4 are allowed for No. 5 bars and smaller when the area of reinforcement provided is at least twice that required by analysis, and the following requirements are met:

R12.15.4 — See R12.14.3.5. This section describes the situation where welded splices or mechanical connections of less strength than 125 percent of the specified yield strength of the reinforcement may be used. It provides a relaxation in the splice requirements where the splices or connections are staggered and excess reinforcement area is available. The criterion of twice the computed tensile force is used to cover sections containing partial tensile splices with various percentages of total steel continuous. The usual partial tensile splice will be a flare groove weld between bars or bar and structural steel piece.

12.15.4.1 — Splices shall be staggered at least 24 in. and in such manner as to develop at every section at least twice the calculated tensile force at that section but not less than 20,000 psi for total area of reinforcement provided.

12.15.4.2 — In computing tensile forces developed at each section, rate the spliced reinforcement at the specified splice strength. Unspliced reinforcement shall be rated at that fraction of f_y defined by the ratio of the shorter actual development length to ℓ_d required to develop the specified yield strength f_y.

To detail such welding, the length of weld must be specified. Such welds are rated as the product of total weld length times effective size of groove weld (established by bar size) times allowable stress permitted by **"Structural Welding Code—Reinforcing Steel"** (ANSI/AWS D1.4).

A full welded splice or connection conforming to 12.14.3.3 or 12.14.3.4 can be used without the stagger requirement in lieu of the lower strength weld or connection.

CODE

12.15.5 — Splices in "tension tie members" shall be made with a full welded splice or full mechanical connection in accordance with 12.14.3.3 or 12.14.3.4 and splices in adjacent bars shall be staggered at least 30 in.

COMMENTARY

R12.15.5 — A tension tie member, as envisioned by ACI Committee 318, has the following characteristics: member having an axial tensile force sufficient to create tension over the cross section; a level of stress in the reinforcement such that every bar must be fully effective; and limited concrete cover on all sides. Examples of members which may be classified as tension ties are arch ties, hangers carrying load to an overhead supporting structure, and main tension elements in a truss.

In determining if a member should be classified as a tension tie, consideration must be given to the importance, function, proportions, and stress conditions of the member related to the above characteristics. For example, the usual large circular tank, with many bars and with splices well staggered and widely spaced should not be classified as a tension tie member, and Class B splices may be used.

12.16 — Splices of deformed bars in compression

R12.16 — Splices of deformed bars in compression

Bond research has been primarily related to bars in tension. Bond behavior of compression bars is not complicated by the problem of transverse tension cracking and thus compression splices do not require provisions as strict as those specified for tension splices. The minimum lengths specified for column splices contained originally in the 1956 ACI Building Code have been carried forward in the later code editions, and extended to compression bars in beams and to higher strength steels. No changes have been made in the provisions for compression splices since the 1971 code edition.

12.16.1 — Compression lap splice length shall be $0.0005 f_y d_b$, for f_y of 60,000 psi or less, or $(0.0009 f_y - 24) d_b$ for f_y greater than 60,000 psi, but not less than 12 in. For f_c' less than 3000 psi, length of lap shall be increased by one-third.

R12.16.1 — Essentially, lap requirements for compression splices have remained the same since the 1963 ACI Building Code.

The 1963 ACI Building Code values were modified in the 1971 code to recognize various degrees of confinement and to permit design with reinforcement up to 80,000 psi yield strength. Tests[12.1,12.18] have shown that splice strengths in compression depend considerably on end bearing and hence do not increase proportionally in strength when the splice length is doubled. Accordingly, for yield strengths above 60,000 psi, compression lap lengths are significantly increased, except where spiral enclosures are used (as in spiral columns) the increase is about 10 percent at 75,000 psi.

12.16.2 — When bars of different size are lap spliced in compression, splice length shall be the larger of development length of larger bar, or splice length of smaller bar. Lap splices of No. 14 and No. 18 bars to No. 11 and smaller bars shall be permitted.

R12.16.2 — The lap splice length is to be computed based on the larger of: (1) the compression splice length of the smaller bar or (2) the compression development length of the larger bar. Lap splices are generally prohibited for No. 14 or No. 18 bars; however, for compression only, lap splices are permitted for No. 14 or No. 18 bars to No. 11 or smaller bars.

CODE

12.16.3 — Welded splices or mechanical connections used in compression shall meet requirements of 12.14.3.3 or 12.14.3.4.

12.16.4 — End-bearing splices

12.16.4.1 — In bars required for compression only, transmission of compressive stress by bearing of square cut ends held in concentric contact by a suitable device shall be permitted.

12.16.4.2 — Bar ends shall terminate in flat surfaces within $1\frac{1}{2}$ deg of a right angle to the axis of the bars and shall be fitted within 3 deg of full bearing after assembly.

12.16.4.3 — End-bearing splices shall be used only in members containing closed ties, closed stirrups, or spirals.

12.17 — Special splice requirements for columns

12.17.1 — Lap splices, butt welded splices, mechanical connections, or end-bearing splices shall be used with the limitations of 12.17.2 through 12.17.4. A splice shall satisfy requirements for all load combinations for the column.

COMMENTARY

R12.16.4 — End-bearing splices

R12.16.4.1 — Experience with end-bearing splices has been almost exclusively with vertical bars in columns. If bars are significantly inclined from the vertical, special attention is required to ensure that adequate end-bearing contact can be achieved and maintained.

R12.16.4.2 — These tolerances were added in the 1971 code, representing practice based on tests of full-size members containing No. 18 bars.

R12.16.4.3 — This limitation was added in the 1971 code to ensure a minimum shear resistance in sections containing end-bearing splices.

R12.17 — Special splice requirements for columns

In columns subject to flexure and axial loads, tension stresses may occur on one face of the column for moderate and large eccentricities as shown in Fig. R12.17. When such tensions occur, 12.17 requires tension splices to be used or an adequate tensile resistance provided. Furthermore, a minimum tension capacity is required in each face of all columns even where analysis indicates compression only.

The 1989 Code clarifies this section on the basis that a compressive lap splice has a tension capacity of at least one-

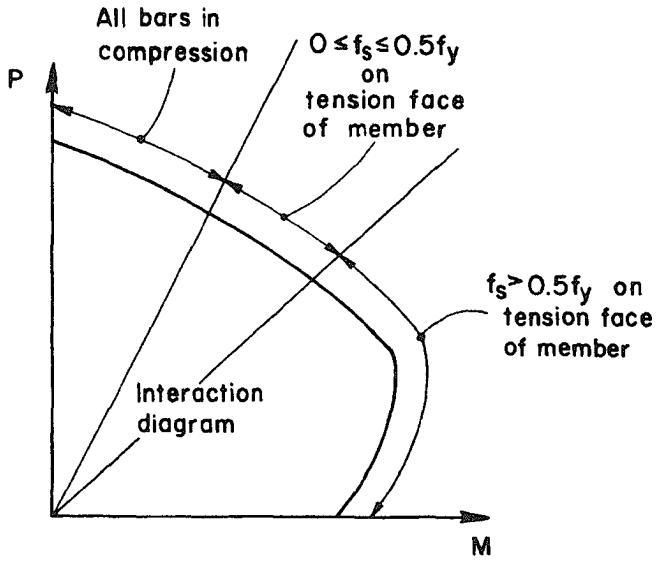


Fig. R12.17—Special splice requirements for columns

CODE

COMMENTARY

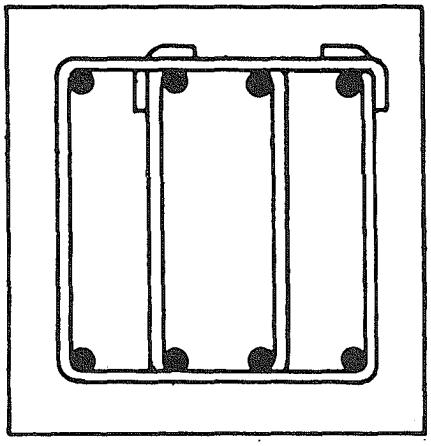

Fig. R.12.17.2—Tie legs which cross the axis of bending are used to compute effective area. In the case shown, four legs are effective

quarter f_y, which simplifies the calculation requirements suggested in the previous code editions.

Note that the column splice must satisfy requirements for all load combinations for the column. Frequently, the basic gravity load combination will govern the design of the column itself, but a load combination including wind or seismic loads may induce greater tension in some column bars, and the column splice must be designed for this tension.

Section 12.17 has been reorganized to define more clearly the requirements for different types of bar splices in columns.

12.17.2 — Lap splices in columns

R12.17.2 — Lap splices in columns

12.17.2.1 — Where the bar stress due to factored loads is compressive, lap splices shall conform to 12.16.1, 12.16.2, and, where applicable, to 12.17.2.4 or 12.17.2.5.

R12.17.2.1 — The 1989 code was simplified for column bars always in compression on the basis that a compressive lap splice is adequate for sufficient tension to preclude special requirements.

12.17.2.2 — Where the bar stress due to factored loads is tensile and does not exceed $0.5f_y$ in tension, lap splices shall be Class B tension lap splices if more than one-half of the bars are spliced at any section, or Class A tension lap splices if half or fewer of the bars are spliced at any section and alternate lap splices are staggered by ℓ_d.

12.17.2.3 — Where the bar stress due to factored loads is greater than $0.5f_y$ in tension, lap splices shall be Class B tension lap splices.

12.17.2.4 — In tied reinforced compression members, where ties throughout the lap splice length have

R12.17.2.4 — Reduced lap lengths are allowed when the splice is enclosed throughout its length by minimum ties.

CODE

an effective area not less than $0.0015hs$, lap splice length shall be permitted to be multiplied by 0.83, but lap length shall not be less than 12 in. Tie legs perpendicular to dimension h shall be used in determining effective area.

12.17.2.5 — In spirally reinforced compression members, lap splice length of bars within a spiral shall be permitted to be multiplied by 0.75, but lap length shall not be less than 12 in.

12.17.3 — Welded splices or mechanical connectors in columns

Welded splices or mechanical connectors in columns shall meet the requirements of 12.14.3.3 or 12.14.3.4.

12.17.4 — End-bearing splices in columns

End-bearing splices complying with 12.16.4 shall be permitted to be used for column bars stressed in compression provided the splices are staggered or additional bars are provided at splice locations. The continuing bars in each face of the column shall have a tensile strength, based on the specified yield strength f_y, not less than $0.25f_y$ times the area of the vertical reinforcement in that face.

12.18 — Splices of welded deformed wire fabric in tension

12.18.1 — Minimum length of lap for lap splices of welded deformed wire fabric measured between the ends of each fabric sheet shall be not less than $1.3\ell_d$ nor 8 in., and the overlap measured between outermost cross wires of each fabric sheet shall be not less than 2 in. ℓ_d shall be the development length for the specified yield strength f_y in accordance with 12.7.

12.18.2 — Lap splices of welded deformed wire fabric, with no cross wires within the lap splice length, shall be determined as for deformed wire.

COMMENTARY

Compression splice lengths may be multiplied by 0.83 for tied compression members when the tie area throughout the lap length is at least $0.0015hs$, but the splice length may not be less than 12 in.

The tie legs perpendicular to each direction are computed separately and the requirement must be satisfied in each direction. This is illustrated in Fig. R12.17.2, where four legs are effective in one direction and two legs in the other direction. This calculation is critical in one direction which normally can be determined by inspection.

R12.17.2.5 — Compression lap lengths may be reduced when the lap splice is enclosed throughout its length by spirals because of increased splitting resistance. Spirals should meet requirements of 7.10.4 and 10.9.3.

R12.17.3 — Welded splices or mechanical connectors in columns

Welded splices or couplers are allowed for splices in columns but must be designed as a full welded splice or a full mechanical connection developing 125 percent f_y as required by 12.16.3 and 12.14.3.3, or 12.14.3.4. Splice capacity is traditionally tested in tension and full strength is required to reflect the high compression loads possible in column reinforcement due to creep effects. If a coupler developing less than a full mechanical connection is desired, then the splice must conform to all requirements of end bearing splices of 12.16.4 and 12.17.4.

R12.17.4 — End-bearing splices in columns

End-bearing splices used to splice column bars always in compression must have tension capacity of 25 percent of the yield strength of the steel area on each face of the column, either by staggering the end-bearing splices or by adding additional steel through the splice location. The end-bearing splice must conform to 12.16.4.

R12.18 — Splices of welded deformed wire fabric in tension

Splice provisions for deformed fabric are based on available tests.[12.19] The requirements were simplified (1976 code supplement) from provisions of the 1971 ACI Building Code by assuming that only one cross wire of each fabric sheet is overlapped and by computing the splice length as $1.3\ell_d$. The development length ℓ_d is that computed in accordance with the provisions of 12.7 without regard to the 8 in. minimum. The 8 in. applies to the overall splice length. See Fig. R12.18. If no cross wires are within the lap length, the provisions for deformed wire apply.

CODE

12.18.3—When any plain wires are present in the deformed wire fabric in the direction of the lap splice or when deformed wire fabric is lap spliced to plain wire fabric, the fabric shall be lap spliced in accordance with 12.19.

COMMENTARY

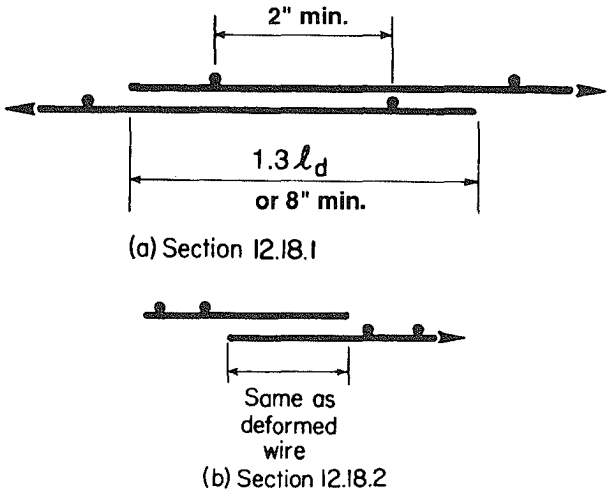

Fig. R12.18—Lap splices of deformed fabric

12.19 — Splices of welded plain wire fabric in tension

Minimum length of lap for lap splices of welded plain wire fabric shall be in accordance with the following.

12.19.1 — When area of reinforcement provided is less than twice that required by analysis at splice location, length of overlap measured between outermost cross wires of each fabric sheet shall be not less than one spacing of cross wires plus 2 in., nor less than **1.5**ℓ_d, nor 6 in. ℓ_d shall be the development length for the specified yield strength f_y in accordance with 12.8.

12.19.2 — When area of reinforcement provided is at least twice that required by analysis at splice location, length of overlap measured between outermost cross wires of each fabric sheet shall be not less than **1.5** ℓ_d, nor 2 in. ℓ_d shall be the development length for the specified yield strength f_y in accordance with 12.8.

R12.19 — Splices of welded plain wire fabric in tension

The strength of lap splices of welded plain wire fabric is dependent primarily on the anchorage obtained from the cross wires rather than on the length of wire in the splice. For this reason, the lap is specified in terms of overlap of cross wires rather than in wire diameters or inches. The 2 in. additional lap required is to assure overlapping of the cross wires and to provide space for satisfactory consolidation of the concrete between cross wires. Research[12.20] has shown

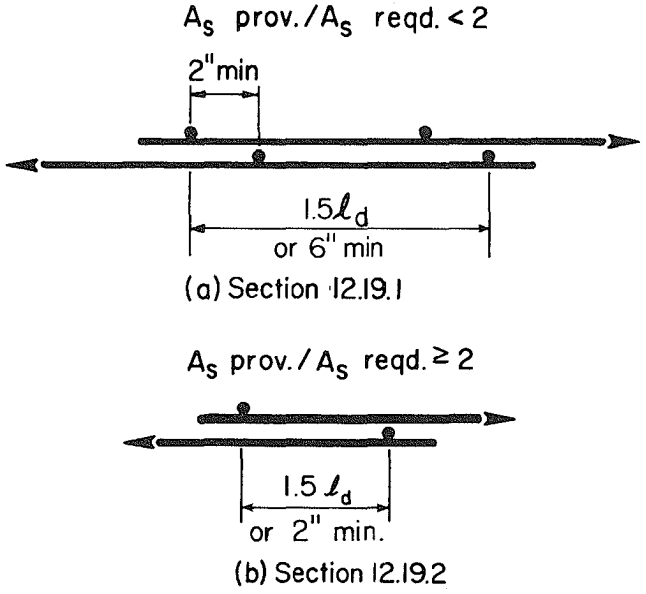

Fig. R12.19—Lap splices of plain fabric

CODE

COMMENTARY

an increased splice length is required when fabric of large, closely spaced wires, is lapped and as a consequence additional splice length requirements are provided for these fabrics, in addition to an absolute minimum of 6 in. The development length ℓ_d is that computed in accordance with the provisions of 12.8 without regard to the 6 in. minimum. Splice requirements are illustrated in Fig. R12.19.

PART 5 — STRUCTURAL SYSTEMS OR ELEMENTS

CHAPTER 13 — TWO-WAY SLAB SYSTEMS

CODE

13.0 — Notation

b_1 = width of the critical section defined in 11.12.1.2 measured in the direction of the span for which moments are determined, in.

b_2 = width of the critical section defined in 11.12.1.2 measured in the direction perpendicular to b_1, in.

c_1 = size of rectangular or equivalent rectangular column, capital, or bracket measured in the direction of the span for which moments are being determined, in.

c_2 = size of rectangular or equivalent rectangular column, capital, or bracket measured transverse to the direction of the span for which moments are being determined, in.

C = cross-sectional constant to define torsional properties

$$= \sum\left(1 - 0.63\frac{x}{y}\right)\frac{x^3 y}{3}$$

The constant C for T- or L-sections shall be permitted to be evaluated by dividing the section into separate rectangular parts and summing the values of C for each part

E_{cb} = modulus of elasticity of beam concrete

E_{cs} = modulus of elasticity of slab concrete

h = overall thickness of member, in.

I_b = moment of inertia about centroidal axis of gross section of beam as defined in 13.2.4

I_s = moment of inertia about centroidal axis of gross section of slab

= $h^3/12$ times width of slab defined in notations α and β_t

K_t = torsional stiffness of torsional member; moment per unit rotation. See R13.7.5.

ℓ_n = length of clear span in direction that moments are being determined, measured face-to-face of supports

ℓ_1 = length of span in direction that moments are being determined, measured center-to-center of supports

ℓ_2 = length of span transverse to ℓ_1, measured center-to-center of supports. See also 13.6.2.3 and 13.6.2.4

M_o = total factored static moment

M_u = factored moment at section

V_c = nominal shear strength provided by concrete. See 11.12.2.1

COMMENTARY

The design methods given in Chapter 13 are based on analysis of the results of an extensive series of tests[13.1-13.7] and the well established performance record of various slab systems. Much of Chapter 13 is concerned with the selection and distribution of flexural reinforcement. It is, therefore, advisable before discussing the various rules for design, to caution the designer that the problem related to safety of a slab system is the transmission of load from the slab to the columns by flexure, torsion, and shear. Design criteria for shear and torsion in slabs are given in Chapter 11.

