Although actual damage can occur as a result of complex relationships between damageability and component demands of various types, in this methodology, the occurrence of all damage states within a fragility group is predicted by a single demand parameter. The demand parameter assigned to a fragility group is the one that best predicts the occurrence of the potential damage states with the least amount of uncertainty. For most structural systems (e.g., shear walls, braced frames, steel and concrete moment frames), and for many nonstructural components, story drift ratio has been selected as the best indicator of potential damageability. Floor acceleration and floor velocity are also commonly used. When considered appropriate or necessary, it is possible to use other demand parameters (e.g., plastic rotations, axial forces, or other local component actions).

Since most buildings include drift-sensitive components that generally align with principal orthogonal axes of the building, drift ratios in each direction are necessary to calculate performance impacts. In most cases, failure modes related to acceleration or velocity (e.g., failure of equipment base anchorage, or sliding of unanchored contents) are insensitive to the direction of the applied demand. In some cases, such as tall book cases, failure modes may be sensitive to directionality, but it may be difficult to determine the actual

orientation of such objects with respect to the building axes. For these reasons, peak values of floor acceleration or floor velocity (independent of direction) are used to calculate performance impacts.

This methodology estimates maximum peak floor acceleration and velocity by multiplying maximum values obtained from analysis by a factor of 1.2. This factor is an approximation that accounts for vector summation effects, but acknowledges that the peak value of acceleration (or velocity) is unlikely to occur simultaneously along the two building axes. It is possible to change this factor, and it is possible to designate acceleration- and velocity-sensitive performance groups as sensitive to a particular direction, if the orientation of the components is known.

3.8 Component Fragility

3.8.1 Fragility Functions

Component fragility functions are distributions that indicate the conditional probability of incurring a damage state given a value of demand. This methodology assumes that fragility functions are lognormal distributions.

The type and extent of damage that a component will experience is uncertain. Component fragility functions are statistical distributions that indicate the conditional probability of incurring damage at a given value of demand. Fragility functions are assumed to be lognormal distributions. A unique fragility function is required for each sequential damage state, and for each group of mutually exclusive or simultaneous damage states.

Figure 3-4 shows a representative family of sequential fragility functions (i.e., fragility curves) for a reduced beam section (RBS) special steel moment frame beam-column connection. For this fragility group, three damage states are defined:

- **Damage State DS1.** Beam flange and web local buckling requiring heat straightening of the buckled region.
- **Damage State DS2.** Lateral-torsional distortion of the beam in the hinge region requiring partial replacement of the beam flange and web, and corresponding work on adjacent structural and nonstructural components.
- **Damage State DS3.** Low-cycle fatigue fracture of the beam flanges in the hinge region requiring replacement of a large section of the beam in the fractured region, and corresponding work on adjacent structural and nonstructural components.

The fragility function for each damage state is defined by a median demand value, θ, at which there is a 50% chance that the damage state will initiate, and a dispersion, β, which indicates uncertainty that the damage state will initiate at this value of demand. If a large number of components are subjected to demand, θ, and the performance of these components is

uncorrelated, half of the components will experience this damage state, and half will not.

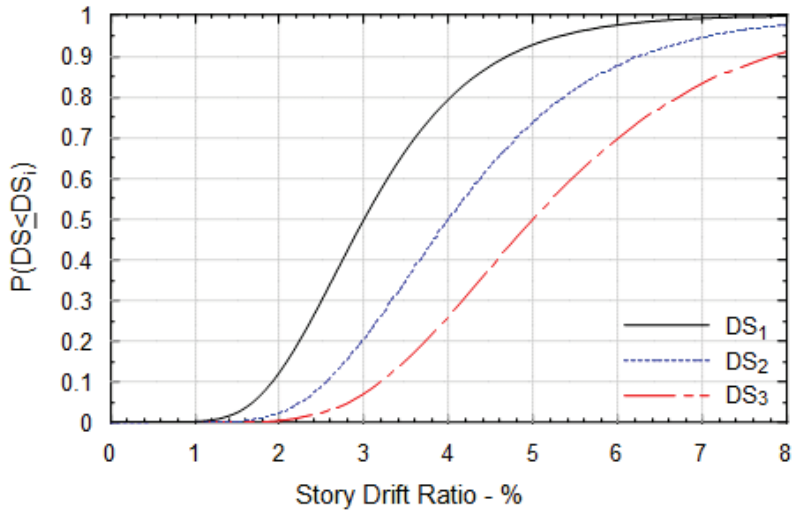

Figure 3-4 Example family of fragility curves for special steel moment frame beam-column connections.

Dispersion is associated solely with uncertainty in the onset of damage as a function of demand, and is independent of uncertainty associated with the intensity of shaking or the prediction of demand. Dispersion reflects uncertainty associated with variability in construction and material quality, the level of knowledge regarding the likely behavior of a component subjected to a specified value of demand, and the extent to which the occurrence of damage can be predicted by a single demand parameter. As the value of β increases, the shape of the curve flattens, indicating a wider range of demands over which there is significant probability that the damage state will initiate.

For the damage states represented in Figure 3-4, median and dispersion values are: (1) $\theta = 3\%$ story drift ratio, $\beta = 0.35$ for DS1; (2) $\theta = 4\%$ story drift ratio, $\beta = 0.35$ for DS2; and (3) $\theta = 5\%$ story drift ratio, $\beta = 0.35$ for DS3. Therefore, at a story drift ratio of 4%:

- The probability that some damage will occur is equal to the probability that DS1 will initiate, which is 80%, since these damage states are sequential, and DS1 must occur before any of the other damage states can occur.
- The probability that no damage will occur is equal to the probability that neither DS1, DS2, nor DS3 will initiate, which is 1.00 – 0.80 = 20%.
- The probability that damage will be in any one damage state is equal to the difference between the probabilities associated with a given damage

state and the next higher damage state. For DS1, this is 0.80 – 0.50 = 30%; for DS2 this is 0.5 – 0.26 = 24%, and for DS3, this is 0.26 – 0.0 = 26%.

For each realization in which collapse does not occur, fragility functions are used in conjunction with calculated demands to determine a damage state for each component. Collectively in a given realization, the set of damage states determined for all components in a building define the building damage state.

3.8.2 Fragility Development

Component fragilities can be developed by laboratory testing, earthquake experience data, analysis, judgment, or a combination of these.

Component fragility functions can be developed through laboratory testing, collection of earthquake experience data following damaging earthquakes, analysis, engineering judgment, or a combination of these methods. FEMA 461, *Interim Testing Protocols for Determining the Seismic Performance Characteristics of Structural and Nonstructural Components* (FEMA, 2007), provides recommended procedures for laboratory testing intended to develop fragility data. Appendix H provides quantitative procedures for developing the median, θ, and dispersion, β, for fragility functions based on various levels of available data:

- **Actual Demand Data.** Data are available from a sufficient number of test specimens, and each tested specimen experienced the damage state of interest at a known value of demand.
- **Bounding Demand Data.** Test data or earthquake experience data are available from a sufficient number of specimens, but the damage state of interest only occurred in some specimens. For the other specimens, testing was terminated before the damage state of interest occurred, or the earthquake did not result in damage to the specimens. The maximum demand that each specimen was subjected to is known, but this maximum demand may not be the demand at which the damage state initiated.
- **Capable Demand Data.** Test data or earthquake experience data are available from a sufficient number of specimens, but the damage state of interest did not occur in any of the specimens. The maximum value of demand that each specimen was subjected to is known.
- **Derivation.** No data are available, but it is possible to model the behavior and analytically estimate the level of demand at which the damage state of interest will occur.
- **Expert Opinion.** No data are available and analysis of the behavior is not feasible, but one or more knowledgeable individuals can offer an

opinion as to the level of demand at which damage is likely to occur, based on experience or engineering judgment.

3.8.3 Provided Fragility Functions

Each of the approaches identified in Section 3.8.2 were used in the development of fragility functions provided with the methodology. A summary list of available fragility functions is presented in Appendix D. Complete fragility information is contained in fragility specifications comprising the *Fragility Database*, provided as part of *Volume 3 – Supporting Electronic Materials and Background Documentation*. Guidance on selecting appropriate fragilities from the list of provided fragilities, and assigning them within the building performance model, is provided in *Volume 2 – Implementation Guide*.

Over 700 fragilities have been developed and provided as part of this methodology.

Fragility and consequence data have been developed for more than 700 common structural and nonstructural components and contents found in typical buildings and occupancies. Structural fragility functions cover the following common structural systems:

- Steel moment frames
- Steel concentrically braced frames
- Steel eccentrically braced frames
- Concrete moment frames
- Concrete shear walls
- Masonry shear walls
- Cold-formed steel walls
- Light-framed wood walls

Fragility functions are also provided for the following common nonstructural systems and contents:

- Exterior wall construction
- Exterior glazing systems
- Roof tiles, masonry chimneys, and parapets
- Interior partitions
- Ceilings
- Stairs
- Elevators

- Mechanical equipment and distribution systems (e.g., chillers, cooling towers, air handling units, piping, and ducting)
- Electrical equipment and distribution systems (e.g., transformers, switchgear, distribution panels, battery racks, recessed lighting, and pendant lighting)
- Access floors, workstations, bookcases, filing cabinets, and storage racks

Provided structural and nonstructural fragilities capture the range of performance capability considering differences in vulnerability to damage. Variations include:

- Special versus ordinary system detailing requirements found in material design standards such as ANSI/AISC 341-10, *Seismic Provisions for Structural Steel Buildings* (AISC, 2010a), and ACI 318-11, *Building Code Requirements for Structural Concrete and Commentary* (ACI, 2011a).
- Differences in behavior associated with configuration, such as steel braced frames with chevron, single diagonal, or X-brace configurations, moment frame connections with beams on one or both sides, and shear walls with slender or low aspect ratios.
- Differences in behavior associated with member properties, such as steel braced frames consisting of hollow structural section (HSS), wide flange (WF), and buckling-restrained braces (BRB).
- Designs using varying limit state assumptions, such as shear-controlled or flexure-controlled behaviors, moment frames with strong-column-weak-beam proportioning, and connections designed to develop the capacity of the members.
- Nonstructural systems and equipment installed with (or without) seismic bracing and anchorage.

The list of provided fragilities is further expanded to consider differences in consequences, especially those related to repair costs. Although damage states and repair actions for a specific fragility group might be identical, differences in cost associated with the size of a component, quantity of material, or finish quality are significant enough to warrant the development of additional fragility groups. Examples include variation in:

- Steel section weight and concrete member size
- Concrete and masonry wall thickness
- Concrete and masonry wall height

- Partition wall finishes
- Ceiling area
- Diameter of piping
- Cross-sectional area of ducting
- Capacity of equipment (e.g., tons of cooling capacity, cubic feet per minute of air flow, amps, or kilovolt-amperes)

3.8.4 Calculated Fragilities

Some component types and damage modes require building-specific calculation of fragility parameters.

Some fragilities require building-specific calculation of fragility parameters for certain component types or damage states. Examples include fragilities related to mechanical equipment anchorage for which the possible modes of damage are known (e.g., anchorage failure), but the capacity must be determined for the specific case under consideration.

The following procedures can be used to estimate fragility parameters for components with failure modes that can be predicted using design formulations contained within industry standard design specifications, such as ACI 318-11, and ANSI/AISC 360-10, *Specification for Structural Steel Buildings* (AISC, 2010b). These procedures can also be used to develop calculation-based fragility parameters for components that lack experimental or experience data, but have failure modes that can be predicted using rational calculation procedures based on engineering mechanics. Procedures are based on the type of limit state associated with the damage, including:

- Strength-limited damage states
- Ductility-limited damage states
- Displacement-limited damage states
- Code-based limit states
- Overturning limit states (for unanchored components)
- Sliding limit states (for unanchored components)

Strength-Limited Damage States

An obvious damage state for many components is the limit of essentially elastic behavior. This procedure is applicable to the calculation of fragility parameters based on the component design strength, ϕR_n, determined in accordance with an appropriate industry design standard. For ductile behavior modes (e.g., flexure), the median strength is determined as:

$$\theta_{ductile} = C_q e^{(2.054\beta)} \phi R_n \qquad (3\text{-}1)$$

For brittle failure modes, the median strength is determined as:

$$\theta_{brittle} = C_q e^{(2.81\beta)} \phi R_n \tag{3-2}$$

where the dispersion, β, and coefficient, C_q, are determined as described below.

The total dispersion, β, is a function of the uncertainty in the ability of a design equation to predict the actual failure demand, β_D, dispersion in material strength, β_M, and uncertainties associated with construction quality, β_C. The total dispersion is computed as:

$$\beta = \sqrt{\beta_D^2 + \beta_M^2 + \beta_C^2} \tag{3-3}$$

Design equations for brittle failure modes have higher inherent uncertainty than equations for ductile failure modes. For ductile failure modes that are well-predicted by classical methods of engineering mechanics (e.g., yield strength of a prismatic member loaded in flexure), a design uncertainty of $\beta_D = 0.05$ is recommended. For ductile failure modes with more complex behavioral characteristics (e.g., elastic buckling of a bar), a larger value of $\beta_D = 0.10$ is recommended.

For brittle failure modes (e.g., tensile failure of a wood post, shear failure of lightly reinforced concrete, and crushing failure of masonry or concrete), higher values of design uncertainty are recommended. Values can be obtained from the commentary underlying the applicable design standard, or from the fundamental research upon which it was based. Alternatively, a default value for brittle failure modes can be taken as $\beta_D = 0.25$.

Material strength variability is a function of the material itself. In relative terms, wood tends to have higher variability than concrete due to ambiguity associated with grading procedures and non-uniformity in individual pieces of wood. Some grades of steel (e.g., ASTM A992) have relatively low material variability, while other grades (e.g., ASTM A36) can have material variability on the order of concrete. Values for dispersion in material strength can be obtained from industry data. Alternatively, default values from Table 3-4 can be used.

Uncertainty associated with construction quality is based on consideration of the sensitivity of a particular behavior mode to the level of quality control that is provided during construction. For example, the strength of a post-installed expansion anchor will be sensitive to the quality of installation in terms of hole size and tightening torque. Other behaviors might not be as

sensitive to construction quality. Table 3-5 provides recommended values for uncertainty associated with construction quality, β_C.