In the 1995 code, some sections have been renumbered (13.3, 13.4, and 13.5 were 13.4, 13.5, and 13.3, respectively, in the 1989 code) for ease of use in the design process, and parts of the commentary (especially in R13.6 and R13.7) have been removed.

Design aids for use in the engineering analysis and design of two-way slab systems are given in ACI 340.4R [SP-17(S)].[13.8] Design aids are provided to simplify application of the Direct Design and Equivalent Frame Methods of Chapter 13.

CODE

V_u = factored shear force at section
w_d = factored dead load per unit area
w_ℓ = factored live load per unit area
w_u = factored load per unit area
x = shorter overall dimension of rectangular part of cross section
y = longer overall dimension of rectangular part of cross section
α = ratio of flexural stiffness of beam section to flexural stiffness of a width of slab bounded laterally by centerlines of adjacent panels (if any) on each side of the beam

$$= \frac{E_{cb}I_b}{E_{cs}I_s}$$

α_1 = α in direction of ℓ_1
α_2 = α in direction of ℓ_2
β_t = ratio of torsional stiffness of edge beam section to flexural stiffness of a width of slab equal to span length of beam, center-to-center of supports

$$= \frac{E_{cb}C}{2E_{cs}I_s}$$

γ_f = fraction of unbalanced moment transferred by flexure at slab-column connections. See 13.5.3.2
γ_v = fraction of unbalanced moment transferred by eccentricity of shear at slab-column connections
$= 1 - \gamma_f$
ρ = ratio of nonprestressed tension reinforcement
ρ_b = reinforcement ratio producing balanced strain conditions
ϕ = strength reduction factor

COMMENTARY

13.1 — Scope

13.1.1—Provisions of Chapter 13 shall apply for design of slab systems reinforced for flexure in more than one direction, with or without beams between supports.

13.1.2 — For a slab system supported by columns or walls, the dimensions c_1 and c_2 and the clear span ℓ_n shall be based on an effective support area defined by the intersection of the bottom surface of the slab, or of the drop panel if there is one, with the largest right circular cone, right pyramid, or tapered wedge whose surfaces are located within the column and capital or bracket and are oriented no greater than 45 deg to the axis of the column.

13.1.3 — Solid slabs and slabs with recesses or pockets made by permanent or removable fillers between ribs or joists in two directions are included within the scope of Chapter 13.

R13.1 — Scope

The fundamental design principles contained in Chapter 13 are applicable to all planar structural systems subjected to transverse loads. However, some of the specific design rules, as well as historical precedents, limit the types of structures to which Chapter 13 is applicable. General characteristics of slab systems which may be designed according to Chapter 13 are described in this section. These systems include "flat slabs," "flat plates," "two-way slabs," and "waffle slabs." Slabs with paneled ceilings are two-way wide-band beam systems.

True "one-way slabs," slabs reinforced to resist flexural stresses in only one direction, are excluded. Also excluded are soil supported slabs, such as "slabs on grade," which do not transmit vertical loads from other parts of the structure to the soil.

For slabs with beams, the explicit design procedures of Chapter 13 apply only when the beams are located at the

CODE

13.1.4 — Minimum thickness of slabs designed in accordance with Chapter 13 shall be as required by 9.5.3.

COMMENTARY

edges of the panel and when the beams are supported by columns or other essentially nondeflecting supports at the corners of the panel. Two-way slabs with beams in one direction with both slab and beams supported by girders in the other direction may be designed under the general requirements of Chapter 13. Such designs must be based upon analysis compatible with the deflected position of the supporting beams and girders.

For slabs supported on walls, the explicit design procedures in this chapter envision the wall as a beam of infinite stiffness; therefore, each wall should support the entire length of an edge of the panel. (See 13.2.3). Wall-like columns less than a full panel length can be treated as columns.

13.2 — Definitions

R13.2 — Definitions

13.2.1 — Column strip is a design strip with a width on each side of a column centerline equal to 0.25 ℓ_2 or $0.25\ell_1$, whichever is less. Column strip includes beams, if any.

13.2.2 — Middle strip is a design strip bounded by two column strips.

13.2.3 — A panel is bounded by column, beam, or wall centerlines on all sides.

R13.2.3 — A panel, by definition, includes all flexural elements between column centerlines. Thus, the column strip includes the beam, if any.

13.2.4 — For monolithic or fully composite construction, a beam includes that portion of slab on each side of the beam extending a distance equal to the projection of the beam above or below the slab, whichever is greater, but not greater than four times the slab thickness.

R13.2.4 — For monolithic or fully composite construction, the beams include portions of the slab as flanges. Two examples of the rule in this section are provided in Fig. R13.2.4.

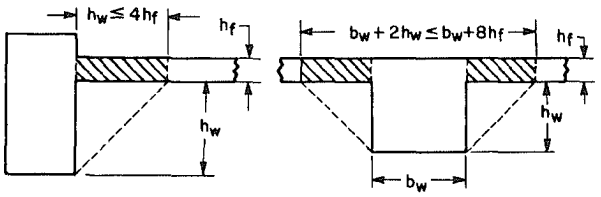

Fig. R13.2.4—Examples of the portion of slab to be included with the beam under 13.2.4

13.3 — Slab reinforcement

R13.3 — Slab reinforcement

13.3.1 — Area of reinforcement in each direction for two-way slab systems shall be determined from moments at critical sections, but shall not be less than required by 7.12.

13.3.2 — Spacing of reinforcement at critical sections shall not exceed two times the slab thickness, except for portions of slab area of cellular or ribbed construc-

R13.3.2 — The requirement that the center-to-center spacing of the reinforcement be not more than two times the slab thickness applies only to the reinforcement in solid slabs,

CODE

tion. In the slab over cellular spaces, reinforcement shall be provided as required by 7.12.

13.3.3 — Positive moment reinforcement perpendicular to a discontinuous edge shall extend to the edge of slab and have embedment, straight or hooked, at least 6 in. in spandrel beams, columns, or walls.

13.3.4 — Negative moment reinforcement perpendicular to a discontinuous edge shall be bent, hooked, or otherwise anchored, in spandrel beams, columns, or walls, to be developed at face of support according to provisions of Chapter 12.

13.3.5 — Where a slab is not supported by a spandrel beam or wall at a discontinuous edge, or where a slab cantilevers beyond the support, anchorage of reinforcement shall be permitted within the slab.

13.3.6 — In slabs with beams between supports with a value of α greater than 1.0, special top and bottom slab reinforcement shall be provided at exterior corners in accordance with the following:

13.3.6.1 — The special reinforcement in both top and bottom of slab shall be sufficient to resist a moment equal to the maximum positive moment (per foot of width) in the slab.

13.3.6.2 — The moment shall be assumed to be about an axis perpendicular to the diagonal from the corner in the top of the slab and about an axis parallel to the diagonal from the corner in the bottom of the slab.

13.3.6.3 — The special reinforcement shall be provided for a distance in each direction from the corner equal to one-fifth the longer span.

13.3.6.4 — The special reinforcement shall be placed in a band parallel to the diagonal in the top of the slab and a band perpendicular to the diagonal in the bottom of the slab. Alternatively, the special reinforcement shall be placed in two layers parallel to the sides of the slab in either the top or bottom of the slab.

13.3.7 — Where a drop panel is used to reduce amount of negative moment reinforcement over the column of a flat slab, size of drop panel shall be in accordance with the following:

13.3.7.1 — Drop panel shall extend in each direction from centerline of support a distance not less than one-sixth the span length measured from center-to-center of supports in that direction.

COMMENTARY

and not to that in joists or waffle slabs. This limitation is intended to ensure slab action and reduce cracking and to provide for the possibility of loads concentrated on small areas of the slab. See also R10.6.

R13.3.3-R13.3.5 — Bending moments in slabs at spandrel beams can be subject to great variation. If spandrel beams are built solidly into walls, the slab approaches complete fixity. Without an integral wall, the slab could be largely simply supported, depending on the torsional rigidity of the spandrel beam or slab edge. These requirements provide for unknown conditions that might normally occur in a structure.

CODE

13.3.7.2 — Projection of drop panel below the slab shall be at least one-quarter the slab thickness beyond the drop.

13.3.7.3 — In computing required slab reinforcement, thickness of drop panel below the slab shall not be assumed greater than one-quarter the distance from edge of drop panel to edge of column or column capital.

13.3.8 — Details of reinforcement in slabs without beams

13.3.8.1 — In addition to the other requirements of 13.3, reinforcement in slabs without beams shall have minimum extensions as prescribed in Fig. 13.3.8.

13.3.8.2 — Where adjacent spans are unequal, extensions of negative moment reinforcement beyond the face of support as prescribed in Fig. 13.3.8 shall be based on requirements of the longer span.

13.3.8.3 — Bent bars shall be permitted only when depth-span ratio permits use of bends 45 deg or less.

13.3.8.4 — For slabs in frames not braced against sidesway, lengths of reinforcement shall be determined by analysis but shall not be less than those prescribed in Fig. 13.3.8.

13.3.8.5 — All bottom bars or wires within the column strip, in each direction, shall be continuous or spliced with Class A splices located as shown in Fig. 13.3.8. At least two of the column strip bottom bars or wires in each direction shall pass within the column core and shall be anchored at exterior supports.

13.3.8.6 — In slabs with shearheads and in lift-slab construction, at least two bonded bottom bars or wires in each direction shall pass through the shearhead or lifting collar as close to the column as practicable and be continuous or spliced with a Class A splice. At exterior columns, the reinforcement shall be anchored at the shearhead or lifting collar.

COMMENTARY

R13.3.8 — Details of reinforcement in slabs without beams

In 1989, bent bars were removed from Fig. 13.3.8 of this code. This was done because bent bars are seldom used and are difficult to place properly. Bent bars placed in accordance with Fig. 13.4.8 of the 1983 ACI Code are permitted.

R13.3.8.4 — Where two-way slabs act as primary members of a laterally unbraced frame resisting lateral loads, the resulting moments due to the combined lateral and gravity loadings preclude use of the arbitrary lengths and minimum extensions of bars in Fig. 13.3.8.

R13.3.8.5 — The continuous column strip bottom reinforcement provides the slab some residual ability to span to the adjacent supports should a single support be damaged. The two continuous column strip bottom bars or wires through the column may be termed "integrity steel," and are provided to give the slab some residual capacity following a single punching shear failure.[13.9]

R13.3.8.6 — In 1992, this provision was added to require the same "integrity" steel as for other two-way slabs without beams in case of a single punching shear failure at a support. (See Fig. R13.3.8.6 for location of integrity steel.)

CODE COMMENTARY

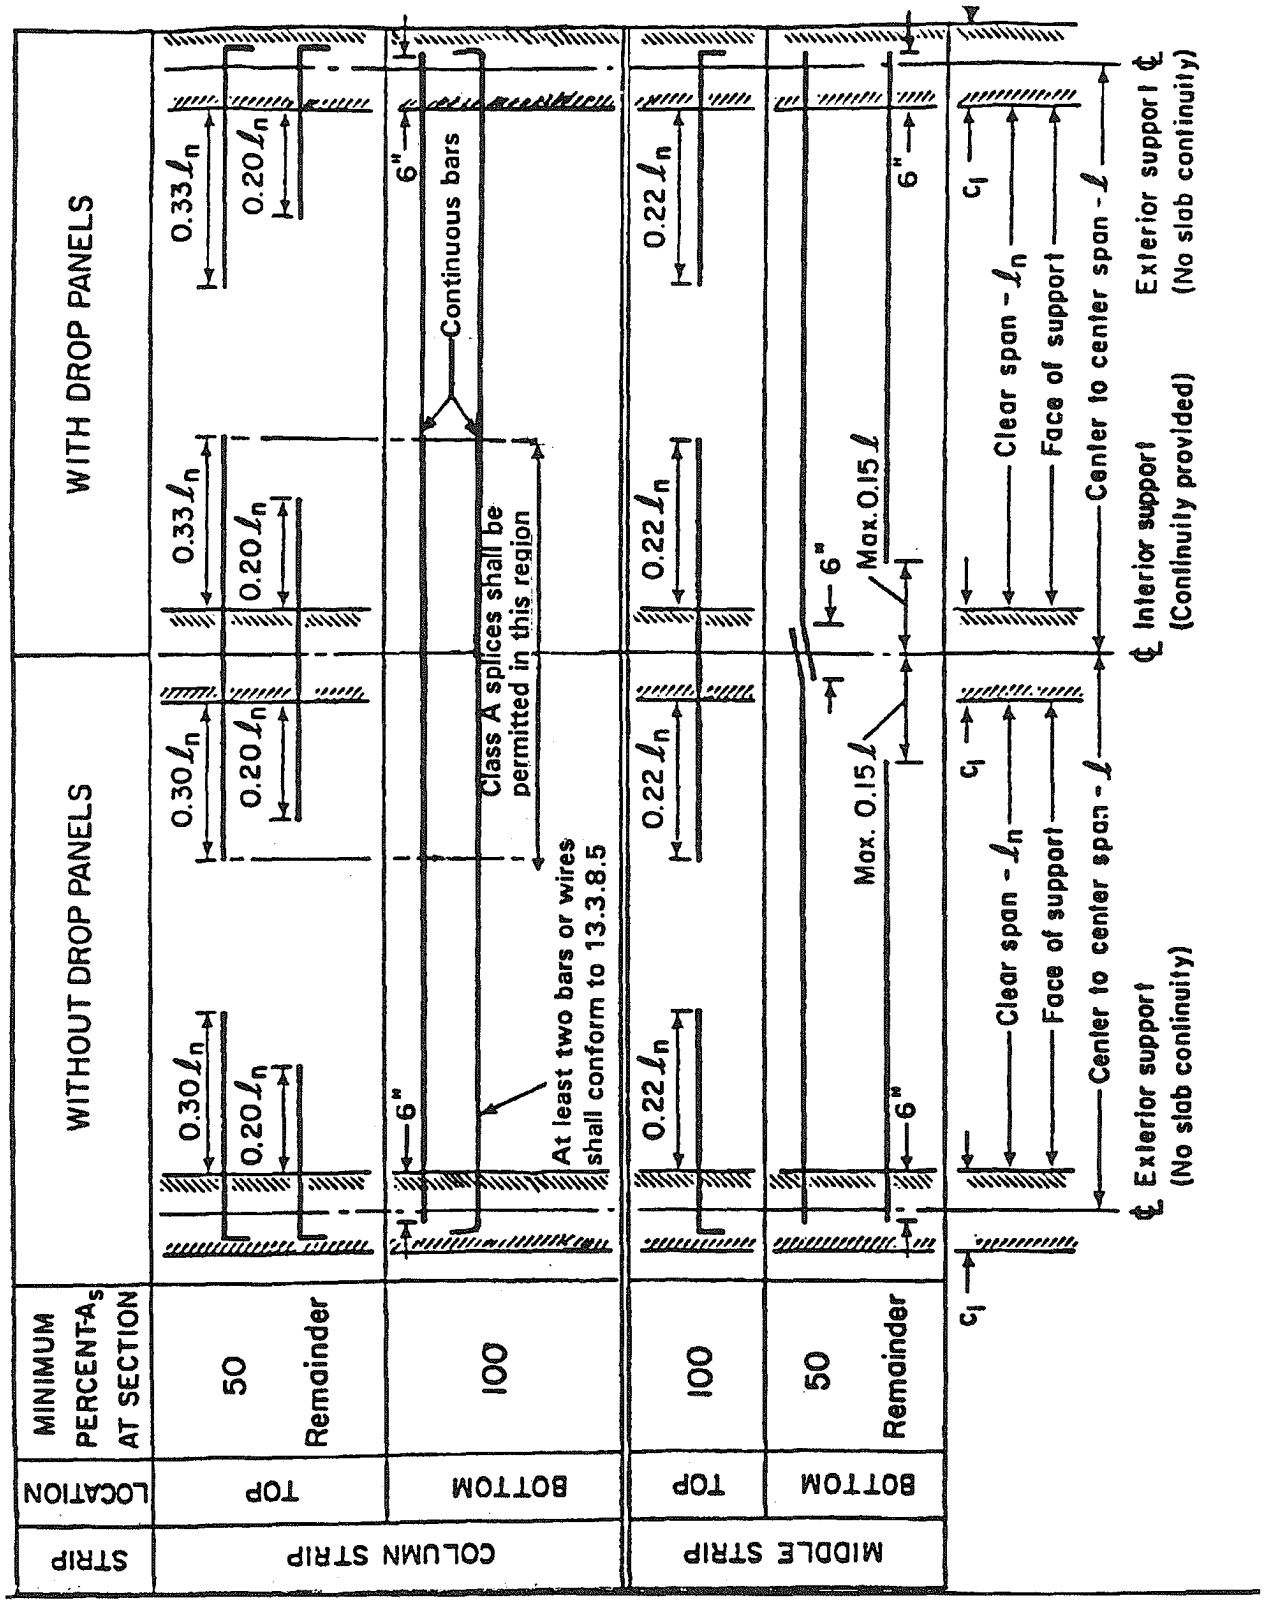

Fig. 13.3.8—Minimum extensions for reinforcement in slabs without beams. (See 12.11.1 for reinforcement extension into supports)

CODE

COMMENTARY

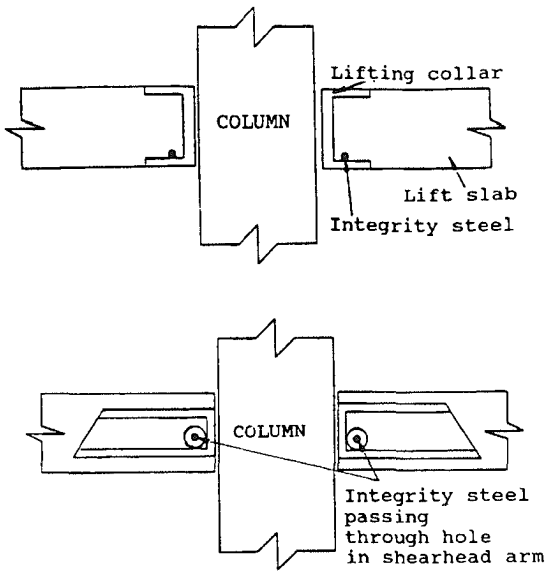

Fig. R13.3.8.6—Location of integrity steel

13.4 — Openings in slab systems

13.4.1 — Openings of any size shall be permitted in slab systems if shown by analysis that the design strength is at least equal to the required strength considering 9.2 and 9.3, and that all serviceability conditions, including the specified limits on deflections, are met.

13.4.2 — As an alternate to special analysis as required by 13.4.1, openings shall be permitted in slab systems without beams only in accordance with the following:

13.4.2.1 — Openings of any size shall be permitted in the area common to intersecting middle strips, provided total amount of reinforcement required for the panel without the opening is maintained.

13.4.2.2 — In the area common to intersecting column strips, not more than one-eighth the width of column strip in either span shall be interrupted by openings. An amount of reinforcement equivalent to that interrupted by an opening shall be added on the sides of the opening.

13.4.2.3 — In the area common to one column strip and one middle strip, not more than one-quarter of the reinforcement in either strip shall be interrupted by openings. An amount of reinforcement equivalent to that interrupted by an opening shall be added on the sides of the opening.