Table 3-4 Default Values of Dispersion, β_M, Associated with Material Strength

Material	Description	Dispersion, β_M
Steel	ASTM A36[1]	0.15
	All grades except ASTM A36	0.10
Concrete	Ready-mix conforming to ASTM C94[2]	0.12
	Other – based on cylinder test results	0.20 [3]
Wood	Machine-stress graded	0.12
	Visually graded	0.20
	Ungraded	0.30
Masonry	Engineered concrete or brick masonry conforming to ACI 530.1 [4]	0.15
	Other masonry	0.25

Notes: (1) *Standard Specification for Carbon Structural Steel* (ASTM, 2012).

(2) *Standard Specification for Ready-Mixed Concrete* (ASTM, 2013).

(3) β_M can be taken as the coefficient of variation (COV) obtained from cylinder test results. Alternatively, a default value of 0.2 can be used.

(4) *Building Code Requirements and Specification for Masonry Structures* (ACI, 2011b).

Table 3-5 Default Values of Uncertainty, β_C, Associated with Construction Quality

Sensitivity to Construction Quality	Degree of Construction Quality Control		
	Very Good	Average	Low
Low	0	0	0
Moderate	0	0.10	0.15
High	0	0.15	0.25

Coefficient, C_q, further adjusts the value of median strength based on the sensitivity of the behavior mode to construction quality. In most cases, the value of C_q can be taken as unity. However, in some cases a lesser value is warranted. Alternate values of C_q are established based on judgment, and should be used in cases where potential variations in capacity are extremely sensitive to construction quality, and the actual condition of the construction is not known. For example, in the case of post-installed expansion anchors, where it is uncertain as to whether or not the anchors have been properly set, an alternate value C_q should be considered. For tension loading, one possible value could be 0.5, representing the average between 1.0 for a proper

installation (i.e., full tension capacity) and 0.0 for an improper installation (i.e., no tension capacity).

Ductility-Limited Damage States

Some damage states in ductile components will initiate when inelastic deformation reaches a particular ductility level. Without appropriate test data to characterize the ductility at which a particular damage state occurs, estimates of this threshold should be considered highly uncertain. When appropriate test data are not available, the following procedure can be used to characterize ductility-limited damage states:

1. Calculate the median value and dispersion for the elastic limit of the component (i.e., onset of yield), using the procedures for strength-limited damage states.
2. Calculate the median deformation of the component, δ_y, at the onset of yield, using elastic deformation analysis under the applied median yield load.
3. Judgmentally classify the behavior mode as one of "limited ductility" associated with $\mu = 2$, "moderate ductility" associated with $\mu = 4$, or "high ductility" associated with $\mu = 6$, where μ is the presumed ratio between the deformation at the onset of the damage state to the deformation at onset of yield.
4. Calculate the median displacement demand for the onset of the damage state as $\theta = \mu\delta_y$.
5. Calculate the dispersion, β, for the damage state as:

$$\beta = \sqrt{\beta_1^2 + 0.16} \leq 0.6 \tag{3-4}$$

where β_1 is the dispersion associated with the onset of yield, calculated using the procedures for strength-based damage states.

Displacement-Limited Damage States

Some damage states are best characterized by an imposed displacement. Examples include beams resting on a bearing seat of limited length, or attachments for precast panels that rely on slotted connections to accommodate movement. In such cases, the median displacement demand at initiation of failure should be taken as the calculated available length of travel based on the specified travel allowance dimension (i.e., length of bearing seat, or length of slotted holes). The dispersion should be estimated based on the likelihood that the initial position of the structure is out of tolerance. Normal construction tolerances can be considered as representing

one standard deviation on the displacement dimension. The dispersion can then be taken as equal to the coefficient of variation, which is approximated by the standard deviation value (i.e., construction tolerance), divided by the median (i.e., travel allowance dimension).

Code-Based Limit States

In some cases, there may be insufficient information to calculate the capacity of a component. For example, information on the anchorage capacity of a piece of equipment may not be available because the anchorage has not yet been designed, or in the case of an existing installation, the details of the anchorage are not known. In such cases, the code-based design strength for the code in effect at the time of installation can be used to establish the capacity of the component. The following procedure can be used:

1. Identify the governing code for the installation, and compute the design strength (or displacement capacity) in terms of a convenient demand parameter, such as spectral acceleration, force, or story drift ratio. The code-based capacity is then taken as the presumed value of ϕR_n.
2. Decide whether the damage state is a ductile or brittle failure mode. If it is unknown which is likely, a separate calculation can be performed for ductile and brittle assumptions, and the results averaged.
3. Assign a default dispersion of $\beta = 0.5$.
4. If the mode is considered ductile, determine the median value of θ using use Equation 3-1. If the mode is considered nonductile, determine the median value of θ using Equation 3-2. In either case, a value of $C_q = 0.5$ should be assumed.

Overturning Limit States for Unanchored Components

In the case of unanchored components, limiting behavior modes include overturning and sliding damage states. The procedure for determining overturning fragilities for unanchored components has been adapted from ASCE/SEI 43-05, *Seismic Design Criteria for Structures, Systems, and Components in Nuclear Facilities* (ASCE, 2005). Fragility parameters include the median peak total floor velocity, $\hat{V}_{PT}$, at which overturning initiates, and a dispersion reflecting the uncertainty in this behavior mode. The assumptions, derivation, and basis for the procedure are presented in Appendix K.

The demand parameter is peak total floor velocity, V_{PT}, defined as the peak value of the sum of the ground velocity and the relative velocity between the

ground and the floor level. This can be visualized as the peak velocity of the floor relative to a fixed point in space during response to earthquake shaking.

Unanchored components are assumed to exhibit an oscillatory rocking behavior until a critical displacement is reached and the object becomes unstable. Components are assumed to have a rectangular shape with height, $2h$, and width, $2b$, uniform weight distribution, and are assumed to overturn about a single axis with the smallest base dimension, $2b$, as shown in Figure 3-5.

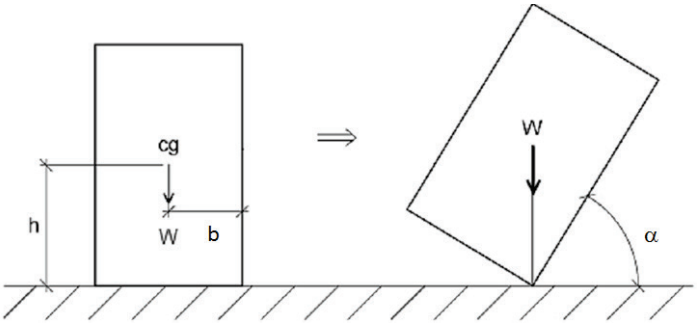

Figure 3-5 Overturning of unanchored components.

The critical tipping angle, α, at which the component will become unstable, is given by:

$$\alpha = \arctan\left(\frac{b}{h}\right) \tag{3-5}$$

The spectral acceleration capacity for overturning of the component, S_{aO}, is determined from the critical tip angle, α, and the dimensions of the component:

$$S_{aO} = \frac{2B}{\alpha} \tag{3-6}$$

where B is given by the equation:

$$B = \cos(\alpha) + \frac{b}{h}\sin(\alpha) - 1 \tag{3-7}$$

To determine if behavior is controlled by overturning or sliding, the value of S_{aO} is compared with the static coefficient of friction, μ_S. A value of S_{aO} that exceeds μ_S indicates that the component will likely slide rather than overturn (i.e., enough force will be generated to overcome the static coefficient of friction before the component has been pushed to the critical tipping angle). Conversely, values of S_{aO} that are less than μ_S indicate that the object will likely overturn rather than slide.