13.4.2.4 — Shear requirements of 11.12.5 shall be satisfied.

R13.4 — Openings in slab systems

See R11.12.5.

CODE

13.5 — Design procedures

13.5.1 — A slab system shall be designed by any procedure satisfying conditions of equilibrium and geometric compatibility, if shown that the design strength at every section is at least equal to the required strength considering 9.2 and 9.3, and that all serviceability conditions, including specified limits on deflections, are met.

13.5.1.1 — Design of a slab system for gravity loads, including the slab and beams (if any) between supports and supporting columns or walls forming orthogonal frames, by either the Direct Design Method of 13.6 or the Equivalent Frame Method of 13.7 shall be permitted.

13.5.1.2 — For lateral loads, analysis of unbraced frames shall take into account effects of cracking and reinforcement on stiffness of frame members.

COMMENTARY

R13.5 — Design procedures

R13.5.1 — This section permits a designer to base a design directly on fundamental principles of structural mechanics, provided it can be demonstrated explicitly that all safety and serviceability criteria are satisfied. The design of the slab may be achieved through the combined use of classic solutions based on a linearly elastic continuum, numerical solutions based on discrete elements, or yield-line analyses, including, in all cases, evaluation of the stress conditions around the supports in relation to shear and torsion as well as flexure. The designer must consider that the design of a slab system involves more than its analysis, and justify any deviations in physical dimensions of the slab from common practice on the basis of knowledge of the expected loads and the reliability of the calculated stresses and deformations of the structure.

R13.5.1.1 — For gravity load analysis of two-way slab systems, two analysis methods are specified in 13.6 and 13.7. The specific provisions of both design methods are limited in application to orthogonal frames subject to gravity loads only. Both methods apply to two-way slabs with beams as well as to flat slabs and flat plates. In both methods, the distribution of moments to the critical sections of the slab reflects the effects of reduced stiffness of elements due to cracking and support geometry.

R13.5.1.2 — For lateral load analysis, moment magnification is proportional to actual lateral displacement (drift). During the life of a structure, construction loads, ordinary occupancy loads, anticipated overloads, and volume changes will cause cracking of slabs. Cracking reduces stiffness of the slab members, especially slabs of unbraced frames. When lateral loads are considered to act on a structure, slab cracking increases drift (lateral deflection). To assure that lateral drift caused by wind or small earthquakes is not underestimated, cracking of slabs must be considered in stiffness assumptions.

If stiffness values are not obtained by a comprehensive analysis taking into account effects of cracking and reinforcement on stiffness, an effective moment of inertia of slab members may be computed by use of a fully cracked section. Alternatively, test results for full-size specimens indicated that stiffness values based on Eq. (9-7) are reasonable.[13.10,13.11]

The designer may select any approach that is shown to satisfy equilibrium and geometrical compatibility and to be in reasonable agreement with available test data. Some of the available design procedures are summarized in Reference 13.12. For slabs of unbraced frames, an "equivalent width" in the range of 25 to 50 percent of the full panel width has been used to reflect reduced stiffness due to cracking of slab members. The stiffness of slab members depends also on other parameters such as ℓ_2/ℓ_1, c_1/ℓ_1, c_2/c_1, and on concentration of reinforcement in the slab width defined in 13.5.3.2

CODE

COMMENTARY

for unbalanced moment transfer by flexure. This added concentration of reinforcement will increase stiffness[13.12] by preventing premature yielding and softening in the slab and column region.

In unbraced frames a "lower bound" stiffnesses assumption for the slab-beams should be used to assure that a reasonable estimate of drift is obtained. In framing systems with frame-shear wall interaction, a more rigorous calculation of stiffnesses is desirable so that the frame members are properly proportioned to resist the lateral forces and moments their relative stiffnesses will attract.

13.5.1.3 — Combining the results of the gravity load analysis with the results of the lateral load analysis shall be permitted.

13.5.2 — The slab and beams (if any) between supports shall be proportioned for factored moments prevailing at every section.

13.5.3 — When gravity load, wind, earthquake, or other lateral forces cause transfer of moment between slab and column, a fraction of the unbalanced moment shall be transferred by flexure in accordance with 13.5.3.2 and 13.5.3.3.

13.5.3.1 — Fraction of unbalanced moment not transferred by flexure shall be transferred by eccentricity of shear in accordance with 11.12.6.

13.5.3.2 — A fraction of the unbalanced moment given by $\gamma_f M_u$ shall be considered to be transferred by flexure within an effective slab width between lines that are one and one-half slab or drop panel thicknesses **(1.5*h*)** outside opposite faces of the column or capital, where M_u is the moment to be transferred and

$$\gamma_f = \frac{1}{1 + (2/3)\sqrt{b_1/b_2}} \qquad (13\text{-}1)$$

13.5.3.3 — For unbalanced moments about an axis parallel to the edge at exterior supports, the value of γ_f by Eq. (13-1) shall be permitted to be increased up to 1.0 provided that V_u at an edge support does not exceed $0.75\phi V_c$ or at a corner support does not exceed $0.5\phi V_c$. For unbalanced moments at interior supports, and for unbalanced moments about an axis transverse to the edge at exterior supports, the value of γ_f in Eq. (13-1) shall be permitted to be increased by up to 25 percent provided that V_u at the support does not exceed $0.4\phi V_c$. The reinforcement ratio ρ, within the effective slab width defined in 13.5.3.2, shall not exceed $0.375\rho_b$. No adjustments to γ_f shall be permitted for prestressed slab systems.

R13.5.3 — This section is concerned primarily with slab systems without beams. Tests and experience have shown that, unless special measures are taken to resist the torsional and shear stresses, all reinforcement resisting that part of the moment to be transferred to the column by flexure should be placed between lines that are one and one-half the slab or drop panel thickness, **1.5*h***, on each side of the column. The calculated shear stresses in the slab around the column must conform to the requirements of 11.12.2. See R11.12.2.1 and R11.12.2 for more details on application of this section.

R13.5.3.3 — The 1989 code procedures remain unchanged, except that under certain conditions the designer is permitted to adjust the level of moment transferred by shear without revising member sizes. Recent evaluation of available tests indicate that some flexibility in distribution of unbalanced moments transferred by shear and flexure at both exterior and interior supports is possible. Changes in the 1995 Code were made to recognize, to some extent, design practices prior to the 1971 code.[13.13]

At exterior supports, for unbalanced moments about an axis parallel to the edge, the portion of moment transferred by eccentricity of shear $\gamma_v M_u$ may be reduced provided that the factored shear at the support (excluding the shear produced by moment transfer) does not exceed 75 percent of the shear capacity ϕV_c as defined in 11.12.2.1 for edge columns or 50 percent for corner columns. Tests indicate that

CODE

COMMENTARY

there is no significant interaction between shear and unbalanced moment at the exterior support in such cases.[13.14,13.15] Note that as $\gamma_v M_u$ is decreased, $\gamma_f M_u$ is increased.

Evaluation of tests of interior supports indicates that some flexibility in distributing unbalanced moments by shear and flexure is also possible, but with more severe limitations than for exterior supports. For interior supports, the unbalanced moment transferred by flexure is permitted to be increased up to 25 percent provided that the factored shear (excluding the shear caused by the moment transfer) at the interior supports does not exceed 40 percent of the shear capacity ϕV_c as defined in 11.12.2.1.

Tests of slab-column connections indicate that a large degree of ductility is required, because the interaction between shear and unbalanced moment is critical. When the factored shear is large, the column-slab joint cannot always develop all of the reinforcement provided in the effective width. The modifications for edge, corner, or interior slab-column connections specified in 13.5.3.3 are permitted only when the reinforcement ratio (within the effective width) required to develop the unbalanced moment $\gamma_f M_u$ does not exceed $\mathbf{0.375}\rho_b$. The use of Eq. (13-1), without the modification permitted in 13.5.3.3, will generally indicate overstress conditions on the joint. The provisions of 13.5.3.3 are intended to improve ductile behavior of the column-slab joint. When a reversal of moments occurs at opposite faces of an interior support, both top and bottom reinforcement should be concentrated within the effective width. A ratio of top to bottom reinforcement of about 2 has been observed to be appropriate.

13.5.3.4 — Concentration of reinforcement over the column by closer spacing or additional reinforcement shall be used to resist moment on the effective slab width defined in 13.5.3.2.

13.5.4 — Design for transfer of load from slabs to supporting columns or walls through shear and torsion shall be in accordance with Chapter 11.

13.6 — Direct design method

R13.6 — Direct design method

The Direct Design Method consists of a set of rules for distributing moments to slab and beam sections to satisfy safety requirements and most serviceability requirements simultaneously. Three fundamental steps are involved as follows:

(1) Determination of the total factored static moment (see 13.6.2).

(2) Distribution of the total factored static moment to negative and positive sections (see 13.6.3).

(3) Distribution of the negative and positive factored moments to the column and middle strips and to the beams, if any (see 13.6.4 through 13.6.6). The distribu-

CODE

13.6.1 — Limitations

Design of slab systems within the following limitations by the Direct Design Method shall be permitted.

13.6.1.1 — There shall be a minimum of three continuous spans in each direction.

13.6.1.2 — Panels shall be rectangular, with a ratio of longer to shorter span center-to-center of supports within a panel not greater than 2.

13.6.1.3 — Successive span lengths center-to-center of supports in each direction shall not differ by more than one-third the longer span.

13.6.1.4 — Offset of columns by a maximum of 10 percent of the span (in direction of offset) from either axis between centerlines of successive columns shall be permitted.

13.6.1.5 — All loads shall be due to gravity only and uniformly distributed over an entire panel. Live load shall not exceed two times dead load.

13.6.1.6 — For a panel with beams between supports on all sides, the relative stiffness of beams in two perpendicular directions

$$\frac{\alpha_1 \ell_2^2}{\alpha_2 \ell_1^2} \qquad (13\text{-}2)$$

shall not be less than 0.2 nor greater than 5.0.

COMMENTARY

tion of moments to column and middle strips is also used in the Equivalent Frame Method (see 13.7).

R13.6.1 — Limitations

The direct design method was developed from considerations of theoretical procedures for the determination of moments in slabs with and without beams, requirements for simple design and construction procedures, and precedents supplied by performance of slab systems. Consequently, the slab systems to be designed using the direct design method must conform to the limitations in this section.

R13.6.1.1 — The primary reason for the limitation in this section is the magnitude of the negative moments at the interior support in a structure with only two continuous spans. The rules given for the direct design method assume tacitly that the slab system at the first interior negative moment section is neither fixed against rotation nor discontinuous.

R13.6.1.2 — If the ratio of the two spans (long span/short span) of a panel exceeds two, the slab resists the moment in the shorter span essentially as a one-way slab.

R13.6.1.3 — The limitation in this section is related to the possibility of developing negative moments beyond the point where negative moment reinforcement is terminated, as prescribed in Fig. 13.3.8 of the code.

R13.6.1.4 — Columns can be offset within specified limits from a regular rectangular array. A cumulative total offset of 20 percent of the span is established as the upper limit.

R13.6.1.5 — The direct design method is based on tests for uniform gravity loads and resulting column reactions determined by statics.[13.16] Lateral loads such as wind or seismic require a frame analysis. Inverted foundation mats designed as two-way slabs (see 15.10) involve application of known column loads. Therefore, even where the soil reaction is assumed to be uniform, a frame analysis is required.

In the 1995 code, the limit of applicability of the direct design method for ratios of live load to dead load has been reduced from 3 to 2. In most slab systems, the live to dead load ratio will be less than 2 and it is not necessary to check the effects of pattern loading. Section 13.6.10 in the 1989 code has been eliminated because it is no longer needed.

R13.6.1.6 — The elastic distribution of moments will deviate significantly from those assumed in the direct design method unless the given requirements for stiffness are satisfied.

CODE

13.6.1.7 — Moment redistribution as permitted by 8.4 shall not be applied for slab systems designed by the Direct Design Method. See 13.6.7.

13.6.1.8 — Variations from the limitations of 13.6.1 shall be permitted if demonstrated by analysis that requirements of 13.5.1 are satisfied.

13.6.2 — Total factored static moment for a span

13.6.2.1 — Total factored static moment for a span shall be determined in a strip bounded laterally by centerline of panel on each side of centerline of supports.

13.6.2.2 — Absolute sum of positive and average negative factored moments in each direction shall not be less than

$$M_o = \frac{w_u \ell_2 \ell_n^2}{8} \qquad (13\text{-}3)$$

13.6.2.3 — Where the transverse span of panels on either side of the centerline of supports varies, ℓ_2 in Eq. (13-3) shall be taken as the average of adjacent transverse spans.

13.6.2.4 — When the span adjacent and parallel to an edge is being considered, the distance from edge to panel centerline shall be substituted for ℓ_2 in Eq. (13-3).

13.6.2.5 — Clear span ℓ_n shall extend from face to face of columns, capitals, brackets, or walls. Value of ℓ_n used in Eq. (13-3) shall not be less than **0.65** ℓ_1. Circular or regular polygon shaped supports shall be treated as square supports with the same area.

13.6.3 — Negative and positive factored moments

13.6.3.1 — Negative factored moments shall be located at face of rectangular supports. Circular or

COMMENTARY

R13.6.1.7 — Moment redistribution as permitted by 8.4 is not intended where approximate values for bending moments are used. For the direct design method, 10 percent modification is allowed by 13.6.7.

R13.6.1.8 — The designer is permitted to use the direct design method even if the structure does not fit the limitations in this section, provided it can be shown by analysis that the particular limitation does not apply to that structure. For example, in the case of a slab system carrying a nonmovable load (such as a water reservoir in which the load on all panels is expected to be the same), the designer need not satisfy the live load limitation of 13.6.1.5.

R13.6.2 — Total factored static moment for a span

R13.6.2.2 — Eq. (13-3) follows directly from Nichol's derivation[13.17] with the simplifying assumption that the reactions are concentrated along the faces of the support perpendicular to the span considered. In general, the designer will find it expedient to calculate static moments for two adjacent half panels, which include a column strip with a half middle strip along each side.

R13.6.2.5 — If a supporting member does not have a rectangular cross section or if the sides of the rectangle are not parallel to the spans, it is to be treated as a square support having the same area, as illustrated in Fig. R13.6.2.5.

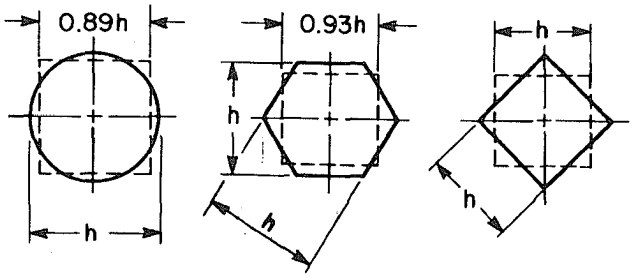

Fig. R13.6.2.5—Examples of equivalent square section for supporting members

R13.6.3 — Negative and positive factored moments

CODE

regular polygon shaped supports shall be treated as square supports with the same area.

13.6.3.2 — In an interior span, total static moment M_o shall be distributed as follows:

Negative factored moment 0.65

Positive factored moment.....0.35

13.6.3.3 — In an end span, total factored static moment M_o shall be distributed as follows:

	(1)	(2)	(3)	(4)	(5)
	Exterior edge unrestrained	Slab with beams between all supports	Slab without beams between interior supports		Exterior edge fully restrained
			Without edge beam	With edge beam	
Interior negative factored moment	0.75	0.70	0.70	0.70	0.65
Positive factored moment	0.63	0.57	0.52	0.50	0.35
Exterior negative factored moment	0	0.16	0.26	0.30	0.65

13.6.3.4 — Negative moment sections shall be designed to resist the larger of the two interior negative factored moments determined for spans framing into a common support unless an analysis is made to distribute the unbalanced moment in accordance with stiffnesses of adjoining elements.

13.6.3.5 — Edge beams or edges of slab shall be proportioned to resist in torsion their share of exterior negative factored moments.

13.6.3.6 — The gravity load moment to be transferred between slab and edge column in accordance with 13.5.3.1 shall be $0.3M_o$.

COMMENTARY

R13.6.3.3 — The moment coefficients for an end span are based on the equivalent column stiffness expressions from References 13.18, 13.19, and 13.20. The coefficients for an unrestrained edge would be used, for example, if the slab were simply supported on a masonry or concrete wall. Those for a restrained edge would apply if the slab were constructed integrally with a concrete wall having a flexural stiffness so large compared to that of the slab that little rotation occurs at the slab-to-wall connection.

For other than unrestrained or fully restrained edges, coefficients in the table were selected to be near the upper bound of the range for positive moments and interior negative moments. As a result, exterior negative moments were usually closer to a lower bound. The exterior negative moment capacity for most slab systems is governed by minimum reinforcement to control cracking. The final coefficients selected have been adjusted so that the absolute sum of the positive and average moments equal M_o.

For two-way slab systems with beams between supports on all sides (two-way slabs), moment coefficients of Column (2) apply. For slab systems without beams between interior supports (flat plates and flat slabs), the moment coefficients of Column (3) or (4) apply, without or with an edge (spandrel) beam, respectively.

In the 1977 ACI Building Code, distribution factors defined as a function of the stiffness ratio of the equivalent exterior support were used for proportioning the total static moment M_o in an end span. The approach may be used in place of values in 13.6.3.3.

R13.6.3.4 — The differences in slab moment on either side of a column or other type of support must be accounted for in the design of the support. If an analysis is made to distribute unbalanced moments, flexural stiffness may be obtained on the basis of the gross concrete section of the members involved.

R13.6.3.5 — Moments perpendicular to, and at the edge of, the slab structure must be transmitted to the supporting columns or walls. Torsional stresses caused by the moment assigned to the slab must be investigated.

CODE

13.6.4 — Factored moments in column strips

13.6.4.1 — Column strips shall be proportioned to resist the following portions in percent of interior negative factored moments:

ℓ_2/ℓ_1	0.5	1.0	2.0
$(\alpha_1\ell_2/\ell_1) = 0$	75	75	75
$(\alpha_1\ell_2/\ell_1) \geq 1.0$	90	75	45

Linear interpolations shall be made between values shown.

13.6.4.2 — Column strips shall be proportioned to resist the following portions in percent of exterior negative factored moments:

ℓ_2/ℓ_1		0.5	1.0	2.0
$(\alpha_1\ell_2/\ell_1) = 0$	$\beta_t = 0$	100	100	100
	$\beta_t \geq 2.5$	75	75	75
$(\alpha_1\ell_2/\ell_1) \geq 1.0$	$\beta_t = 0$	100	100	100
	$\beta_t \geq 2.5$	90	75	45

Linear interpolations shall be made between values shown.

13.6.4.3 — Where supports consist of columns or walls extending for a distance equal to or greater than three-quarters the span length ℓ_2 used to compute M_o, negative moments shall be considered to be uniformly distributed across ℓ_2.

13.6.4.4 — Column strips shall be proportioned to resist the following portions in percent of positive factored moments:

ℓ_2/ℓ_1	0.5	1.0	2.0
$(\alpha_1\ell_2/\ell_1) = 0$	60	60	60
$(\alpha_1\ell_2/\ell_1) \geq 1.0$	90	75	45

Linear interpolations shall be made between values shown.

13.6.4.5 — For slabs with beams between supports, the slab portion of column strips shall be proportioned to resist that portion of column strip moments not resisted by beams.

13.6.5 — Factored moments in beams

13.6.5.1 — Beams between supports shall be pro-

COMMENTARY

R13.6.4, R13.6.5, and R13.6.6 — Factored moments in column strips, beams, and middle strips

The rules given for assigning moments to the column strips, beams, and middle strips are based on studies of moments in linearly elastic slabs with different beam stiffness[13.21] tempered by the moment coefficients that have been used successfully in the past.

For the purpose of establishing moments in the half column strip adjacent to an edge supported by a wall, ℓ_n in Eq. (13-3) may be assumed equal to ℓ_n of the parallel adjacent column to column span, and the wall may be considered as a beam having a moment of inertia I_b equal to infinity.

R13.6.4.2 — The effect of the torsional stiffness parameter β_t is to assign all of the exterior negative factored moment to the column strip, and none to the middle strip, unless the beam torsional stiffness is high relative to the flexural stiffness of the supported slab. In the definition of β_t, the shear modulus has been taken as $E_{cb}/2$.

Where walls are used as supports along column lines, they can be regarded as very stiff beams with an $\alpha_1\ell_2/\ell_1$ value greater than one. Where the exterior support consists of a wall perpendicular to the direction in which moments are being determined, β_t may be taken as zero if the wall is of masonry without torsional resistance, and β_t may be taken as 2.5 for a concrete wall with great torsional resistance which is monolithic with the slab.

R13.6.5 — Factored moments in beams

Loads assigned directly to beams are in addition to the uni-

CODE

portioned to resist 85 percent of column strip moments if ($\alpha_1 \ell_2/\ell_1$) is equal to or greater than 1.0.

13.6.5.2 — For values of $\alpha_1 \ell_2/\ell_1$ between 1.0 and zero, proportion of column strip moments resisted by beams shall be obtained by linear interpolation between 85 and zero percent.

13.6.5.3 — In addition to moments calculated for uniform loads according to 13.6.2.2, 13.6.5.1, and 13.6.5.2, beams shall be proportioned to resist all moments caused by concentrated or linear loads applied directly to beams, including weight of projecting beam stem above or below the slab.

13.6.6 — Factored moments in middle strips

13.6.6.1 — That portion of negative and positive factored moments not resisted by column strips shall be proportionately assigned to corresponding half middle strips.

13.6.6.2 — Each middle strip shall be proportioned to resist the sum of the moments assigned to its two half middle strips.

13.6.6.3 — A middle strip adjacent to and parallel with an edge supported by a wall shall be proportioned to resist twice the moment assigned to the half middle strip corresponding to the first row of interior supports.

13.6.7 — Modification of factored moments

Modification of negative and positive factored moments by 10 percent shall be permitted provided the total static moment for a panel in the direction considered is not less than that required by Eq. (13-3).

13.6.8 — Factored shear in slab systems with beams

13.6.8.1 — Beams with $\alpha_1 \ell_2/\ell_1$ equal to or greater than 1.0 shall be proportioned to resist shear caused by factored loads on tributary areas bounded by 45 deg lines drawn from the corners of the panels and the centerlines of the adjacent panels parallel to the long sides.

13.6.8.2 — In proportioning of beams with $\alpha_1 \ell_2/\ell_1$ less than 1.0 to resist shear, linear interpolation, assuming beams carry no load at $\alpha_1 = 0$, shall be permitted.

13.6.8.3 — In addition to shears calculated according to 13.6.8.1 and 13.6.8.2, beams shall be proportioned to resist shears caused by factored loads applied directly on beams.

13.6.8.4 — Computation of slab shear strength on

COMMENTARY

form dead load of slab, uniform superimposed dead loads such as ceiling, floor finish, or assumed equivalent partition loads, and uniform live loads; all of which are normally included with w_u in Eq. (13-3). Loads applied directly to beams include line loads such as partition walls over (or along) beam centerlines, concentrated loads such as posts above or hangers below the beams, plus additional dead (line) load of the projecting beam stem. For the purpose of assigning directly applied loads, only loads located within the width of beam stem should be considered as directly applied to the beams. (The effective width of a beam as defined in 13.2.4 is solely for strength and relative stiffness calculations.) Line loads and concentrated loads located on the slab away from the beam stem require special consideration to determine their apportionment to slab and beams.

R13.6.8 — Factored shear in slab systems with beams

The tributary area for computing shear on an interior beam is shown shaded in Fig. R13.6.8. If the stiffness for the beam $\alpha_1 \ell_2/\ell_1$ is less than one, the shear on the beam may be

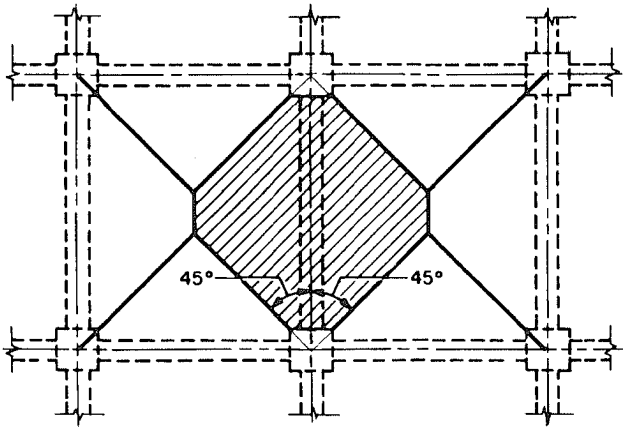

Fig. R13.6.8—Tributary area for shear on an interior beam

CODE

the assumption that load is distributed to supporting beams in accordance with 13.6.8.1 or 13.6.8.2 shall be permitted. Resistance to total shear occurring on a panel shall be provided.

13.6.8.5 — Shear strength shall satisfy requirements of Chapter 11.

13.6.9 — Factored moments in columns and walls

13.6.9.1 — Columns and walls built integrally with a slab system shall resist moments caused by factored loads on the slab system.

13.6.9.2 — At an interior support, supporting elements above and below the slab shall resist the moment specified by Eq. (13-4) in direct proportion to their stiffnesses unless a general analysis is made.

$$M = 0.07[(w_d + 0.5w_\ell)\ell_2\ell_n^2 - w_d'\ell_2'(\ell_n')^2] \qquad (13\text{-}4)$$

where w_d', ℓ_2', and ℓ_n' refer to shorter span.

13.7 — Equivalent frame method

13.7.1 — Design of slab systems by the Equivalent Frame Method shall be based on assumptions given in 13.7.2 through 13.7.6, and all sections of slabs and supporting members shall be proportioned for moments and shears thus obtained.

13.7.1.1 — Where metal column capitals are used, it shall be permitted to take account of their contributions to stiffness and resistance to moment and to shear.

13.7.1.2 — Neglecting the change in length of columns and slabs due to direct stress, and deflections due to shear, shall be permitted.

13.7.2 — Equivalent frame

13.7.2.1 — The structure shall be considered to be made up of equivalent frames on column lines taken longitudinally and transversely through the building.

13.7.2.2 — Each frame shall consist of a row of columns or supports and slab-beam strips, bounded laterally by the centerline of panel on each side of the centerline of columns or supports.

13.7.2.3 — Columns or supports shall be assumed

COMMENTARY

obtained by linear interpolation. In such cases, the beams framing into the column will not account for all the shear force applied on the column. The remaining shear force will produce shear stresses in the slab around the column which must be checked in the same manner as for flat slabs, as required by 13.6.8.4. Sections 13.6.8.1 through 13.6.8.3 do not apply to the calculation of torsional moments on the beams. These moments must be based on the calculated flexural moments acting on the sides of the beam.

R13.6.9 — Factored moments in columns and walls

Eq. (13-4) refers to two adjoining spans, with one span longer than the other, with full dead load plus one-half live load applied on the longer span and only dead load applied on the shorter span.

Design and detailing of the reinforcement transferring the moment from the slab to the edge column is critical to both the performance and the safety of flat slabs or flat plates without edge beams or cantilever slabs. It is important that complete design details be shown on design drawings, such as concentration of reinforcement over the column by closer spacing or additional reinforcement.

R13.7 — Equivalent frame method

The Equivalent Frame Method involves the representation of the three-dimensional slab system by a series of two-dimensional frames which are then analyzed for loads acting in the plane of the frames. The negative and positive moments so determined at the critical design sections of the frame are distributed to the slab sections in accordance with 13.6.4 (column strips), 13.6.5 (beams), and 13.6.6 (middle strips). The equivalent frame method is based on studies reported in References 13.18, 13.19, and 13.20. Many of the details of the equivalent frame method given in the Commentary to ACI 318-89 have been removed in ACI 318-95. Computer programs based on the equivalent frame method are available. Most reinforced concrete design textbooks include details of the equivalent frame method.

R13.7.2 — Equivalent frame

Application of the equivalent frame to a regular structure is illustrated in Fig. R13.7.2. The three-dimensional building is divided into a series of two-dimensional frame bents (equivalent frames) centered on column or support centerlines with each frame extending the full height of the building. The width of each equivalent frame is bounded by the centerlines of the adjacent panels. The complete analysis of a slab system for a building consists of analyzing a series of equivalent (interior and exterior) frames spanning longitudinally and transversely through the building.

CODE

to be attached to slab-beam strips by torsional members (see 13.7.5) transverse to the direction of the span for which moments are being determined and extending to bounding lateral panel centerlines on each side of a column.

13.7.2.4 — Frames adjacent and parallel to an edge shall be bounded by that edge and the centerline of adjacent panel.

13.7.2.5 — Analysis of each equivalent frame in its entirety shall be permitted. Alternatively for gravity loading, a separate analysis of each floor or roof with far ends of columns considered fixed shall be permitted.

13.7.2.6 — Where slab-beams are analyzed separately, determination of moment at a given support assuming that the slab-beam is fixed at any support two panels distant therefrom shall be permitted, provided the slab continues beyond that point.

13.7.3 — Slab-beams

13.7.3.1—Determination of the moment of inertia of slab-beams at any cross section outside of joints or column capitals using the gross area of concrete shall be permitted.

13.7.3.2 — Variation in moment of inertia along axis of slab-beams shall be taken into account.

13.7.3.3 — Moment of inertia of slab-beams from center of column to face of column, bracket, or capital shall be assumed equal to the moment of inertia of the slab-beam at face of column, bracket, or capital divided by the quantity $(1 - c_2/\ell_2)^2$ where c_2 and ℓ_2 are measured transverse to the direction of the span for which moments are being determined.

13.7.4 — Columns

13.7.4.1 — Determination of the moment of inertia of columns at any cross section outside of joints or column capitals using the gross area of concrete shall be permitted.

COMMENTARY

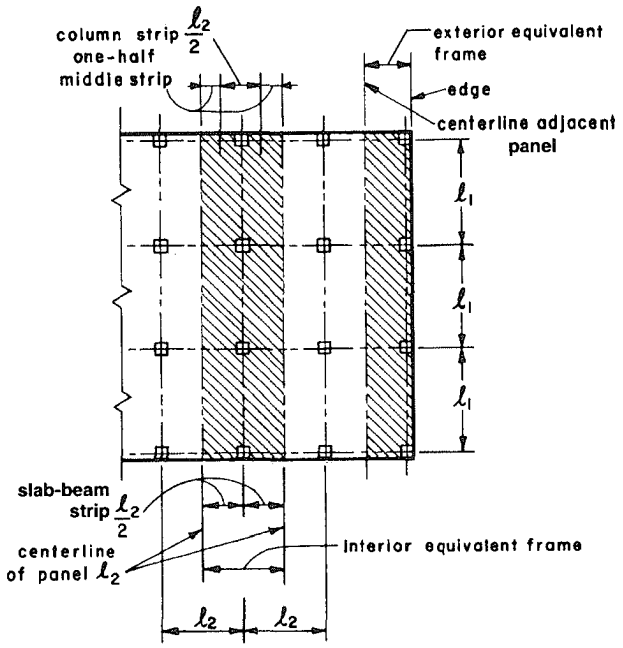

Fig. R13.7.2—Definitions of equivalent frame

The equivalent frame comprises three parts: (1) the horizontal slab strip, including any beams spanning in the direction of the frame, (2) the columns or other vertical supporting members, extending above and below the slab and, (3) the elements of the structure that provide moment transfer between the horizontal and vertical members.

R13.7.3 — Slab-beams

R13.7.3.3 — A support is defined as a column, capital, bracket, or wall. Note that a beam is not considered a support member for the equivalent frame.

R13.7.4 — Columns

Column stiffness is based on the length of the column from middepth of slab above to middepth of slab below. Column moment of inertia is computed on the basis of its cross section, taking into account the increase in stiffness provided by the capital, if any.

CODE

13.7.4.2 — Variation in moment of inertia along axis of columns shall be taken into account.

13.7.4.3 — Moment of inertia of columns from top to bottom of the slab-beam at a joint shall be assumed infinite.

COMMENTARY

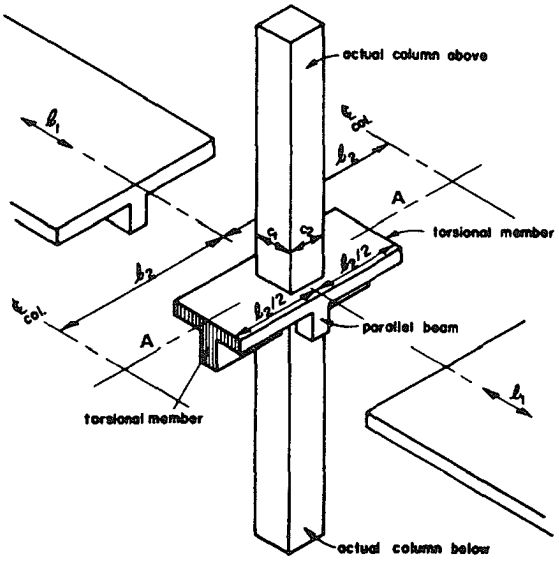

Fig. R13.7.4—Equivalent column (column plus torsional members)

When slab-beams are analyzed separately for gravity loads, the concept of an equivalent column, combining the stiffness of the slab-beam and torsional member into a composite element, is used. The column flexibility is modified to account for the torsional flexibility of the slab-to-column connection which reduces its efficiency for transmission of moments. The equivalent column consists of the actual columns above and below the slab-beam plus "attached" torsional members on each side of the columns extending to the centerline of the adjacent panels as shown in Fig. R13.7.4.

13.7.5 — Torsional members

13.7.5.1 — Torsional members (see 13.7.2.3) shall be assumed to have a constant cross section throughout their length consisting of the largest of

(a) A portion of slab having a width equal to that of the column, bracket, or capital in the direction of the span for which moments are being determined, or

(b) For monolithic or fully composite construction, the portion of slab specified in (a) plus that part of the transverse beam above and below the slab, and

(c) The transverse beam as defined in 13.2.4.

13.7.5.2 — Where beams frame into columns in the direction of the span for which moments are being determined, the torsional stiffness shall be multiplied by the ratio of moment of inertia of slab with such beam to moment of inertia of slab without such beam.

R13.7.5 — Torsional members

Computation of the stiffness of the torsional member requires several simplifying assumptions. If no beam frames into the column, a portion of the slab equal to the width of the column or capital is assumed as the effective beam. If a beam frames into the column, T-beam or L-beam action is assumed, with the flanges extending on each side of the beam a distance equal to the projection of the beam above or below the slab but not greater than four times the thickness of the slab. Furthermore, it is assumed that no torsional rotation occurs in the beam over the width of the support.

The member sections to be used for calculating the torsional stiffness are defined in 13.7.5.1. In the 1989 code, Eq. (13-6) specified the stiffness coefficient K_t of the torsional members. The approximate expression for K_t has been moved to the commentary and the expression for the torsional constant (Eq. 13-7 in the 1989 code) is now defined in 13.0.

Studies of three-dimensional analyses of various slab configurations suggest that a reasonable value of the torsional

CODE

COMMENTARY

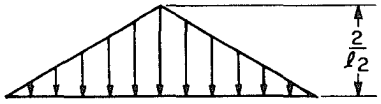

Fig. R13.7.5—Distribution of unit twisting moment along column centerline AA shown in Fig. R13.7.4

stiffness can be obtained by assuming a moment distribution along the torsional member that varies linearly from a maximum at the center of the column to zero at the middle of the panel. The assumed distribution of unit twisting moment along the column centerline is shown in Fig. R13.7.5.

An approximate expression for the stiffness of the torsional member, based on the results of three-dimensional analyses of various slab configurations (References 13.18, 13.19, and 13.20) is given below as

$$K_t = \sum \frac{9E_{cs}C}{\ell_2\left(1-\frac{c_2}{\ell_2}\right)^3}$$

where an expression for C is given in 13.0.

13.7.6 — Arrangement of live load

13.7.6.1 — When loading pattern is known, the equivalent frame shall be analyzed for that load.

13.7.6.2 — When live load is variable but does not exceed three-quarters of the dead load, or the nature of live load is such that all panels will be loaded simultaneously, it shall be permitted to assume that maximum factored moments occur at all sections with full factored live load on entire slab system.

13.7.6.3 — For loading conditions other than those defined in 13.7.6.2, it shall be permitted to assume that maximum positive factored moment near midspan of a panel occurs with three-quarters of the full factored live load on the panel and on alternate panels; and it shall be permitted to assume that maximum negative factored moment in the slab at a support occurs with three-quarters of the full live load on adjacent panels only.

13.7.6.4 — Factored moments shall be taken not less than those occurring with full factored live load on all panels.

R13.7.6 — Arrangement of live load

The use of only three-quarters of the full factored live load for maximum moment loading patterns is based on the fact that maximum negative and maximum positive live load moments cannot occur simultaneously and that redistribution of maximum moments is thus possible before failure occurs. This procedure, in effect, permits some local overstress under the full factored live load if it is distributed in the prescribed manner, but still ensures that the ultimate capacity of the slab system after redistribution of moment is not less than that required to carry the full factored dead and live loads on all panels.

13.7.7 — Factored moments

13.7.7.1 — At interior supports, critical section for negative factored moment (in both column and middle

R13.7.7 — Factored moments

R13.7.7.1-R13.7.7.3 — These sections correct the negative factored moments to the face of the supports. The cor-

CODE

strips) shall be taken at face of rectilinear supports, but not greater than $0.175\ell_1$ from center of a column.

13.7.7.2 — At exterior supports provided with brackets or capitals, critical section for negative factored moment in the span perpendicular to an edge shall be taken at a distance from face of supporting element not greater than one-half the projection of bracket or capital beyond face of supporting element.

13.7.7.3 — Circular or regular polygon shaped supports shall be treated as square supports with the same area for location of critical section for negative design moment.

13.7.7.4 — When slab systems within limitations of 13.6.1 are analyzed by the Equivalent Frame Method, it shall be permitted to reduce the resulting computed moments in such proportion that the absolute sum of the positive and average negative moments used in design need not exceed the value obtained from Eq. (13-3).

13.7.7.5 — Distribution of moments at critical sections across the slab-beam strip of each frame to column strips, beams, and middle strips as provided in 13.6.4, 13.6.5, and 13.6.6 shall be permitted if the requirement of 13.6.1.6 is satisfied.