The estimated median peak total floor velocity, $\hat{V}_{PT}$, is obtained from the equation:

$$\hat{V}_{PT} = \frac{S_{aO} g}{2\pi f_r D_{amp}} \tag{3-8}$$

where:

$$D_{amp} = 2.31 - 0.41 * \ln(100\beta_r) \tag{3-9}$$

and the effective rocking frequency, f_r, and damping ratio, β_r, are determined by:

$$f_r = \frac{1}{2\pi}\sqrt{\frac{2gB}{C_3 \alpha^2 h}} \tag{3-10}$$

$$\beta_r = \frac{\gamma}{\sqrt{4\pi^2 + \gamma^2}} \tag{3-11}$$

where:

$$C_3 = \frac{4}{3}\left(1 + \left(\frac{b}{h}\right)^2\right) \tag{3-12}$$

$$\gamma = -2 * \ln(C_R) \tag{3-13}$$

$$C_R = 1 - \frac{2\left(\frac{b}{h}\right)^2}{C_3} \tag{3-14}$$

A dispersion of $\beta = 0.5$ is recommended for this fragility.

Sliding Limit States for Unanchored Components

The procedure for determining sliding fragilities for unanchored components is similar to the procedure for overturning, and also has been adapted from ASCE/SEI 43-05. Fragility parameters include the median peak total floor velocity, $\hat{V}_{PT}$, at which sliding will have exceeded a limiting displacement, and a dispersion reflecting the uncertainty in this behavior mode. The assumptions, derivation, and basis for the procedure are presented in Appendix K.

Before determining sliding fragility parameters for an unanchored component, it is necessary to determine if behavior will be controlled by sliding or overturning. As in the case of overturning, the spectral acceleration capacity for overturning, S_{aO}, is compared with the static

coefficient of friction, μ_S. Values of S_{aO} that exceed μ_S indicate that the component will likely slide rather than overturn.

The sliding limit state depends on the definition of a critical sliding displacement, δ, at which the component will slide off of a supporting surface or slide into another object, resulting in damage. The median value of peak floor velocity at which the component will slide a distance, δ, is determined by:

$$\hat{V}_{PT} = \frac{\sqrt{2\mu_D g\delta}}{1.37} \tag{3-15}$$

where μ_D is the dynamic coefficient of friction between the component and its supporting surface, g is the acceleration of gravity, and δ is the critical sliding displacement. As with overturning, a dispersion of $\beta = 0.5$ is recommended for this fragility.

3.9 Consequence Functions

Consequence functions are distributions of the likely consequences of damage translated into potential repair and replacement costs, repair time, casualties, unsafe placarding, and other impacts.

Consequence functions are relationships that indicate the potential distribution of losses as a function of damage state. Consequence functions translate damage into potential repair and replacement costs, repair time, casualties, unsafe placarding, and other impacts.

For each damage state, fragility specifications include repair descriptions that provide information on repair actions, materials, and quantities necessary to develop repair cost and repair time consequences. To facilitate casualty estimation, each damage state includes a description regarding potential life safety hazards associated with the damage, and the affected area over which designated life safety hazards would exist. For unsafe placarding, each damage state also includes a description of the extent to which the occurrence of damage is likely to result in posting of an unsafe placard.

Consequence functions for each damage state were developed based on descriptions of repair actions, potential life safety hazards, and unsafe placarding, using the procedures described below. Complete consequence information is contained in fragility specifications comprising the *Fragility Database*, provided as part of *Volume 3 – Supporting Electronic Materials and Background Documentation*. Guidance on modifying available consequence functions, and developing user-defined consequences, is provided in *Volume 2 – Implementation Guide*.

3.9.1 Repair Costs

Repair costs include consideration of all necessary construction activities to return the damaged components to their pre-earthquake condition. Repair actions assume repair or replacement "in-kind," and do not include work associated with bringing a non-conforming installation or structure into compliance with newer criteria. Repair costs are based on the repair measures outlined for each damage state, and include all the steps a contractor would implement to conduct a repair including:

Repair costs include the cost of all construction activities necessary to return damaged components to their pre-earthquake condition.

- Removal or protection of contents adjacent to the damaged area.
- Shoring of the surrounding structure (if necessary).
- Protection of the surrounding area (e.g., from dust and noise) with a temporary enclosure.
- Removal of architectural and mechanical, electrical, and plumbing systems, as necessary, to obtain access for the repair.
- Procurement of new materials and transport to the site.
- Conduct of the repair work.
- Replacement of architectural and mechanical, electrical, and plumbing systems, as necessary.
- Clean-up and replacement of contents.

Consequence functions for repair costs provided with the methodology were developed based on construction cost estimates computed for a reference location in the United States (Northern California) at a reference time (2011), neglecting uncertainty in contractor pricing strategies or construction cost escalation. Repair cost consequences include consideration of economies of scale and efficiencies in construction operations. When a large quantity of the same type of work is necessary, contractor mobilization, demobilization, and overhead costs can be spread over a larger volume of work, resulting in reduced unit rates. A typical consequence function for repair cost is illustrated in Figure 3-6. For each damage state, repair costs are described using the following parameters:

Repair cost consequences include consideration of economies of scale and efficiencies in construction operations.

- **Lower quantity.** Quantity of repair actions of a give type, below which there is no discount reflecting economies of scale or efficiencies in operation.
- **Maximum cost.** The unit cost to perform a repair action, excluding any economies of scale or efficiencies in operation.

- **Upper quantity.** Quantity of repair work, above which no further economies of scale or efficiencies in operation are attainable.
- **Minimum cost.** The unit cost to perform a repair action, considering all possible economies of scale and efficiencies in operation.
- **Dispersion.** Uncertainty in values of unit cost.

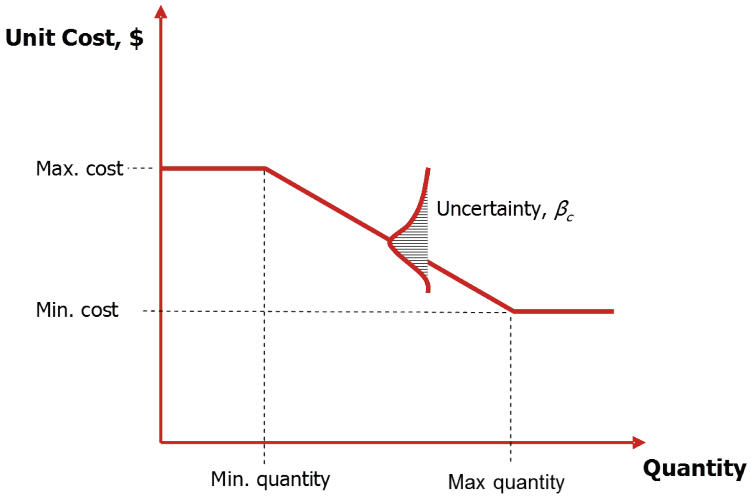

Figure 3-6 Typical consequence function for repair costs.