COMMENTARY

rection is modified at an exterior support in order not to result in undue reductions in the exterior negative moment. Fig. R13.6.2.5 illustrates several equivalent rectangular supports for use in establishing faces of supports for design with nonrectangular supports.

R13.7.7.4 — This section is a holdover from many previous codes and is based on the principle that if two different methods are prescribed to obtain a particular answer, the code should not require a value greater than the least acceptable value. Due to the long satisfactory experience with designs having total factored static moments not exceeding those given by Eq. (13-3) it is considered that these values are satisfactory for design when applicable limitations are met.

CHAPTER 14 — WALLS

CODE

14.0 — Notation

A_g = gross area of section, in.^{2}
f_c' = specified compressive strength of concrete, psi
h = overall thickness of member, in.
k = effective length factor
ℓ_c = vertical distance between supports, in.
P_{nw} = nominal axial load strength of wall designed by 14.4
ϕ = strength reduction factor. See 9.3

14.1 — Scope

14.1.1 — Provisions of Chapter 14 shall apply for design of walls subjected to axial load, with or without flexure.

14.1.2 — Cantilever retaining walls are designed according to flexural design provisions of Chapter 10 with minimum horizontal reinforcement according to 14.3.3.

14.2 — General

14.2.1 — Walls shall be designed for eccentric loads and any lateral or other loads to which they are subjected.

14.2.2 — Walls subject to axial loads shall be designed in accordance with 14.2, 14.3, and either 14.4 or 14.5.

14.2.3 — Design for shear shall be in accordance with 11.10.

14.2.4 — Unless demonstrated by a detailed analysis, horizontal length of wall to be considered as effective for each concentrated load shall not exceed center-to-center distance between loads, nor width of bearing plus four times the wall thickness.

14.2.5 — Compression members built integrally with walls shall conform to 10.8.2.

14.2.6 — Walls shall be anchored to intersecting elements such as floors and roofs, or to columns, pilasters, buttresses, and intersecting walls, and to footings.

COMMENTARY

R14.1 — Scope

Chapter 14 applies generally to walls as vertical load carrying members. Cantilever retaining walls are designed according to the flexural design provisions of Chapter 10. Walls designed to resist shear forces, such as shearwalls, shall be designed in accordance with Chapter 14 and 11.10 as applicable.

In the 1977 code, walls could be designed according to Chapter 14 or 10.15. In the 1983 code these two were combined in Chapter 14.

R14.2 — General

Walls must be designed to resist all loads to which they are subjected, including eccentric axial loads and lateral forces. Design must be carried out in accordance with 14.4 unless the wall meets the requirements of 14.5.1.

In either case, walls may be designed using either the strength design method of the code or the alternate design method of Appendix A in accordance with A.6.3.

CODE

14.2.7 — Quantity of reinforcement and limits of thickness required by 14.3 and 14.5 shall be permitted to be waived where structural analysis shows adequate strength and stability.

14.2.8 — Transfer of force to footing at base of wall shall be in accordance with 15.8.

14.3 — Minimum reinforcement

14.3.1 — Minimum vertical and horizontal reinforcement shall be in accordance with 14.3.2 and 14.3.3 unless a greater amount is required for shear by 11.10.8 and 11.10.9.

14.3.2 — Minimum ratio of vertical reinforcement area to gross concrete area shall be:

(a) 0.0012 for deformed bars not larger than No. 5 with a specified yield strength not less than 60,000 psi, or

(b) 0.0015 for other deformed bars, or

(c) 0.0012 for welded wire fabric (plain or deformed) not larger than W31 or D31.

14.3.3 — Minimum ratio of horizontal reinforcement area to gross concrete area shall be:

(a) 0.0020 for deformed bars not larger than No. 5 with a specified yield strength not less than 60,000 psi, or

(b) 0.0025 for other deformed bars, or

(c) 0.0020 for welded wire fabric (plain or deformed) not larger than W31 or D31.

14.3.4 — Walls more than 10 in. thick, except basement walls, shall have reinforcement for each direction placed in two layers parallel with faces of wall in accordance with the following:

(a) One layer consisting of not less than one-half and not more than two-thirds of total reinforcement required for each direction shall be placed not less than 2 in. nor more than one-third the thickness of wall from exterior surface.

(b) The other layer, consisting of the balance of required reinforcement in that direction, shall be placed not less than $^3/_4$ in. nor more than one-third the thickness of wall from interior surface.

COMMENTARY

R14.3 — Minimum reinforcement

The requirements of 14.3 are similar to those in previous ACI Building Codes. These apply to walls designed according to 14.4 or 14.5. For walls resisting horizontal shear forces in the plane of the wall, reinforcement designed according to 11.10.9.2 and 11.10.9.4 may exceed the minimum reinforcement specified in 14.3.

CODE

14.3.5 — Vertical and horizontal reinforcement shall not be spaced farther apart than three times the wall thickness, nor 18 in.

14.3.6 — Vertical reinforcement need not be enclosed by lateral ties if vertical reinforcement area is not greater than 0.01 times gross concrete area, or where vertical reinforcement is not required as compression reinforcement.

14.3.7 — In addition to the minimum reinforcement required by 14.3.1, not less than two No. 5 bars shall be provided around all window and door openings. Such bars shall be extended to develop the bar beyond the corners of the openings but not less than 24 in.

14.4 — Walls designed as compression members

Except as provided in 14.5, walls subject to axial load or combined flexure and axial load shall be designed as compression members in accordance with provisions of 10.2, 10.3, 10.10, 10.11, 10.12, 10.13, 10.14, 10.17, 14.2, and 14.3.

14.5 — Empirical design method

14.5.1 — Walls of solid rectangular cross section shall be permitted to be designed by the empirical provisions of 14.5 if resultant of all factored loads is located within the middle third of the overall thickness of wall and all limits of 14.2, 14.3, and 14.5 are satisfied.

14.5.2 — Design axial load strength ϕP_{nw} of a wall satisfying limitations of 14.5.1 shall be computed by Eq. (14-1) unless designed in accordance with 14.4.

$$\phi P_{nw} = 0.55\phi f_c' A_g\left[1-\left(\frac{k\ell_c}{32h}\right)^2\right] \qquad (14\text{-}1)$$

where ϕ = **0.70** and effective length factor k shall be:

For walls braced top and bottom against lateral translation and

(a) restrained against rotation at one or both ends (top and/or bottom) 0.8

(b) unrestrained against rotation at both ends..... 1.0

For walls not braced against lateral translation..... 2.0

COMMENTARY

R14.5 — Empirical design method

The empirical design method applies only to solid rectangular cross sections. All other shapes must be designed according to 14.4.

Eccentric loads and lateral forces are used to determine the total eccentricity of the factored axial load P_u. When the resultant load for all applicable load combinations falls within the middle third of the wall thickness (eccentricity not greater than $h/6$) at all sections along the length of the undeformed wall, the empirical design method may be used. The design is then carried out considering P_u as the concentric load. The factored axial load P_u must be less than or equal to the design axial load strength ϕP_{nw} computed by Eq. (14-1), $P_u \le \phi P_{nw}$.

With the 1980 supplement, (Eq. 14-1) was revised to reflect the general range of end conditions encountered in wall designs. The wall strength equation in the 1977 code edition was based on the assumption of a wall with top and bottom fixed against lateral movement, and with moment restraint at one end corresponding to an effective length factor between 0.8 and 0.9. Axial load strength values determined from the original equation were unconservative when compared to test results[14.1] for walls with pinned conditions at both ends as can occur in some precast and tilt-up applications, or when the top of the wall is not effectively braced against translation, as occurs with many free-standing walls

CODE

COMMENTARY

or in large structures where significant roof diaphragm deflections occur due to wind and seismic loads. Eq. (14-1) gives the same results as the 1977 code for walls braced against translation and with reasonable base restraint against rotation.[14.2] Values of effective vertical length factors k are given for commonly occurring wall end conditions. The end condition "restrained against rotation" required for a k-factor of 0.8 implies attachment to a member having flexural stiffness EI/ℓ at least as large as that of the wall.

The slenderness portion of Eq. (14-1) results in relatively comparable strengths by either 14.3 or 14.4 for members loaded at the middle third of the thickness with different braced and restrained end conditions. See Fig. R14.5.

14.5.3 — Minimum thickness of walls designed by empirical design method

14.5.3.1 — Thickness of bearing walls shall not be less than $^1/_{25}$ the supported height or length, whichever is shorter, nor less than 4 in.

14.5.3.2 — Thickness of exterior basement walls and foundation walls shall not be less than $7^1/_2$ in.

R14.5.3 — Minimum thickness of walls designed by empirical design method

The minimum thickness requirements need not be applied to walls designed according to 14.4.

14.6 — Nonbearing walls

14.6.1 — Thickness of nonbearing walls shall not be less than 4 in., nor less than $^1/_{30}$ the least distance between members that provide lateral support.

14.7 — Walls as grade beams

14.7.1 — Walls designed as grade beams shall have top and bottom reinforcement as required for moment in accordance with provisions of 10.2 through 10.7. Design for shear shall be in accordance with provisions of Chapter 11.

14.7.2 — Portions of grade beam walls exposed above grade shall also meet requirements of 14.3.

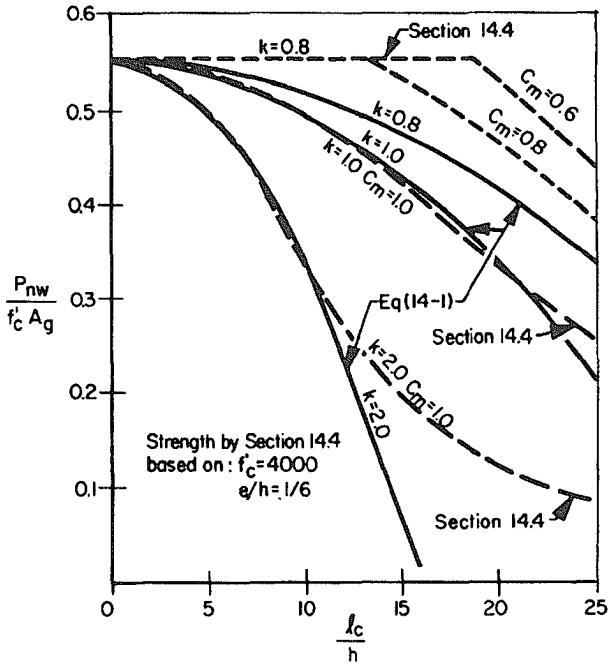

Fig. R14.5—Empirical design of walls, Eq. (14-1), versus 14.4

CHAPTER 15 — FOOTINGS

CODE

COMMENTARY

15.0 — Notation

A_g = gross area of section, in.^{2}
d_p = diameter of pile at footing base
β = ratio of long side to short side of footing

15.1 — Scope

15.1.1 — Provisions of Chapter 15 shall apply for design of isolated footings and, where applicable, to combined footings and mats.

15.1.2 — Additional requirements for design of combined footings and mats are given in 15.10.

R15.1 — Scope

While the provisions of Chapter 15 apply to isolated footings supporting a single column or wall, most of the provisions are generally applicable to combined footings and mats supporting several columns or walls or a combination thereof.[15.1,15.2]

15.2 — Loads and reactions

15.2.1 — Footings shall be proportioned to resist the factored loads and induced reactions, in accordance with the appropriate design requirements of this code and as provided in Chapter 15.

15.2.2 — Base area of footing or number and arrangement of piles shall be determined from unfactored forces and moments transmitted by footing to soil or piles and permissible soil pressure or permissible pile capacity selected through principles of soil mechanics.

15.2.3 — For footings on piles, computations for moments and shears may be based on the assumption that the reaction from any pile is concentrated at pile center.

R15.2 — Loads and reactions

Footings are required to be proportioned to sustain the applied factored loads and induced reactions which include axial loads, moments, and shears that have to be resisted at the base of the footing or pile cap.

After the permissible soil pressure or the permissible pile capacity has been determined by principles of soil mechanics and in accord with the general building code, the size of the base area of a footing on soil or the number and arrangement of the piles must be established on the basis of unfactored (service) loads (*D, L, W, E*, etc.) in whatever combination that will govern the design.

Only the computed end moments that exist at the base of a column (or pedestal) need be transferred to the footing; the minimum moment requirement for slenderness considerations given in 10.12.3.2 need not be considered for transfer of forces and moments to footings.

In cases in which eccentric loads or moments must be considered, the extreme soil pressure or pile reaction obtained from this loading must be within the permissible values. Similarly, the resultant reactions due to service loads combined with moments and/or shears caused by wind or earthquake loads must not exceed the increased values that may be permitted by the general building code.

To proportion a footing or pile cap for strength, the contact soil pressure or pile reaction due to the applied factored loading (see 8.1.1) must be determined. For a single concentrically loaded spread footing, the soil reaction q_s due to the factored loading is $q_s = U/A_f$ where U is the factored con-

CODE

COMMENTARY

centric load to be resisted by the footing, and A_f is the base area of the footing as determined by the principles stated previously using the unfactored loads and the permissible soil pressure.

It is important to note that q_s is only a calculated reaction to the factored loading, used to produce in the footing or pile cap the same required strength conditions regarding flexure, shear, and development of reinforcement as in any other member.

In the case of eccentric loading, load factors may cause eccentricities and reactions that are different from those obtained by unfactored loads.

When the alternate design method of Appendix A is used for design of footings, the soil bearing pressures or pile reactions are those caused by the service loads (without load factors). The permissible soil pressures or permissible pile reactions are equated directly with the applied service load pressures or reactions to determine base area of footing or number and arrangement of piles. When lateral loads due to wind or earthquake are included in the governing load combination for footings, advantage may be taken of the 25 percent reduction in required strength in accordance with Section A.2.2.

15.3 — Footings supporting circular or regular polygon shaped columns or pedestals

For location of critical sections for moment, shear, and development of reinforcement in footings, it shall be permitted to treat circular or regular polygon shaped concrete columns or pedestals as square members with the same area.

15.4 — Moment in footings

R15.4 — Moment in footings

15.4.1 — External moment on any section of a footing shall be determined by passing a vertical plane through the footing, and computing the moment of the forces acting over entire area of footing on one side of that vertical plane.

15.4.2 — Maximum factored moment for an isolated footing shall be computed as prescribed in 15.4.1 at critical sections located as follows:

(a) At face of column, pedestal, or wall, for footings supporting a concrete column, pedestal, or wall.

(b) Halfway between middle and edge of wall, for footings supporting a masonry wall.

CODE

(c) Halfway between face of column and edge of steel base plate, for footings supporting a column with steel base plate.

15.4.3 — In one-way footings, and two-way square footings, reinforcement shall be distributed uniformly across entire width of footing.

15.4.4 — In two-way rectangular footings, reinforcement shall be distributed as follows:

15.4.4.1 — Reinforcement in long direction shall be distributed uniformly across entire width of footing.

15.4.4.2 — For reinforcement in short direction, a portion of the total reinforcement given by Eq. (15-1) shall be distributed uniformly over a band width (centered on centerline of column or pedestal) equal to the length of short side of footing. Remainder of reinforcement required in short direction shall be distributed uniformly outside center band width of footing.

$$\frac{\text{Reinforcement in band width}}{\text{Total reinforcement in short direction}} = \frac{2}{(\beta + 1)} \qquad (15\text{-}1)$$

15.5 — Shear in footings

15.5.1 — Shear strength of footings shall be in accordance with 11.12.

15.5.2 — Location of critical section for shear in accordance with Chapter 11 shall be measured from face of column, pedestal, or wall, for footings supporting a column, pedestal, or wall. For footings supporting a column or pedestal with steel base plates, the critical section shall be measured from location defined in 15.4.2(c).

COMMENTARY

R15.4.4 — As in previous ACI Building Codes, the reinforcement in the short direction of rectangular footings must be distributed so that an area of steel given by Eq. (15-1) is provided in a band width equal to the length of the short side of the footing. The band width is centered about the column centerline.

The remaining reinforcement required in the short direction is to be distributed equally over the two segments outside the band width, one-half to each segment.

R15.5 — Shear in footings

R15.5.1 and R15.5.2 — The shear strength of footings must be determined for the more severe condition of 11.12.1.1 or 11.12.1.2. The critical section for shear is "measured" from the face of supported member (column, pedestal, or wall), except for supported members on steel base plates.

Computation of shear requires that the soil bearing pressure q_s be obtained from the factored loads and the design be in accordance with the appropriate equations of Chapter 11.

Where necessary, shear around individual piles may be investigated in accordance with 11.12.1.2. If shear perime-

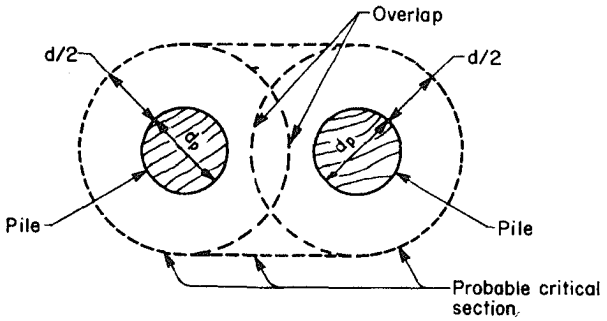

Fig. R15.5—Modified critical section for shear with overlapping critical perimeters

CODE

15.5.3 — Computation of shear on any section through a footing supported on piles shall be in accordance with the following:

15.5.3.1 — Entire reaction from any pile whose center is located $d_p/2$ or more outside the section shall be considered as producing shear on that section.

15.5.3.2 — Reaction from any pile whose center is located $d_p/2$ or more inside the section shall be considered as producing no shear on that section.

15.5.3.3 — For intermediate positions of pile center, the portion of the pile reaction to be considered as producing shear on the section shall be based on straight-line interpolation between full value at $d_p/2$ outside the section and zero value at $d_p/2$ inside the section.

15.6 — Development of reinforcement in footings

15.6.1 — Development of reinforcement in footings shall be in accordance with Chapter 12.

15.6.2 — Calculated tension or compression in reinforcement at each section shall be developed on each side of that section by embedment length, hook (tension only) or mechanical device, or a combination thereof.

15.6.3 — Critical sections for development of reinforcement shall be assumed at the same locations as defined in 15.4.2 for maximum factored moment, and at all other vertical planes where changes of section or reinforcement occur. See also 12.10.6.

15.7 — Minimum footing depth

Depth of footing above bottom reinforcement shall not be less than 6 in. for footings on soil, nor less than 12 in. for footings on piles.

15.8 — Transfer of force at base of column, wall, or reinforced pedestal

15.8.1 — Forces and moments at base of column, wall, or pedestal shall be transferred to supporting pedestal or footing by bearing on concrete and by reinforcement, dowels, and mechanical connectors.

COMMENTARY

ters overlap, the critical perimeter b_o should be taken as that portion of the smallest envelope of individual shear perimeter which will actually resist the critical shear for the group under consideration. One such situation is illustrated in Fig. R15.5.

R15.5.3 — When piles are located inside the critical sections d or $d/2$ from face of column, for one-way or two-way shear, respectively, an upper limit on the shear strength at a section adjacent to the face of the column should be considered. The CRSI Handbook[15.3] offers guidance for this situation.