At each point along the consequence function, there is a distribution of potential repair costs. The distribution (and dispersion) was derived from cost data representing 10th, 50th, and 90th percentile estimates of construction cost. Both lognormal and normal distributions were developed from available repair cost data, and the curve with the best fit was used in each case.

Macro-factors are used to account for occupancy-specific conditions that affect repair effort, and to adjust cost data for inflation and building-specific location.

The cost of accessing the damaged area to conduct repairs will affect repair costs. For example, it is more difficult, and, hence, more costly, to repair damage on the tenth floor of a building than on the first floor. Similarly, cost premiums associated with access restrictions and enhanced protection measures in certain occupancies (e.g., healthcare and research laboratories) can affect repair costs. Finally, the presence of hazardous materials within the damaged area will affect the repair actions and approach to construction activities. Each of these considerations will result in increased repair costs. The methodology includes provision for "macro-factors," which are provided on a story-by-story basis, to adjust repair consequences for these effects.

The methodology also considers factors to adjust repair costs for inflation and location relative to the reference location and time used in developing the cost data. Any convenient construction cost index can be used for this

purpose, if normalized to the reference location (Northern California) and time (2011).

3.9.2 Repair Time

The actual time that a building will be unusable for beneficial re-occupancy following an earthquake is difficult to determine. Factors that can affect the length of time for building re-occupancy include:

- Who is responsible for performing repairs (e.g., owner or tenants).
- Financial resources available to the party responsible for performing repairs.
- Availability of design professionals to assess the condition of the building and design repair actions.
- Availability of contractors and availability of equipment and materials necessary to perform repairs.
- The time it takes to procure specialized equipment (i.e., long lead time) and materials for a specific building or occupancy.
- Whether or not the building will remain in service during repairs, which limits repair work to unoccupied areas, versus remaining vacant to provide complete access for conducting repairs on a building-wide basis.
- Whether or not the building has been posted with an unsafe placard, and the length of time necessary to convince a building official that it is safe to conduct repair operations within the building.

Uncertainties in these factors make reliable estimation of overall occupancy interruption time intractable. As a result, the methodology uses the following measures for consequences associated with occupancy interruption:

- The length of time necessary to conduct repairs (i.e., repair time).
- The need to procure items with long lead times.
- The probability that a building will be posted with an unsafe placard.

To estimate repair time, each damage state includes a time-related consequence function that indicates the number of labor hours associated with the specified repair actions. A key parameter for developing repair time estimates is the number of workers assumed to occupy the building at the same time. The methodology uses a "maximum worker per square foot" parameter that can be adjusted to account for whether or not the building is occupied during construction, as well as assumptions about the availability of contractor labor in the region.

Repair time is limited to the number of labor hours associated with the required repair.

Repair time consequences also include consideration of economies of scale and efficiencies in construction operations. For each damage state, repair times are described using the following parameters:

- **Lower quantity.** Quantity of repair actions of a give type, below which there is no reduction in time reflecting economies of scale or efficiencies in operation.
- **Maximum time.** The maximum number of labor hours necessary to perform a repair action, excluding any economies of scale or efficiencies in operation.
- **Upper quantity.** Quantity of repair work, above which no further economies of scale or efficiencies in operation are attainable.
- **Minimum time.** The minimum number of labor hours necessary to perform a repair action, considering all possible economies of scale and efficiencies in operation.
- **Dispersion.** Uncertainty in labor effort associated with a given repair action.

Similar to repair costs, the distribution (and dispersion) for potential repair time was derived from data representing 10^{th}, 50^{th}, and 90^{th} percentile estimates of labor effort. Both lognormal and normal distributions were developed from available data, and the curve with the best fit was used in each case.

Serial repair strategies assume work occurs sequentially between floors. Parallel repair strategies assume work occurs on all floors simultaneously. Repair time estimates include consideration of both serial and parallel repair strategies. Neither strategy is likely to represent the actual schedule used to repair a particular building, but the two extremes are expected to represent a reasonable bound to the probable repair time.

Repair time can be significantly affected by long lead times for procurement of critical equipment and components (e.g., HVAC equipment and elevators). Because lead times vary, and are case-specific, they are not explicitly calculated as part of the methodology. If a damage state requires replacement of a component that is associated with a long lead time, this is indicated in the fragility specification and is flagged as part of the assessment results.

3.9.3 Unsafe Placarding

Each damage state is associated with a potential to result in an unsafe placard. In some cases the potential is high, and in other cases the potential is low or negligible. The most severe damage states in nearly all of the structural fragility groups will trigger a potential for an unsafe placard because it is assumed that the stability of the structure has been compromised, resulting in a risk to life safety. Although nonstructural damage can be an indicator of potential structural damage, it does not, by itself, pose a life safety risk. Most nonstructural fragility groups are not associated with an unsafe placard.

The posting of an unsafe placard is a major contributor to delays in building re-occupancy following an earthquake, and can significantly affect building repair times given the presumed dangerous condition of the building. Estimation of the time associated with unsafe placarding is not explicitly calculated as part of the methodology. Instead, the likelihood of receiving an unsafe placard as a result of damage to a performance group is established. It is anticipated that, if needed or desired, the building-specific time associated with an unsafe placard can be estimated on a case-by-case basis and added to the calculated repair time consequences.

The time associated with unsafe placarding is not estimated. Instead, the likelihood of receiving an unsafe placard for each performance group, and the building as a whole, is established.

For damage states that are determined to have potential to result in an unsafe placard, the median quantity of damage that would trigger such a placard is provided. For example, in the case of reinforced concrete special moment frames, if 20% of the beam-column joints in a performance group reach damage state DS3 (i.e., concrete cracking, spalling of cover, crushing of the core, and fracture and buckling of reinforcement), it is expected that an unsafe placard will be likely.

3.9.4 Casualties

Building collapse is the principle cause of earthquake casualties. However, some damage states associated with individual components or assemblies can have potential casualty consequences. These are generally associated with falling debris (e.g., failed glazing falling out of its frame and injuring nearby occupants), but can also be associated with damage states such as the release of hot water, steam, or toxic materials.

Building collapse is the principle cause of earthquake casualties. This methodology also estimates casualties associated with falling debris and other component damage.

Casualties caused by building collapse are based on possible building collapse modes and the estimated number of building occupants. Assessment of building collapse potential is discussed in Chapter 6. The estimated number of building occupants is determined using the provided population models.

For individual components, each damage state includes a description regarding potential life safety hazards associated with the damage, and the casualty-affected planar area over which designated life safety hazards would exist. The casualty-affected planar area represents the planar area proximate to a component in which damage could result in serious injury or loss of life. The affected area is typically larger than the projected area occupied by the component to account for uncertainty in the area over which debris, spray, or hazardous material release may occur.

Not all occupants within a casualty-affected area will become casualties. Because of this, it is necessary to identify the percentage of individuals that, if located within the casualty-affected area, are likely to be injured by the component. In the case of wall-mounted electronic equipment, for example, a panel might be on the order of 5 to 10 square feet. The assumed casualty-affected area could be on the order of 16 square feet, and the percentages for serious injury and loss of life might be taken as 10% and 5%, respectively. These values are judgmentally determined.

3.10 Fragility Specifications

Damage, fragility, and consequence data provided with the methodology are recorded in fragility specifications comprising the *Fragility Database*. Fragility specifications include basic identifier information, fragility units, damage state and consequence descriptions, photos illustrating damage (when available), fragility parameters, and consequence functions, as illustrated in Figure 3-7, Figure 3-8, and Figure 3-9.

FEMA P-58 Fragility Specification

NISTIR Classification	B1041.031b				*Line 121*
NISTIR Name	ACI 318 OMF with weak joints and beam flexural response, Conc Col & Bm = 24" x 24", Beam both sides				
Description	ACI318 OMF, joint shear failure, beam flexural response. Meets the following requirements: (1) Sum Mcol / Sum Mbeam > 1.2, (2) Beam Vn > Veq, (3) Column Vn > Veq Costing is on a per joint basis.				
Construction Quality:	Not Specified				
Seismic Installation Conditions:	Not Specified				
Fragility Unit of Measure:	EA 1				
Demand Parameter (unit):	Story Drift Ratio	Unit less			
Number of Damage States:	3				
Damage State:	DS1	DS2	DS3		
Type of Damage State:	Sequential	Sequential	Sequential		
DS Hierarchy	Seq(DS1,DS2,DS3)				
Descriptions	Beams or joints exhibit residual crack widths > 0.06 in. No significant spalling. No fracture or buckling of reinforcing.	Beams or joints exhibit residual crack widths > 0.06 in. Spalling of cover concrete exposes beam and joint transverse reinforcement but not longitudinal reinforcement. No fracture or buckling of reinforcing.	Beams or joints exhibit residual crack widths > 0.06 in. Spalling of cover concrete exposes a significant length of beam longitudinal reinforcement. Crushing of core concrete may occur. Fracture or buckling of reinf. requiring replacement may occur.

Chapter 4
Define Earthquake Hazards

4.1 Introduction

Earthquake hazards are defined in terms of earthquake shaking. Earthquake effects also include ground fault rupture, landslide, liquefaction, lateral spreading, seiches, and tsunamis, but consideration of these effects are beyond the scope of the current version of the methodology.

Earthquake hazards are defined in terms of earthquake shaking. Other earthquake effects are beyond the scope of the current version of the methodology.

Earthquake shaking occurs in three dimensions, and can be completely defined by two orthogonal horizontal components and one vertical component. In most cases, however, vertical shaking is not a key contributor to earthquake damage and has little impact on seismic performance. Therefore, in most performance assessments, only horizontal earthquake shaking is considered.

This chapter describes how earthquake hazards are defined, selected, and specified in the performance assessment process. Appendix B presents background information on characterization of ground shaking hazards, and procedures that can be used to characterize vertical shaking, if deemed significant for the building under consideration.

Earthquake ground shaking is characterized by target acceleration response spectra. For nonlinear response history analysis, shaking effects are assessed by simultaneously evaluating response to orthogonal pairs of horizontal ground motion components. The ground motion pairs are scaled for consistency with the target response spectrum for the desired ground shaking intensity level. For simplified analysis, shaking is characterized by spectral response accelerations at the first mode period along each axis of the building.

Characterization of earthquake hazards varies by type of performance assessment. For intensity-based assessments, ground shaking intensity can be represented by any user-defined acceleration response spectrum (e.g., a code design spectrum). For scenario-based assessments, ground shaking intensity is represented by acceleration response spectra derived for specific magnitude-distance pairs (e.g., a known event on a specified fault) using ground motion prediction equations, also called attenuation relationships. For time-based assessments, ground-shaking intensity is represented by a

series of seismic hazard curves, and acceleration response spectra derived from these curves, at selected annual frequencies of exceedance.

4.2 Building Location and Site Conditions

4.2.1 Seismic Environment and Hazard

Earthquake hazard at a site is determined by earthquake sources in the vicinity, the propagation of seismic waves to the building, and modifications based on local site conditions.

Earthquake shaking hazards are determined by the location of the site relative to causative faults and sources, and regional and site-specific geologic characteristics. Local topographic conditions (e.g., hills, valleys, and canyons) can also affect the characteristics of shaking at a site, however, these are special cases that require site-specific investigation, and are not considered here.

4.2.2 Location

For intensity-based assessments, the location of the site need not be defined. For scenario-based assessments, the distance from the building site to the causative fault must be known. Time-based assessments require seismic hazard curves that predict the annual frequency of exceedance of key spectral response parameters. To develop hazard curves, the exact location of the site (in terms of latitude and longitude) must be identified. To adequately locate a site, latitude and longitude should be defined to a minimum of three decimal places.

4.2.3 Local Soil Conditions

The properties of site soils must be defined to enable:

- Selection of appropriately shaped spectra for intensity-based assessments.
- Selection of appropriate ground motion prediction equations for scenario-based assessments.
- Development of seismic hazard curves and response spectra for time-based assessments.

In the Western United States, it is generally sufficient to define the soil conditions to a depth of 30 m (100 ft) below the ground surface. As a minimum, it is necessary to have sufficient data to characterize the Site Class in accordance with ASCE/SEI 7-10, *Minimum Design Loads for Buildings and Other Structures* (ASCE, 2010) so that site coefficients can be assigned. For sites categorized as Site Class E or F, additional information will be needed for the necessary site response analysis. Such information will generally include the depth, classification, and shear wave velocity of materials in the soil column above bedrock.

4.3 Ground Motion Prediction Equations

Ground motion prediction equations are used to derive acceleration response spectra used in scenario-based assessments. They also form the basis for probabilistic seismic hazard analyses used to develop hazard curves for time-based assessments. Ground motion prediction equations provide estimated values of ground shaking intensity parameters, such as peak ground acceleration, peak ground velocity, and spectral response acceleration at particular structural periods, for user-specified combinations of earthquake magnitude and site-to-source distance.

Ground motion prediction equations provide estimates of spectral response acceleration parameters for specified earthquake magnitude and site-to-source distance based on regression analyses of past strong motion recordings.

Seismologists derive ground motion prediction equations from regression analyses on values of intensity parameters obtained from strong motion recordings in past earthquakes. Regression analyses consider site-to-source distance, earthquake magnitude, and other parameters. Strong motion recordings are typically obtained from pairs of instruments arranged to capture orthogonal components of motion. At any instant in time, each orthogonal component will have a different amplitude, and it is possible that neither component will represent the maximum amplitude at a given time. Most ground motion prediction equations provide geometric mean (geomean) spectral response accelerations represented by the quantity:

$$S_{gm}(T) = \sqrt{S_x(T) \times S_y(T)} \qquad (4\text{-}1)$$

where $S_x(T)$ and $S_y(T)$ are orthogonal components of spectral response acceleration at period T. The X and Y directions could represent the actual recorded orientations, or they could represent a rotated axis orientation. Some equations rotate the motion to capture fault-normal and fault-parallel orientations, while others use an arbitrary rotation intended to capture a maximum orientation. The geomean approximately represents a statistical mean response. As a mean value, actual shaking in any direction has an equal probability of being higher or lower than the geomean. For example, maximum response acceleration can be as high as130% of the geomean or more, while the minimum response acceleration can as low as 80% of the geomean, or less. Except within a few kilometers of the rupture zone, the orientation of maximum spectral response with respect to the strike of the fault is random, and varies with period.

Scenario assessments can be used to assess the effects of a repeat of an historic earthquake, or to explore the effects of a selected-magnitude event on a nearby fault. The United States Geological Survey (USGS) posts information on best-estimate maximum magnitudes for active faults in the

Western United States and the Inner Mountain seismic region on the USGS website at http://www.usgs.gov/.