R15.8 — Transfer of force at base of column, wall, or reinforced pedestal

Section 15.8 provides the specific requirements for force transfer from a column, wall, or pedestal (supported member) to a pedestal or footing (supporting member). Force transfer must be by bearing on concrete (compressive force

CODE

COMMENTARY

only) and by reinforcement (tensile or compressive force). Reinforcement may consist of extended longitudinal bars, dowels, anchor bolts, or suitable mechanical connectors.

The requirements of 15.8.1 apply to both cast-in-place construction and precast construction. Additional requirements for cast-in-place construction are given in 15.8.2. Section 15.8.3 gives additional requirements for precast construction.

15.8.1.1 — Bearing on concrete at contact surface between supported and supporting member shall not exceed concrete bearing strength for either surface as given by 10.17.

R15.8.1.1 — Compressive force may be transmitted to a supporting pedestal or footing by bearing on concrete. For strength design, unit bearing strength on the actual loaded area will be equal to $0.85\phi f_c'$ (where $\phi = 0.7$), if the loaded area is equal to the area on which it is supported.

In the common case of a column bearing on a footing larger than the column, bearing strength must be checked at the base of the column and the top of the footing. Strength in the lower part of the column must be checked since the column reinforcement cannot be considered effective near the column base because the force in the reinforcement is not developed for some distance above the base, unless dowels are provided, or the column reinforcement is extended into the footing. The unit bearing stress on the column will normally be $0.85\ \phi f_c'$ (with $\phi = 0.7$, this becomes $0.6f_c'$). The permissible bearing strength on the footing may be increased in accordance with 10.17 and will usually be two times $0.85\phi f_c'$. The compressive force which exceeds that developed by the permissible bearing strength at the base of the column or at the top of the footing must be carried by dowels or extended longitudinal bars.

For the alternate design method of Appendix A, permissible bearing stresses are limited to 50 percent of the values in 10.17.

15.8.1.2 — Reinforcement, dowels, or mechanical connectors between supported and supporting members shall be adequate to transfer:

(a) all compressive force that exceeds concrete bearing strength of either member,

(b) any computed tensile force across interface.

In addition, reinforcement, dowels or mechanical connectors shall satisfy 15.8.2 or 15.8.3.

R15.8.1.2 — All tensile forces, whether created by uplift, moment, or other means, must be transferred to supporting pedestal or footing entirely by reinforcement or suitable mechanical connectors. Generally, mechanical connections would be used only in precast construction.

15.8.1.3 — If calculated moments are transferred to supporting pedestal or footing, reinforcement, dowels or mechanical connectors shall be adequate to satisfy 12.17.

R15.8.1.3 — If computed moments are transferred from the column to the footing, the concrete in the compression zone of the column will generally be stressed to $0.85f_c'$ under factored load conditions and, as a result, all the reinforcement will generally have to be doweled into the footing.

CODE

15.8.1.4 — Lateral forces shall be transferred to supporting pedestal or footing in accordance with shear-friction provisions of 11.7, or by other appropriate means.

15.8.2 — In cast-in-place construction, reinforcement required to satisfy 15.8.1 shall be provided either by extending longitudinal bars into supporting pedestal or footing, or by dowels.

15.8.2.1 — For cast-in-place columns and pedestals, area of reinforcement across interface shall be not less than 0.005 times gross area of supported member.

15.8.2.2 — For cast-in-place walls, area of reinforcement across interface shall be not less than minimum vertical reinforcement given in 14.3.2.

15.8.2.3 — At footings, No. 14 and No. 18 longitudinal bars, in compression only, may be lap spliced with dowels to provide reinforcement required to satisfy 15.8.1. Dowels shall not be larger than No. 11 bar and shall extend into supported member a distance not less than the development length of No. 14 or No. 18 bars or the splice length of the dowels, whichever is greater, and into the footing a distance not less than the development length of the dowels.

15.8.2.4 — If a pinned or rocker connection is provided in cast-in-place construction, connection shall conform to 15.8.1 and 15.8.3.

15.8.3 — In precast construction, anchor bolts or suitable mechanical connectors shall be permitted for satisfying 15.8.1.

15.8.3.1 — Connection between precast columns or pedestals and supporting members shall meet the requirements of 16.5.1.3(a).

COMMENTARY

R15.8.1.4 — The shear-friction method given in 11.7 may be used to check for transfer of lateral forces to supporting pedestal or footing. Shear keys may be used, provided that the reinforcement crossing the joint satisfies 15.8.2.1, 15.8.3.1, and the shear-friction requirements of 11.7. In precast construction, resistance to lateral forces may be provided by shear-friction, shear keys, or mechanical devices.

R15.8.2.1 and R15.8.2.2 — A minimum amount of reinforcement is required between all supported and supporting members to ensure ductile behavior. The code does not require that all bars in a column be extended through and be anchored into a footing. However, reinforcement with an area of 0.005 times the column area or an equal area of properly spliced dowels must extend into the footing with proper anchorage. This reinforcement is required to provide a degree of structural integrity during the construction stage and during the life of the structure.

R15.8.2.3 — Lap splices of No. 14 and No. 18 longitudinal bars in compression only to dowels from a footing are specifically permitted in 15.8.2.3. The dowel bars must be No. 11 or smaller in size. The dowel lap splice length must meet the larger of the two criteria: (a) be able to transfer the stress in the No. 14 and No. 18 bars, and (b) fully develop the stress in the dowels as a splice.

This provision is an exception to 12.14.2.1, which prohibits lap splicing of No. 14 and No. 18 bars. This exception results from many years of successful experience with the lap splicing of these large column bars with footing dowels of the smaller size. The reason for the restriction on dowel bar size is recognition of the anchorage length problem of the large bars, and to encourage use of the smaller size dowels with probable resulting economies in footing depths. A similar exception is allowed for compression splices between different size bars in 12.16.2.

R15.8.3.1 and R15.8.3.2 — For cast-in-place columns, 15.8.2.1 requires a minimum area of reinforcement equal to $0.005A_g$ across the column-footing interface to provide

CODE

15.8.3.2 — Connection between precast walls and supporting members shall meet the requirements of 16.5.1.3(b) and (c).

COMMENTARY

some degree of structural integrity. For precast columns this requirement is expressed in terms of an equivalent tensile force which must be transferred. Thus, across the joint, $A_s f_y = 200A_g$ [see 16.5.1.3(a)]. The minimum tensile strength required for precast wall-to-footing connection [see 16.5.1.3(b)] is somewhat less than that required for columns, since an overload would be distributed laterally and a sudden failure would be less likely. Since the tensile strength values of 16.5.1.3 have been arbitrarily chosen, it is not necessary to include a strength reduction factor ϕ for these calculations.

15.8.3.3 — Anchor bolts and mechanical connectors shall be designed to reach their design strength prior to anchorage failure or failure of surrounding concrete.

R15.8.3.3 — Anchor bolts and mechanical connectors must be designed to reach their design strength before the bolt or connector yields, slips, or pulls out of the concrete.

15.9 — Sloped or stepped footings

15.9.1 — In sloped or stepped footings, angle of slope or depth and location of steps shall be such that design requirements are satisfied at every section. (See also 12.10.6.)

15.9.2 — Sloped or stepped footings designed as a unit shall be constructed to assure action as a unit.

15.10 — Combined footings and mats

15.10.1 — Footings supporting more than one column, pedestal, or wall (combined footings or mats) shall be proportioned to resist the factored loads and induced reactions, in accordance with appropriate design requirements of this code.

15.10.2 — The Direct Design Method of Chapter 13 shall not be used for design of combined footings and mats.

15.10.3 — Distribution of soil pressure under combined footings and mats shall be consistent with properties of the soil and the structure and with established principles of soil mechanics.

R15.10 — Combined footings and mats

R15.10.1 — Any reasonable assumption with respect to the distribution of soil pressure or pile reactions can be used as long as it is consistent with the type of structure and the properties of the soil, and conforms with established principles of soil mechanics (see 15.1). Similarly, as prescribed in 15.2.2 for isolated footings, the base area or pile arrangement of combined footings and mats should be determined using the unfactored forces and/or moments transmitted by the footing to the soil, considering permissible soil pressures and pile reactions.

Design methods using factored loads and strength reduction factors ϕ can be applied to combined footings or mats, regardless of the soil pressure distribution.

Detailed recommendations for design of combined footings and mats are given in **"Suggested Design Procedures for Combined Footings and Mats"** reported by ACI Committee 336.[15.1] See also Reference 15.2.

Notes

CHAPTER 16 — PRECAST CONCRETE

CODE

COMMENTARY

16.0 — Notation

A_g = gross area of column, in.^{2}
ℓ = clear span, in.

16.1 — Scope

16.1.1 — All provisions of this code, not specifically excluded and not in conflict with the provisions of Chapter 16, shall apply to structures incorporating precast concrete structural members.

R16.1 — Scope

R16.1.1 — See 2.1 for definition of precast concrete.

Design and construction requirements for precast concrete structural members differ in some respects from those for cast-in-place concrete structural members and these differences are addressed in this chapter. Where provisions for cast-in-place concrete apply equally to precast concrete, they have not been repeated. Similarly, items related to composite concrete in Chapter 17 and to prestressed concrete in Chapter 18 that apply to precast concrete are not restated.

More detailed recommendations concerning precast concrete are given in References 16.1 through 16.7. Tilt-up concrete construction is a form of precast concrete. It is recommended that Reference 16.8 be reviewed for tilt-up structures.

16.2 — General

16.2.1 — Design of precast members and connections shall include loading and restraint conditions from initial fabrication to end use in the structure, including form removal, storage, transportation, and erection.

R16.2 — General

R16.2.1 — Stresses developed in precast members during the period from casting to final connection may be greater than the service load stresses. Handling procedures may cause undesirable deformations. Hence, care must be given to the methods of storing, transporting, and erecting precast members so that performance at service loads and strength under factored loads meet code requirements.

16.2.2 — When precast members are incorporated into a structural system, the forces and deformations occurring in and adjacent to connections shall be included in the design.

R16.2.2 — The structural behavior of precast members may differ substantially from that of similar members that are cast-in-place. Design of connections to minimize or transmit forces due to shrinkage, creep, temperature change, elastic deformation, differential settlement, wind, and earthquake require special consideration in precast construction.

16.2.3 — Tolerances for both precast members and interfacing members shall be specified. Design of precast members and connections shall include the effects of these tolerances.

R16.2.3 — Design of precast members and connections is particularly sensitive to tolerances on the dimensions of individual members and on their position in the structure. To prevent misunderstanding, the tolerances used in design should be specified in the contract documents. The designer may specify the tolerance standard assumed in design. It is especially important to specify any deviations from accepted standards.

CODE

COMMENTARY

The tolerances required by 7.5 are considered to be a minimum acceptable standard for reinforcement in precast concrete. The designer should refer to publications of the Precast/Prestressed Concrete Institute (References 16.9, 16.10, 16.11) for guidance on industry established standard product and erection tolerances. Added guidance is given in Reference 16.12.

16.2.4 — In addition to the requirements for drawings and specifications in 1.2, the following shall be included in either the contract documents or shop drawings:

(a) Details of reinforcement, inserts and lifting devices required to resist temporary loads from handling, storage, transportation, and erection.

(b) Required concrete strength at stated ages or stages of construction.

R16.2.4 — The additional requirements may be included in either contract documents or shop drawings depending on the assignment of responsibility for design.

16.3 — Distribution of forces among members

R16.3 — Distribution of forces among members

16.3.1 — Distribution of forces that are perpendicular to the plane of members shall be established by analysis or by test.

R16.3.1 — Concentrated point and line loads can be distributed among members provided they have sufficient torsional stiffness and that shear can be transferred across joints. Torsionally stiff members such as hollow-core or solid slabs have more favorable load distribution properties than do torsionally flexible members such as double tees with thin flanges. The actual distribution of the load depends on many factors discussed in detail in References 16.13 through 16.19. Large openings can cause significant changes in distribution of forces.

16.3.2 — Where the system behavior requires in-plane forces to be transferred between the members of a precast floor or wall system, the following shall apply:

16.3.2.1 — In-plane force paths shall be continuous through both connections and members.

16.3.2.2 — Where tension forces occur, a continuous path of steel or steel reinforcement shall be provided.

R16.3.2 — In-plane forces result primarily from diaphragm action in floors and roofs, causing tension or compression in the chords and shear in the body of the diaphragm. A continuous path of steel and/or steel reinforcement, using lap splices or positive mechanical connections, must be provided to carry the tension, whereas the shear and compression may be carried by the net concrete section. A continuous path of steel through a connection may include bolts, weld plates, headed studs or other steel devices. Tension forces in the connections are to be transferred to the primary reinforcement in the members.

In-plane forces in precast wall systems result primarily from diaphragm reactions and external lateral loads.

Connection details should provide for the forces and deformations due to shrinkage, creep, and thermal effects. Connection details may be selected to accommodate volume changes and rotations caused by temperature gradients and long-term deflections. When these effects are restrained, connections and members should be designed to provide adequate strength and ductility.

CODE

COMMENTARY

16.4 — Member design

R16.4 — Member design

16.4.1 — In one-way precast floor and roof slabs and in one-way precast, prestressed wall panels, all not wider than 12 ft, and where members are not mechanically connected to cause restraint in the transverse direction, the shrinkage and temperature reinforcement requirements of 7.12 in the direction normal to the flexural reinforcement shall be permitted to be waived. This waiver shall not apply to members which require reinforcement to resist transverse flexural stresses.

R16.4.1 — For prestressed concrete members, not wider than 12 ft, such as hollow-core slabs, solid slabs, or slabs with closely spaced ribs, there is usually no need to provide transverse reinforcement to withstand shrinkage and temperature stresses in the short direction. This is generally true also for nonprestressed floor and roof slabs. The 12 ft width is less than that in which shrinkage and temperature stresses can build up to a magnitude requiring transverse reinforcement. In addition, much of the shrinkage occurs before the members are tied into the structure. Once in the final structure, the members are usually not as rigidly connected transversely as monolithic concrete, thus, the transverse restraint stresses due to both shrinkage and temperature change are significantly reduced.

The waiver does not apply, for example, to members such as single and double tees with thin, wide flanges.

16.4.2 — For precast, nonprestressed walls the reinforcement shall be designed in accordance with the provisions of Chapters 10 or 14 except that the area of horizontal and vertical reinforcement shall each be not less than 0.001 times the gross cross-sectional area of the wall panel. Spacing of reinforcement shall not exceed 5 times the wall thickness or 30 in. for interior walls or 18 in. for exterior walls.

R16.4.2 — This minimum area of wall reinforcement, in lieu of the minimum values in 14.3, has generally been used for many years with no problems, and is recommended by the Precast/Prestressed Concrete Institute [16.4] and the Canadian building code.[16.20] The provisions for reduced minimum reinforcement and greater spacing recognize that precast wall panels have very little restraint at their edges during early stages of curing and, therefore, develop less shrinkage stress than comparable cast-in-place walls.

16.5 — Structural integrity

R16.5 — Structural integrity

16.5.1 — Except where the provisions of 16.5.2 govern, the following minimum provisions for structural integrity shall apply to all precast concrete structures:

R16.5.1 — The general provisions of 7.13.3 apply to all precast concrete structures. Sections 16.5.1 and 16.5.2 give minimum requirements to satisfy 7.13.3. It is not intended that these minimum requirements override other applicable provisions of the code for design of precast concrete structures.

The overall integrity of a structure can be substantially enhanced by minor changes in the amount, location, and detailing of member reinforcement and in the detailing of connection hardware.

16.5.1.1 — Longitudinal and transverse ties required by 7.13.3 shall connect members to a lateral load resisting system.

R16.5.1.1 — Individual members may be connected into this lateral load resisting system by alternative methods. For example, a load-bearing spandrel could be connected to a diaphragm (part of the lateral load resisting system). Structural integrity could be achieved by connecting the spandrel into all or a portion of the deck members forming the diaphragm. Alternatively, the spandrel could be connected only to its supporting columns, which in turn must be connected to the diaphragm.

CODE

16.5.1.2 — Where precast elements form floor or roof diaphragms, the connections between diaphragm and those members being laterally supported shall have a nominal tensile strength capable of resisting not less than 300 lb per lin ft.

16.5.1.3 — Vertical tension tie requirements of 7.13.3 shall apply to all vertical structural members, except cladding, and shall be achieved by providing connections at horizontal joints in accordance with the following:

(a) Precast columns shall have a nominal strength in tension not less than **200** A_g in pounds. For columns with a larger cross section than required by consideration of loading, a reduced effective area A_g, based on cross section required but not less than one-half the total area, shall be permitted.

(b) Precast wall panels shall have a minimum of two ties per panel, with a nominal tensile strength not less than 10,000 lb per tie.

(c) When design forces result in no tension at the base, the ties required by 16.5.1.3(b) shall be permitted to be anchored into an appropriately reinforced concrete floor slab on grade.

16.5.1.4 — Connection details that rely solely on friction caused by gravity loads shall not be used.

16.5.2 — For precast concrete bearing wall structures three or more stories in height, the following minimum provisions shall apply:

COMMENTARY

R16.5.1.2 — Diaphragms are typically provided as part of the lateral load resisting system. The ties prescribed in 16.5.1.2 are the minimum required to attach members to the floor or roof diaphragms. The tie force is equivalent to the service load value of 200 lb/ft given in the Uniform Building Code.

R16.5.1.3 — Base connections and connections at horizontal joints in precast columns and wall panels, including shear walls, must be designed to transfer all design forces and moments. The minimum tie requirements of 16.5.1.3 are not additive to these design requirements. Industry practice is to place the wall ties symmetrically about the vertical centerline of the wall panel and within the outer quarters of the panel width, wherever possible.

R16.5.1.4 — In the event of damage to a beam, it is important that displacement of its supporting members be minimized, so that other members will not lose their load-carrying capacity. This is a situation that shows why connection details which rely solely on friction caused by gravity loads are not to be used. An exception could be heavy modular unit structures (one or more cells in cell-type structures) where resistance to overturning or sliding in any direction has a large factor of safety. Acceptance of such systems should be based on the provisions of 1.4.

R16.5.2 — The structural integrity minimum tie provisions for bearing wall structures, often called large panel structures, are intended to provide catenary hanger supports in case of loss of a bearing wall support, as shown by test.[16.21] Forces induced by loading, temperature change, creep, and wind or seismic action may require a larger amount of tie force. It is intended that the general precast concrete provisions of 16.5.1 apply to bearing wall structures less than three stories in height.

Minimum ties in structures three or more stories in height, in accordance with 16.5.2.1, 16.5.2.2, 16.5.2.3, 16.5.2.4, and 16.5.2.5, are required for structural integrity (Fig. R16.5.2). These provisions are based on the Precast/Prestressed Concrete Institute's recommendations for design of precast concrete bearing wall buildings.[16.22] Tie capacity is based on yield strength.