Fault directivity effects can have a substantial impact on the amplitude, duration, and period content of shaking, and should be considered for scenario-based assessments if the selected earthquake is M_w 6.0 or greater, and the building site is located within 20 km to 30 km of the presumed fault rupture zone. Directivity should be specified as: (1) forward directivity (rupture progresses towards the site); (2) reverse directivity (rupture progresses away from the site); (3) null directivity; or (4) unspecified directivity (random direction of rupture progression). Appendix B and NIST GCR 11-917-15, *Selecting and Scaling Earthquake Ground Motions for Performing Response History Analyses* (NIST, 2011), provide guidance on consideration of fault-rupture directivity.

At sites located within the forward directivity region of strike-slip faulting, ground shaking often exhibits directivity effects, and shaking in the fault-normal direction contains velocity pulses and significantly larger amplitudes than shaking in the fault-parallel direction. Hazard assessments on sites within 20 km of strike-slip faults should consider these effects.

Some ground motion prediction equations are quite complex. Simpler models, often called attenuation relationships, take the basic form:

$$\ln Y = c_1 + c_2 M - c_3 \ln R - c_4 R + \gamma \tag{4-2}$$

where Y is the median value of the strong-motion parameter of interest (e.g., geometric mean spectral acceleration at a particular period), M is the earthquake magnitude, R is the source-to-site distance, and γ is a standard error term. Additional terms can be used to account for other effects including near-source directivity, faulting mechanism (e.g., strike-slip, and reverse strike-slip), and site conditions.

Although many ground motion prediction equations have been developed, most apply to a specific geographic region based on the data set of ground motion records used to develop the relationships. It is important to ensure that the selected equation is appropriate to the particular building site and earthquake source mechanism.

Appendix B provides a list of selected ground motion prediction equations for North America. The Open Seismic Hazard Analysis website, http://www.opensha.org/, provides a ground motion prediction equation plotter that can be used to generate median spectra and dispersions for models including Boore and Atkinson (2008), Campbell and Bozorgnia

(2008), and Chiou and Youngs (2008) used by the USGS to produce the national seismic hazard maps referenced in ASCE/SEI 7-10.

For a particular earthquake scenario and site, different attenuation relationships can provide significantly different estimates of the probable values of spectral response acceleration. These are caused by differences in the data set of records used to develop each relationship, as well as differences in the functional form of the relationships. Figure 4-1 plots values of 0.2 second spectral response acceleration versus site-to-source distance, derived from three ground motion prediction equations, for two earthquake magnitudes. Differences between the values predicted by each equation are evident in the figure, and these differences are sources of uncertainty in determining ground motion intensity for a scenario.

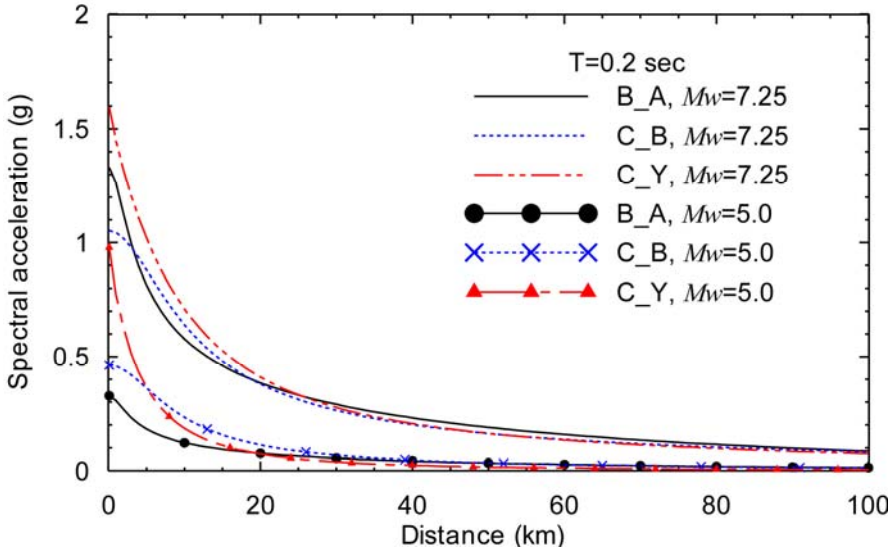

Figure 4-1 Differences between Boore and Atkinson (B_A), Campbell and Bozorgnia (C_B), and Chiou and Youngs (C_Y) ground motion prediction equations.

Ground motion prediction equations can be used to develop acceleration response spectra by repeatedly applying the equation to a range of periods. Some prediction equations use shear-wave velocity in the upper 30 m of soil as an input variable, while others are applicable only for a particular soil type. If the selected equation has an input variable for shear wave velocity in the upper 30 m, the site-specific value should be used in seismic hazard calculations.

If the selected equation uses a generic description of the reference soil type (e.g., soft rock) and reports the reference shear wave velocity, spectra should be adjusted for the site-specific shear wave velocity in the upper 30 m of the

soil column. Adjustments can be made using site-response analysis or factors for Site Class, as specified in ASCE/SEI 7-10, or other references.

Each relationship includes a measure of uncertainty associated with the lack of a perfect match between values predicted by the equation and the measured values upon which they were based. Some models permit calculation of a distribution of response acceleration values. Figure 4-2 illustrates a range of response spectra plotted for different probabilities of exceedance for a M_w 7.25 earthquake, all derived from a single ground motion prediction equation.

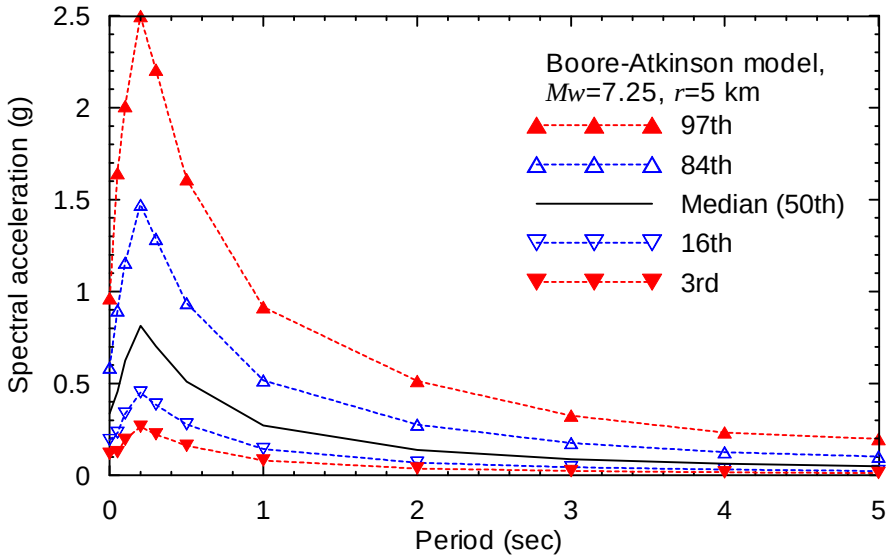

Figure 4-2 Response spectra with different probabilities of exceedance derived from a single ground-motion prediction equation for an earthquake scenario of M_w=7.25 and r=5 km.