CODE

COMMENTARY

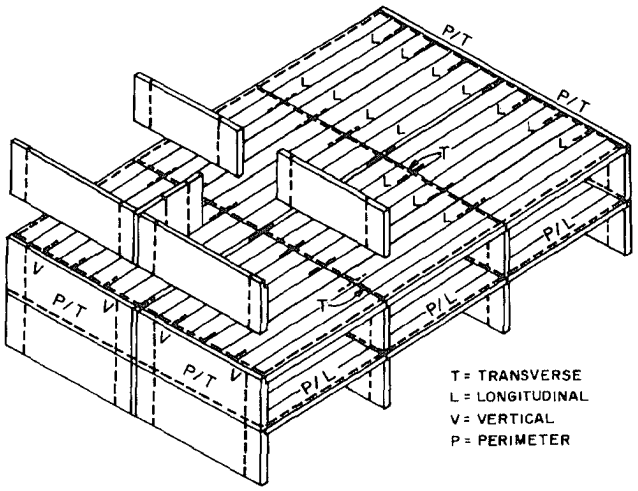

Fig. R16.5.2—Typical arrangement of tensile ties in large panel structures

16.5.2.1 — Longitudinal and transverse ties shall be provided in floor and roof systems to provide a nominal strength of 1500 lb per foot of width or length. Ties shall be provided over interior wall supports and between members and exterior walls. Ties shall be positioned in or within 2 ft of the plane of the floor or roof system.

R16.5.2.1 — Longitudinal ties may project from slabs and be lap spliced, welded, or mechanically connected, or they may be embedded in grout joints, with sufficient length and cover to develop the required force. Bond length for unstressed prestressing steel should be sufficient to develop the yield strength.[16.23] It is not uncommon to have ties positioned in the walls reasonably close to the plane of the floor or roof system.

16.5.2.2 — Longitudinal ties parallel to floor or roof slab spans shall be spaced not more than 10 ft on centers. Provisions shall be made to transfer forces around openings.

16.5.2.3 — Transverse ties perpendicular to floor or roof slab spans shall be spaced not greater than the bearing wall spacing.

R16.5.2.3 — Transverse ties may be uniformly spaced either encased in the panels or in a topping, or they may be concentrated at the transverse bearing walls.

16.5.2.4 — Ties around the perimeter of each floor and roof, within 4 ft of the edge, shall provide a nominal strength in tension not less than 16,000 lb.

R16.5.2.4 —The perimeter tie requirements need not be additive with the longitudinal and transverse tie requirements.

16.5.2.5 — Vertical tension ties shall be provided in all walls and shall be continuous over the height of the building. They shall provide a nominal tensile strength not less than 3000 lb per horizontal foot of wall. Not less than two ties shall be provided for each precast panel.

16.6 — Connection and bearing design

R16.6 — Connection and bearing design

16.6.1 — Forces shall be permitted to be transferred between members by grouted joints, shear keys, mechanical connectors, reinforcing steel connections, reinforced topping, or a combination of these means.

R16.6.1 — The code permits a variety of methods for connecting members. These are intended for transfer of forces both in-plane and perpendicular to the plane of the members.

CODE

16.6.1.1 — The adequacy of connections to transfer forces between members shall be determined by analysis or by test. Where shear is the primary imposed loading, it shall be permitted to use the provisions of 11.7 as applicable.

COMMENTARY

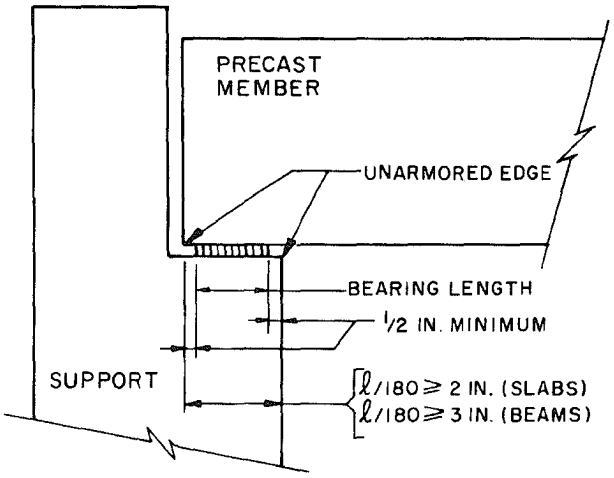

Fig. R16.6.2—Bearing length versus length of member on support

16.6.1.2 — When designing a connection using materials with different structural properties, their relative stiffnesses, strengths, and ductilities shall be considered.

R16.6.1.2 — The designer should be aware that the various components in a connection (e.g. bolts, welds, plates, inserts, etc.) have different properties that can affect the overall behavior of the connection.

16.6.2 — Bearing for precast floor and roof members on simple supports shall satisfy the following:

16.6.2.1—The allowable bearing stress at the contact surface between supported and supporting members and between any intermediate bearing elements shall not exceed the bearing strength for either surface and the bearing element. Concrete bearing strength shall be as given in 10.17.

R16.6.2.1 — When tensile forces occur in the plane of the bearing, it may be desirable to reduce the allowable bearing stress and/or provide confinement reinforcement. Guidelines are provided in Reference 16.4.

16.6.2.2 — Unless shown by test or analysis that performance will not be impaired, the following minimum requirements shall be met:

(a) Each member and its supporting system shall have design dimensions selected so that, after consideration of tolerances, the distance from the edge of the support to the end of the precast member in the direction of the span is at least $\ell/180$ of the clear span ℓ, but not less than:

For solid or hollow-core slabs ..... 2 in.
For beams or stemmed members..... 3 in.

(b) Bearing pads at unarmored edges shall be set back a minimum of $1/2$ in. from the face of the support, or at least the chamfer dimension at chamfered edges.

R16.6.2.2 — This section differentiates between bearing length and length of the end of a precast member over the support (Fig. R16.6.2).

Bearing pads distribute concentrated loads and reactions over the bearing area, and allow limited horizontal and rotational movements for stress relief. To prevent spalling under heavily loaded bearing areas, bearing pads should not extend to the edge of the support unless the edge is armored. Edges can be armored with anchored steel plates or angles. Section 11.9.7 gives requirements for bearing on brackets or corbels.

16.6.2.3 — The requirements of 12.11.1 shall not apply to the positive bending moment reinforcement for statically determinate precast members, but at least one-third of such reinforcement shall extend to the center of the bearing length.

R16.6.2.3 — It is unnecessary to develop positive bending moment reinforcement beyond the ends of the precast element if the system is statically determinate.

CODE

16.7 — Items embedded after concrete placement

16.7.1 — When approved by the engineer, embedded items (such as dowels or inserts) that either protrude from the concrete or remain exposed for inspection shall be permitted to be embedded while the concrete is in a plastic state provided that:

16.7.1.1 — Embedded items are not required to be hooked or tied to reinforcement within the concrete.

16.7.1.2 — Embedded items are maintained in the correct position while the concrete remains plastic.

16.7.1.3 — The concrete is properly consolidated around the embedded item.

16.8 — Marking and identification

16.8.1 — Each precast member shall be marked to indicate its location and orientation in the structure and date of manufacture.

16.8.2 — Identification marks shall correspond to placing drawings.

16.9 — Handling

16.9.1 — Member design shall consider forces and distortions during curing, stripping, storage, transportation, and erection so that precast members are not overstressed or otherwise damaged.

16.9.2 — Precast members and structures shall be adequately supported and braced during erection to ensure proper alignment and structural integrity until permanent connections are completed.

16.10 — Strength evaluation of precast construction

16.10.1 — A precast element to be made composite with cast-in-place concrete shall be permitted to be tested in flexure as a precast element alone in accordance with the following:

COMMENTARY

R16.7 — Items embedded after concrete placement

R16.7.1 — Section 16.7.1 is an exception to the provisions of 7.5.1. Many precast products are manufactured in such a way that it is difficult, if not impossible, to position reinforcement which protrudes from the concrete before the concrete is placed. Experience has shown that such items as ties for horizontal shear and inserts can be placed while the concrete is plastic, if proper precautions are taken. This exception is not applicable to reinforcement which is completely embedded, or to embedded items which must be hooked or tied to embedded reinforcement.

R16.9 — Handling

R16.9.1 — The code requires acceptable performance at service loads and adequate strength under factored loads. However, handling loads should not produce permanent stresses, strains, cracking, or deflections inconsistent with the provisions of the code. A precast member should not be rejected for minor cracking or spalling where strength and durability are not affected. Guidance on assessing cracks in precast members is given in two Precast/Prestressed Concrete Institute reports on fabrication and shipment cracks.[16.24, 16.25]

R16.9.2 — It is important that all temporary erection connections, bracing, and shoring be shown on contract or erection drawings, as well as the sequencing of removal of these items.

R16.10 — Strength evaluation of precast construction

When the strength of a precast member in a structure is in doubt, the strength evaluation procedures of Chapter 20 are applicable. This section amplifies Chapter 20 to include the testing and evaluation of individual precast members before they are integrated into the structure.

CODE

16.10.1.1 — Test loads shall be applied only when calculations indicate the isolated precast element will not be critical in compression or buckling.

16.10.1.2 — The test load shall be that load which, when applied to the precast member alone, induces the same total force in the tension reinforcement as would be induced by loading the composite member with the test load required by 20.3.2.

16.10.2 — The provisions of 20.5 shall be the basis for acceptance or rejection of the precast element.

COMMENTARY

CHAPTER 17 — COMPOSITE CONCRETE FLEXURAL MEMBERS

CODE

17.0 — Notation

A_c = area of contact surface being investigated for horizontal shear, in.^{2}
A_v = area of ties within a distance s, in.^{2}
b_v = width of cross section at contact surface being investigated for horizontal shear
d = distance from extreme compression fiber to centroid of tension reinforcement for entire composite section, in.
h = overall thickness of composite member, in.
s = spacing of ties measured along the longitudinal axis of the member, in.
V_{nh} = nominal horizontal shear strength
V_u = factored shear force at section
λ = correction factor related to unit weight of concrete
ρ_v = ratio of tie reinforcement area to area of contact surface
= $A_v/b_v s$
ϕ = strength reduction factor. See 9.3

17.1 — Scope

17.1.1 — Provisions of Chapter 17 shall apply for design of composite concrete flexural members defined as precast and/or cast-in-place concrete elements constructed in separate placements but so interconnected that all elements respond to loads as a unit.

17.1.2 — All provisions of this code shall apply to composite concrete flexural members, except as specifically modified in Chapter 17.

17.2 — General

17.2.1 — The use of an entire composite member or portions thereof for resisting shear and moment shall be permitted.

17.2.2 — Individual elements shall be investigated for all critical stages of loading.

17.2.3 — If the specified strength, unit weight, or other properties of the various elements are different, properties of the individual elements or the most critical values, shall be used in design.

COMMENTARY

R17.1 — Scope

R17.1.1 — The scope of Chapter 17 is intended to include all types of composite concrete flexural members. In some cases with fully cast-in-place concrete, it may be necessary to design the interface of consecutive placements of concrete as required for composite members. Composite structural steel-concrete members are not covered in this chapter, because design provisions for such composite members are covered in Reference 17.1.

R17.2 — General

CODE

17.2.4 — In strength computations of composite members, no distinction shall be made between shored and unshored members.

17.2.5 — All elements shall be designed to support all loads introduced prior to full development of design strength of composite members.

17.2.6 — Reinforcement shall be provided as required to control cracking and to prevent separation of individual elements of composite members.

17.2.7 — Composite members shall meet requirements for control of deflections in accordance with 9.5.5.

17.3 — Shoring

When used, shoring shall not be removed until supported elements have developed design properties required to support all loads and limit deflections and cracking at time of shoring removal.

17.4 — Vertical shear strength

17.4.1 — When an entire composite member is assumed to resist vertical shear, design shall be in accordance with requirements of Chapter 11 as for a monolithically cast member of the same cross-sectional shape.

17.4.2 — Shear reinforcement shall be fully anchored into interconnected elements in accordance with 12.13.

17.4.3 — Extended and anchored shear reinforcement shall be permitted to be included as ties for horizontal shear.

17.5 — Horizontal shear strength

17.5.1 — In a composite member, full transfer of horizontal shear forces shall be assured at contact surfaces of interconnected elements.

17.5.2 — Unless calculated in accordance with 17.5.3, design of cross sections subject to horizontal shear shall be based on

COMMENTARY

R17.2.4 — Tests have indicated that the strength of a composite member is the same whether or not the first element cast is shored during casting and curing of the second element.

R17.2.6 — The extent of cracking permitted is dependent on such factors as environment, aesthetics, and occupancy. In addition, composite action should not be impaired.

R17.2.7 — The premature loading of precast elements can cause excessive deflections as the result of creep and shrinkage. This is especially so at early ages when the moisture content is high and the strength low.

The transfer of shear by direct bond is important if excessive deflection from slippage is to be prevented. A shear key is an added mechanical factor of safety but it cannot operate until slippage occurs.

R17.3 — Shoring

The provisions of 9.5.5 cover the requirements pertaining to deflections of shored and unshored members.

R17.5 — Horizontal shear strength

R17.5.1 — Full transfer of horizontal shear between segments of composite members should be assured by horizontal shear strength at contact surfaces or properly anchored ties, or both.

R17.5.2 — The nominal horizontal shear strengths V_{nh} apply when the design is based on the load factors and ϕ-factors of Chapter 9.

CODE

$$V_u \le \phi V_{nh} \qquad (17\text{-}1)$$

where V_u is factored shear force at section considered and V_{nh} is nominal horizontal shear strength in accordance with the following.

17.5.2.1 — When contact surfaces are clean, free of laitance, and intentionally roughened, shear strength V_{nh} shall not be taken greater than $80b_vd$ in pounds.

17.5.2.2 — When minimum ties are provided in accordance with 17.6, and contact surfaces are clean and free of laitance, but not intentionally roughened, shear strength V_{nh} shall not be taken greater than $80b_vd$ in pounds.

17.5.2.3 — When ties are provided in accordance with 17.6, and contact surfaces are clean, free of laitance, and intentionally roughened to a full amplitude of approximately 1/4 in., shear strength V_{nh} shall be taken equal to $(260 + 0.6\rho_v f_y)\lambda b_v d$ in pounds, but not greater than $500b_vd$ in pounds. Values for λ in 11.7.4.3 shall apply.

17.5.2.4 — When factored shear force V_u at section considered exceeds ϕ $(500b_vd)$, design for horizontal shear shall be in accordance with 11.7.4.

17.5.2.5 — When determining nominal horizontal shear strength over prestressed concrete elements, d shall be as defined or $0.8h$, whichever is greater.

17.5.3 — As an alternative to 17.5.2, horizontal shear shall be determined by computing the actual change in compressive or tensile force in any segment, and provisions shall be made to transfer that force as horizontal shear to the supporting element. The factored horizontal shear force shall not exceed horizontal shear strength ϕV_{nh} as given in 17.5.2.1 through 17.5.2.4, where area of contact surface A_c shall be substituted for b_vd.

17.5.3.1 — When ties provided to resist horizontal shear are designed to satisfy 17.5.3, the tie area to tie spacing ratio along the member shall approximately reflect the distribution of shear forces in the member.

COMMENTARY

When the alternate design method of Appendix A is used for design of composite members, V_u is the shear due to service loads, and 55 percent of the values given in 17.5.2 are applicable. See A.7.3. Also, when gravity loads are combined with lateral loads due to wind or earthquake in the governing load combination for horizontal shear, advantage may be taken of the 25 percent reduction in required strength in accordance with A.2.2.

In reviewing composite concrete flexural members for handling and construction loads, V_u may be replaced by the handling service load shear in Eq. (17-1). The handling load horizontal shear should be compared with a nominal horizontal shear strength value of $0.55V_{nh}$ (as provided in Appendix A for the Alternate Design Method) to ensure that an adequate factor of safety results for handling and construction loads.

Prestressed members used in composite construction may have variations in depth of tension reinforcement along member length due to draped or depressed tendons. Because of this variation, the definition of d used in Chapter 11 for determination of vertical shear strength is also appropriate when determining horizontal shear strength.

R17.5.2.3 — The permitted horizontal shear strengths and the requirement of 1/4 in. amplitude for intentional roughness are based on tests discussed in References 17.2 through 17.4.

R17.5.3.1 — The distribution of horizontal shear stresses along the contact surface in a composite member will reflect the distribution of shear along the member. Horizontal shear failure will initiate where the horizontal shear stress is a

CODE	COMMENTARY
	maximum and will spread to regions of lower stress. Because the slip at peak horizontal shear resistance is small for a concrete to concrete contact surface, longitudinal redistribution of horizontal shear resistance is very limited. The spacing of the ties along the contact surface should, therefore, be such as to provide horizontal shear resistance distributed approximately as the shear acting on the member is distributed.
17.5.4 — When tension exists across any contact surface between interconnected elements, shear transfer by contact shall be permitted only when minimum ties are provided in accordance with 17.6.	**R17.5.4** — Proper anchorage of ties extending across interfaces is required to maintain contact of the interfaces.
17.6 — Ties for horizontal shear	**R17.6 — Ties for horizontal shear**
17.6.1 — When ties are provided to transfer horizontal shear, tie area shall not be less than that required by 11.5.5.3, and tie spacing shall not exceed four times the least dimension of supported element, nor 24 in.	The minimum areas and maximum spacings are based on test data given in References 17.2 through 17.6.
17.6.2 — Ties for horizontal shear shall consist of single bars or wire, multiple leg stirrups, or vertical legs of welded wire fabric (plain or deformed).	
17.6.3 — All ties shall be fully anchored into interconnected elements in accordance with 12.13.	

CHAPTER 18 — PRESTRESSED CONCRETE

CODE

COMMENTARY

18.0 — Notation

A = area of that part of cross section between flexural tension face and center of gravity of gross section, in.^{2}

A_{ps} = area of prestressed reinforcement in tension zone, in.^{2}

A_s = area of nonprestressed tension reinforcement, in.^{2}

A_s' = area of compression reinforcement, in.^{2}

b = width of compression face of member, in.

d = distance from extreme compression fiber to centroid of nonprestressed tension reinforcement, in.

d' = distance from extreme compression fiber to centroid of compression reinforcement, in.

d_p = distance from extreme compression fiber to centroid of prestressed reinforcement

D = dead loads, or related internal moments and forces

e = base of Napierian logarithms

f_c' = specified compressive strength of concrete, psi

$\sqrt{f_c'}$ = square root of specified compressive strength of concrete, psi

f_{ci}' = compressive strength of concrete at time of initial prestress, psi

$\sqrt{f_{ci}'}$ = square root of compressive strength of concrete at time of initial prestress, psi

f_{pc} = average compressive stress in concrete due to effective prestress force only (after allowance for all prestress losses), psi

f_{ps} = stress in prestressed reinforcement at nominal strength, psi

f_{pu} = specified tensile strength of prestressing tendons, psi

f_{py} = specified yield strength of prestressing tendons, psi

f_r = modulus of rupture of concrete, psi

f_{se} = effective stress in prestressed reinforcement (after allowance for all prestress losses), psi

f_y = specified yield strength of nonprestressed reinforcement, psi

h = overall thickness of member, in.

K = wobble friction coefficient per foot of prestressing tendon

l = length of span of two-way flat plates in direction parallel to that of the reinforcement being determined, in. See Eq. (18-8)

l_x = length of prestressing tendon element from jacking end to any point x, ft. See Eq. (18-1) and (18-2)

CODE

L = live loads, or related internal moments and forces

N_c = tensile force in concrete due to unfactored dead load plus live load ($D + L$)

P_s = prestressing tendon force at jacking end

P_x = prestressing tendon force at any point x

α = total angular change of prestressing tendon profile in radians from tendon jacking end to any point x

β_1 = factor defined in 10.2.7.3

γ_p = factor for type of prestressing tendon
= 0.55 for f_{py}/f_{pu} not less than 0.80
= 0.40 for f_{py}/f_{pu} not less than 0.85
= 0.28 for f_{py}/f_{pu} not less than 0.90

μ = curvature friction coefficient

ρ = ratio of nonprestressed tension reinforcement
= A_s/bd

ρ' = ratio of compression reinforcement
= A_s'/bd

ρ_p = ratio of prestressed reinforcement
= A_{ps}/bd_p

ϕ = strength reduction factor. See 9.3

ω = $\rho f_y/f_c'$

ω' = $\rho' f_y/f_c'$

ω_p = $\rho_p f_{ps}/f_c'$

$\omega_w, \omega_{pw}, \omega_w'$ = reinforcement indices for flanged sections computed as for ω, ω_p, and ω' except that b shall be the web width, and reinforcement area shall be that required to develop compressive strength of web only

COMMENTARY

18.1 — Scope

R18.1 — Scope

18.1.1 — Provisions of Chapter 18 shall apply to members prestressed with wire, strands, or bars conforming to provisions for prestressing tendons in 3.5.5.

R18.1.1 — The provisions of Chapter 18 were developed primarily for structural members such as slabs, beams, and columns which are commonly used in buildings. However, many of the provisions may be applied to other types of construction such as pressure vessels, pavements, pipes, and crossties. Application of the provisions is left to the judgment of the engineer in cases not specifically cited in the code.

18.1.2 — All provisions of this code not specifically excluded, and not in conflict with provisions of Chapter 18, shall apply to prestressed concrete.

18.1.3 — The following provisions of this code shall not apply to prestressed concrete, except as specifically noted: Sections 7.6.5, 8.4, 8.10.2, 8.10.3, 8.10.4, 8.11, 10.3.2, 10.3.3, 10.5, 10.6, 10.9.1, and 10.9.2; Chapter 13; and Sections 14.3, 14.5, and 14.6.

R18.1.3 — Some sections of the code are excluded from use in the design of prestressed concrete for specific reasons. The following discussion provides explanation for such exclusions:

Section 7.6.5 — Section 7.6.5 of the code is excluded from application to prestressed concrete since the requirements for bonded reinforcement and unbonded tendons for cast-in-place members are provided in 18.9 and 18.12, respectively.

CODE

COMMENTARY

Section 8.4 — Section 8.4 of the code is excluded since moment redistribution for prestressed concrete is provided in 18.10.4.

Sections 8.10.2, 8.10.3, and 8.10.4 — The empirical provisions of 8.10.2, 8.10.3, and 8.10.4 for T-beams were developed for conventionally reinforced concrete and if applied to prestressed concrete would exclude many standard prestressed products in satisfactory use today. Hence, proof by experience permits variations.

By excluding 8.10.2, 8.10.3, and 8.10.4, no special requirements for prestressed concrete T-beams appear in the code. Instead, the determination of an effective width of flange is left to the experience and judgment of the engineer. Where possible, the flange widths in 8.10.2, 8.10.3, and 8.10.4 should be used unless experience has proven that variations are safe and satisfactory. It is not necessarily conservative in elastic analysis and design considerations to use the maximum flange width as permitted in 8.10.2.

Sections 8.10.1 and 8.10.5 provide general requirements for T-beams that are also applicable to prestressed concrete units. The spacing limitations for slab reinforcement are based on flange thickness, which for tapered flanges can be taken as the average thickness.

Section 8.11 — The empirical limits established for conventionally reinforced concrete joist floors are based on successful past performance of joist construction using "standard" joist forming systems. See R8.11. For prestressed joist construction, experience and judgment should be used. The provisions of 8.11 may be used as a guide.

Sections 10.3.2, 10.3.3, 10.5, 10.9.1, and 10.9.2 — For prestressed concrete, the limitations on reinforcement given in 10.3.2, 10.3.3, 10.5, 10.9.1, and 10.9.2 are replaced by those in 18.8, 18.9, and 18.11.2.

Section 10.6 — When originally prepared, the provisions of 10.6 for distribution of flexural reinforcement were not intended for prestressed concrete members. The behavior of a prestressed member is considerably different from that of a nonprestressed member. Experience and judgment must be used for proper distribution of reinforcement in a prestressed member.

Chapter 13 — The design of prestressed concrete slabs requires recognition of secondary moments induced by the undulating profile of the prestressing tendons. Also volume changes due to the prestressing force can create additional loads on the structure that are not adequately covered in Chapter 13. Because of these unique properties associated with prestressing, many of the design procedures of Chapter 13 are not appropriate for prestressed concrete structures and are replaced by the provisions of 18.12.

Sections 14.5 and 14.6 — The requirements for wall design in 14.5 and 14.6 are largely empirical, utilizing considerations not intended to apply to prestressed concrete.

CODE

18.2 — General

18.2.1 — Prestressed members shall meet the strength requirements specified in this code.

18.2.2 — Design of prestressed members shall be based on strength and on behavior at service conditions at all load stages that will be critical during the life of the structure from the time prestress is first applied.

18.2.3 — Stress concentrations due to prestressing shall be considered in design.

18.2.4 — Provisions shall be made for effects on adjoining construction of elastic and plastic deformations, deflections, changes in length, and rotations due to prestressing. Effects of temperature and shrinkage shall also be included.

18.2.5 — Possibility of buckling in a member between points where concrete and prestressing tendons are in contact and of buckling in thin webs and flanges shall be considered.

18.2.6 — In computing section properties prior to bonding of prestressing tendons, effect of loss of area due to open ducts shall be considered.

COMMENTARY

R18.2 — General

R18.2.1 and R18.2.2 — As has been past practice in the design of prestressed concrete, the design investigation should include all load stages that may be significant. The three major stages are: (1) jacking stage, or prestress transfer stage—when the tensile force in the prestressing tendons is transferred to the concrete and stress levels may be high relative to concrete strength, (2) service load stage—after long-term volume changes have occurred, and (3) the factored load stage—when the strength of the member is checked. There may be other load stages that require investigation. For example, if the cracking load is significant, this load stage may require study, or the handling and transporting stage may be critical.

From the standpoint of satisfactory behavior, the two stages of most importance are those for service load and factored load.

Service load stage refers to the loads defined in the general building code (without load factors), such as live load and dead load, while the factored load stage refers to loads multiplied by the appropriate load factors.

Section 18.3.2 provides assumptions that may be used for investigation at service loads and after transfer of the prestressing force.

R18.2.5 — This refers to the type of post-tensioning where the tendon makes contact with the prestressed concrete member intermittently. Precautions should be taken to prevent buckling of such members.

If the tendon is in complete contact with the member being prestressed, or is an unbonded tendon in a duct not excessively larger than the tendon, it is not possible to buckle the member under the prestressing force being introduced.

R18.2.6 — In considering the area of the open ducts, the critical sections should include those which have coupler sheaths which may be of a larger size than the duct containing the tendon. Also, in some instances, the trumpet or transition piece from the conduit to the anchorage may be of such a size as to create a critical section. If the effect of the open duct area on design is deemed negligible, section properties may be based on total area.

In pretensioned members and in post-tensioned members after grouting, section properties may be based on gross sections, net sections, or effective sections using transformed areas of bonded tendons and nonprestressed reinforcement.

CODE

COMMENTARY

18.3 — Design assumptions

18.3.1 — Strength design of prestressed members for flexure and axial loads shall be based on assumptions given in 10.2, except 10.2.4 shall apply only to reinforcement conforming to 3.5.3.

18.3.2 — For investigation of stresses at transfer of prestress, at service loads, and at cracking loads, straight-line theory shall be used with the following assumptions.

18.3.2.1 — Strains vary linearly with depth through entire load range.

18.3.2.2 — At cracked sections, concrete resists no tension.

18.4 — Permissible stresses in concrete — Flexural members

R18.4 — Permissible stresses in concrete — Flexural members

Permissible stresses in concrete are given to control serviceability. They do not ensure adequate structural strength, which must be checked in conformance with other code requirements.

18.4.1 — Stresses in concrete immediately after prestress transfer (before time-dependent prestress losses) shall not exceed the following:

(a) Extreme fiber stress in compression..... $0.60f_{ci}'$

(b) Extreme fiber stress in tension except as permitted in (c) ..... $3\sqrt{f_{ci}'}$

(c) Extreme fiber stress in tension at ends of simply supported members ..... $6\sqrt{f_{ci}'}$

Where computed tensile stresses exceed these values, bonded auxiliary reinforcement (nonprestressed or prestressed) shall be provided in the tensile zone to resist the total tensile force in concrete computed with the assumption of an uncracked section.

R18.4.1 — The concrete stresses at this stage are caused by the force in the prestressing tendons at transfer reduced by the losses due to elastic shortening of the concrete, relaxation of the tendon, anchorage seating, and the stresses due to the weight of the member. Generally, shrinkage is not included at this stage. These stresses apply to both pretensioned and post-tensioned concrete with proper modifications of the losses at transfer.

R18.4.1(b) and (c) — The tension stress limits of $3\sqrt{f_{ci}'}$ and $6\sqrt{f_{ci}'}$ refer to tensile stress at locations other than the precompressed tensile zone. Where the tensile stresses exceed the permissible values, the total force in the tensile stress zone may be calculated and reinforcement proportioned on the basis of this force at a stress of $0.6f_y$, but not more than 30,000 psi. The effects of creep and shrinkage begin to reduce the tensile stress almost immediately; however, some tension remains in these areas after allowance is made for all prestress losses.

18.4.2 — Stresses in concrete at service loads (after allowance for all prestress losses) shall not exceed the following:

(a) Extreme fiber stress in compression due to prestress plus sustained loads ..... $0.45f_c'$

(b) Extreme fiber stress in compression due to prestress plus total load..... $0.60f_c'$

R18.4.2(a) and (b) — The compression stress limit of $0.45f_c'$ was conservatively established to decrease the probability of failure of prestressed concrete members due to repeated loads. In addition, the early code writers felt that this limit was reasonable to preclude excessive creep deformation. At higher values of stress, creep strains tend to increase more rapidly as applied stress increases. This is not consistent with the design assumption that creep strain is proportional to stress in calculating time-dependent camber and deflection and prestress losses.

CODE

(c) Extreme fiber stress in tension in precompressed tensile zone..... $6\sqrt{f_c'}$

(d) Extreme fiber stress in tension in precompressed tensile zone of members (except two-way slab systems), where analysis based on transformed cracked sections and on bilinear moment-deflection relationships shows that immediate and long-term deflections comply with requirements of 9.5.4, and where cover requirements comply with 7.7.3.2..... $12\sqrt{f_c'}$

COMMENTARY

The change in allowable stress in the 1995 code recognizes that fatigue tests of prestressed concrete have shown that concrete failures are not the controlling criterion, and that designs with large transient live loads compared to sustained dead and live loads have been penalized by the previous single compression stress limit. Therefore, the new stress limit of $\mathbf{0.60}f_c'$ permits a one-third increase in allowable compression stress for members subject to transient loads.

Sustained live load is any portion of the service live load which will be sustained for a sufficient period to cause significant time-dependent deflections. Thus, when sustained dead load and live loads are a large percentage of total service load, the $\mathbf{0.45}f_c'$ limit of 18.4.2(a) may control. On the other hand, when a large portion of the total service load consists of a transient or temporary service live load, the increased stress limit of 18.4.2(b) may control.

The compression stress limit of $\mathbf{0.45}f_c'$ for prestress plus sustained loads will continue to control the long-term behavior of prestressed members.

R18.4.2(c) — The precompressed tensile zone is that portion of the member cross section in which flexural tension occurs under dead and live loads. Prestressed concrete is usually designed so that the prestress force introduces compression into this zone, thus effectively reducing the magnitude of the tensile stress.

The permissible tensile stress of $\mathbf{6}\sqrt{f_c'}$ is compatible with the concrete covers required by 7.7.3.1. For conditions of corrosive environments, defined as an environment in which chemical attack such as seawater, corrosive industrial atmosphere, sewer gas, or other highly corrosive environments are encountered, greater cover than that required by 7.7.3.1 should be used, in accordance with 7.7.3.2, and tension stresses reduced to eliminate possible cracking at service loads. The engineer must use judgment to determine the amount of increased cover and whether reduced tension stresses are required.

R18.4.2(c) and (d) — The permissible concrete tensile stress depends on whether or not enough bonded reinforcement is provided to control cracking. Such bonded reinforcement may consist of prestressed or nonprestressed tendons or of reinforcing bars. It should be noted that the control of cracking depends not only on the amount of reinforcement provided but also on its distribution over the tensile zone.

Because of the bonded reinforcement requirements of 18.9, it is considered that the behavior of segmental members generally will be comparable to that of similarly constructed monolithic concrete members. Therefore, the permissible tensile stress limits of 18.4.2(c) and 18.4.2(d) apply to both segmental and monolithic members. If deflections are important, the built-in cracks of segmental members should be considered in the computations.

CODE

COMMENTARY

R18.4.2(d) — The permissible tensile stress of $12\sqrt{f_c'}$ provides improved service load performance, especially when live loads are of a transient nature. To take advantage of the increased permissible stress, the engineer is required to increase the concrete protection on the reinforcement, as stipulated in 7.7.3.2, and to investigate the deflection characteristics of the member, particularly at the load where the member changes from uncracked behavior to cracked behavior.

The exclusion of two-way slab systems is based on Reference 18.1, which recommends that the permissible tension stress be not greater than $6\sqrt{f_c'}$ for design of prestressed concrete flat plates analyzed by the equivalent frame method or other approximate methods. For flat plate designs based on more exact analyses, or for other two-way slab systems rigorously analyzed and designed for strength and serviceability, the limiting stress may be exceeded in accordance with 18.4.3.

Reference 18.2 provides information on the use of bilinear moment-deflection relationships.

18.4.3 — Permissible stresses in concrete of 18.4.1 and 18.4.2 shall be permitted to be exceeded if shown by test or analysis that performance will not be impaired.

R18.4.3 — This section provides a mechanism whereby development of new products, materials, and techniques in prestressed concrete construction need not be inhibited by limits on stress which represented the most advanced requirements at the time the code provisions were adopted. Approvals for the design should be in accordance with 1.4 of the code.

18.5 — Permissible stresses in prestressing tendons

R18.5 — Permissible stresses in prestressing tendons

The code does not distinguish between temporary and effective prestress tendon stresses. Only one limit on prestress tendon stress is provided because the initial tendon stress (immediately after transfer) can prevail for a considerable time, even after the structure has been put into service. This stress, therefore, must have an adequate safety factor under service conditions and cannot be considered as a temporary stress. Any subsequent decrease in tendon stress due to losses can only improve conditions and, hence, no limit on such stress decrease is provided in the code.

18.5.1 — Tensile stress in prestressing tendons shall not exceed the following:

(a) Due to tendon jacking force ..... $0.94f_{py}$

but not greater than the lesser of $\mathbf{0.80}f_{pu}$ and the maximum value recommended by the manufacturer of prestressing tendons or anchorages.

(b) Immediately after prestress transfer ..... $0.82f_{py}$

but not greater than $\mathbf{0.74}f_{pu}$.

R18.5.1 — With the 1983 code edition, permissible stresses in tendons are revised to recognize the higher yield strength of low-relaxation wire and strand meeting the requirements of ASTM A 421 and A 416 of 3.5.5. For such tendons, it is more appropriate to specify permissible stresses in terms of specified minimum ASTM yield strength rather than specified minimum ASTM tensile strength. For the low-relaxation wire and strands, with f_{py} equal to $\mathbf{0.90}f_{pu}$, the $\mathbf{0.94}f_{py}$ and $\mathbf{0.82}f_{py}$ limits are equivalent to $\mathbf{0.85}f_{pu}$ and $\mathbf{0.74}f_{pu}$, respectively. In the 1986 revision and in the 1989 code, the maximum jacking stress for low-relaxation tendons was reduced to $\mathbf{0.80}f_{pu}$ to ensure closer compatibility with the maximum tendon stress value of $\mathbf{0.74}f_{pu}$ immediately after

CODE

(c) Post-tensioning tendons, at anchorages and couplers, immediately after tendon anchorage.... $0.70f_{pu}$

COMMENTARY

prestress transfer. The higher yield strength of the low-relaxation tendons does not change the effectiveness of tendon anchorages; thus, the permissible stress at post-tensioning anchorages (and couplers) is not increased above the previously permitted value of $0.70f_{pu}$. For ordinary tendons (wire, strands, and bars) with f_{py} equal to $0.85f_{pu}$, the $0.94f_{py}$ and $0.82f_{py}$ limits are equivalent to $0.80f_{pu}$ and $0.70f_{pu}$, respectively, the same as permitted in the 1977 code. For bar tendons with f_{py} equal to $0.80f_{pu}$, the same limits are equivalent to $0.75f_{pu}$ and $0.66f_{pu}$, respectively.

Because of the higher allowable initial stresses permitted since the 1983 code, final stresses can be greater. Designers should be concerned with setting a limit on final stress when the structure is subject to corrosive conditions or repeated loadings.

18.6 — Loss of prestress

18.6.1 — To determine effective prestress f_{se}, allowance for the following sources of loss of prestress shall be considered:

(a) Anchorage seating loss

(b) Elastic shortening of concrete

(c) Creep of concrete

(d) Shrinkage of concrete

(e) Relaxation of tendon stress

(f) Friction loss due to intended or unintended curvature in post-tensioning tendons.

R18.6 — Loss of prestress

R18.6.1 — For an explanation of how to compute prestress losses, see References 18.3 through 18.6. Lump sum values of prestress losses for both pretensioned and post-tensioned members which were indicated in pre-1983 editions of the commentary are considered obsolete. Reasonably accurate estimates of prestress losses can be easily calculated in accordance with the recommendations in Reference 18.6 which include consideration of initial stress level ($0.7f_{pu}$ or higher), type of steel (stress-relieved or low-relaxation; wire, strand, or bar), exposure conditions, and type of construction (pretensioned, bonded post-tensioned, or unbonded post-tensioned).

Actual losses, greater or smaller than the computed values, have little effect on the design strength of the member, but affect service load behavior (deflections, camber, cracking load) and connections. At service loads, overestimation of prestress losses can be almost as detrimental as underestimation, since the former can result in excessive camber and horizontal movement.

18.6.2 — Friction loss in post-tensioning tendons

18.6.2.1 — Effect of friction loss in post-tensioning tendons shall be computed by

$$P_s = P_x e^{(K\ell_x + \mu\alpha)} \quad (18\text{-}1)$$

When $(K\ell_x + \mu\alpha)$ is not greater than 0.3, effect of friction loss shall be permitted to be computed by

$$P_s = P_x(1 + K\ell_x + \mu\alpha) \quad (18\text{-}2)$$

18.6.2.2—Friction loss shall be based on experimentally determined wobble K and curvature μ friction coefficients, and shall be verified during tendon stressing operations.

R18.6.2 — Friction loss in post-tensioning tendons