4.4 Nonlinear Response History Analysis

Basic steps for ground motion selection and scaling include:
1. Development of a target response spectrum.
2. Selection of a suite of ground motions.
3. Scaling of motions for consistency with the target spectrum.

This section describes recommended procedures for selecting and scaling acceleration histories for use with nonlinear response history analysis. These include:

- Development of an appropriate target acceleration response spectrum.
- Selection of an appropriate suite of earthquake ground motions.
- Scaling of motions for consistency with the target spectrum.

These procedures are applicable to intensity-based, scenario-based, and time-based assessments. Appendix B provides an alternate procedure for use with scenario-based assessments that explicitly considers uncertainty in ground motion.

4.4.1 Target Acceleration Response Spectra

For intensity-based assessments, any spectrum can be used as a target spectrum. The spectral shape should be consistent with the geologic characteristics of the site. For scenario-based assessments, the target spectrum should be derived directly from an appropriate ground motion prediction equation. For time-based assessments, one spectrum is required for each of the several seismic hazard intervals used in the analysis. Seismic hazard intervals are selected from the seismic hazard curve for the site.

Target spectra can be Uniform Hazard Spectra, Conditional Mean Spectra, or Conditional Spectra, as defined in Appendix B.

Target spectra can be Uniform Hazard Spectra (UHS), Conditional Mean Spectra (CMS), or Conditional Spectra (CS). These are described in Appendix B. For intensities with high annual frequencies of exceedance (i.e., frequent events), Uniform Hazard and Conditional Mean Spectra should be similar in shape. For intensities with low annual frequencies of exceedance (i.e., rare events), the amplitude of Conditional Mean Spectra will be smaller at some periods than Uniform Hazard Spectra, as the Conditional Mean Spectrum considers the low likelihood of high amplitudes over the entire range of periods given the amplitude at the period of interest. In this regard, the CMS quantifies a less conservative and more realistic "scenario spectrum" for a particular intensity. Conditional Spectra differ from Conditional Mean Spectra in that they consider uncertainty as well as amplitude in determining spectral values at each period. Use of either Conditional Mean Spectra or Conditional Spectra will provide more accurate estimates of median story drift and acceleration response for a given intensity of shaking than Uniform Hazard Spectra, but additional effort is required to generate these spectra.

If Conditional Mean Spectra are used, it is necessary to select an appropriate period upon which to condition the spectrum. If a building has identifiable modes associated with translational response along two orthogonal axes, *X* and *Y*, the corresponding fundamental translational periods associated with each axis are denoted T_1^X and T_1^Y, respectively. Conditional Mean Spectra should be developed based on the hazard at period $\overline{T}$, taken as the average of periods T_1^X and T_1^Y. For buildings without identifiable response modes in each of the *X* and *Y* axes, $\overline{T}$ should be taken as the period of the fundamental mode T_1. Development of Conditional Mean Spectra is described in in Appendix B.

4.4.2 Ground Motion Selection and Scaling

The intent of ground motion selection and scaling is to obtain a set of motions that will produce unbiased estimates of median structural response when used with nonlinear response history analysis. Ground motions are

selected such that, on average, they reasonably match the target spectrum over the period range T_{min} to T_{max}. For buildings with identifiable translational response modes in each of the *X* and *Y* axes, T_{max} is taken as twice the larger value of T_1^X and T_1^Y. For buildings without identifiable response modes in each of the *X* and *Y* axes, T_{max} is taken as twice the period of the fundamental period, T_1. Period, T_{min}, is taken as the smaller of $0.2T_1^X$ and $0.2T_1^Y$. If substantial response, and corresponding damage, is expected to occur in modes with periods less than T_{min} (e.g., in tall buildings where higher modes may contribute significantly to acceleration and drift response), T_{min} should be taken as low enough to capture these important behaviors.

To the extent possible, selected pairs of earthquake ground motions should have a spectral shape that is similar to the target spectrum. In addition, selected records should have faulting mechanisms, earthquake magnitudes, site-to-source distances, and local geology that are similar to those that dominate the seismic hazard at the particular intensity level, although these considerations are not as significant as overall spectral shape. For near-fault sites in the forward directivity region, and for buildings with velocity-sensitive nonstructural components and systems, ground motion selection should also consider the amplitude and shape of the scaled velocity time series. Ground motions are available from a number of sources, including www.peer.berkeley.edu and www.cosmos-eq.org.

Selected pairs of ground motions should have a spectral shape that is similar to the target spectrum over the period range of interest. When the fit is good, at least 7 pairs of motions should be used. When the fit is poor, 11 pairs of motions, or more, are recommended.

Limited study suggests that when the spectral shape of the selected motions matches the target spectrum well, relatively few records can provide a reasonable estimate of median response over the height of the building. Regardless of the fit, at least seven ground motion pairs should be used. When there is significant scatter in the spectral shape of selected records (i.e., there is a poor fit to the target spectrum), eleven or more pairs of motions may be needed to produce reasonable estimates of median response.

Intensity-Based Assessments

Intensity-based assessments require a target acceleration response spectrum and suites of *n* ground motions scaled for compatibility with this spectrum. The following procedure should be used to select and scale ground motions for intensity-based assessments:

1. Select the target response spectrum.
2. Select a candidate suite of ground motion pairs from available sets of recorded motions.
3. Using Equation 4-1, construct the geomean spectrum for each ground motion pair over the period range $T_{min} \le T \le T_{max}$. Compare the geomean

shape with the shape of the target spectrum. Select ground motion pairs with geomean spectral shapes that are similar to the target spectrum over the period range $T_{min} \le T \le T_{max}$. Discard ground motion pairs that do not adequately fit the shape of the target spectrum.

4. Amplitude-scale both components of each ground motion pair by the ratio of $S_a(\overline{T})$ obtained from the target spectrum to the geometric mean $S_{gm}(\overline{T})$ of the recorded components, where $\overline{T}$ is the average of periods T_1^X and T_1^Y.

Scenario-Based Assessments

Scenario-based assessments require a target median response spectrum for the scenario derived from a ground motion prediction equation, a measure of the dispersion associated with this spectrum, and suites of *n* ground motion pairs scaled for compatibility with the spectrum. Ground motion intensity is assumed to be lognormally distributed with median value, θ, and dispersion, β. In this procedure, ground motion dispersion is indirectly considered in the modeling uncertainty assumed in response calculation (Chapter 5). Appendix B presents an alternate procedure for ground motion selection that explicitly considers ground motion dispersion. If the alternate procedure is used, assumptions for modeling uncertainty in response calculation must be adjusted accordingly.

The following procedure should be used to select and scale ground motions for scenario-based assessments:

1. Select the scenario magnitude and site-to-source distance.
2. Select an appropriate ground motion prediction equation for the region, site soil type, and source characteristics.
3. Establish the period range (T_{max}, T_{min}).
4. Construct a median spectrum over the period range $T_{min} \le T \le T_{max}$ using the selected ground motion prediction equation.
5. Select and scale suites of *n* ground motion pairs using Steps 2 through 4 for intensity-based assessments, above.

Time-Based Assessments

Time-based assessments require seismic hazard curves for spectral acceleration, $S_a(\overline{T})$, and suites of ground motion pairs selected and scaled to match spectra derived from the seismic hazard curves in the period range $T_{min} \le T \le T_{max}$ over a range of exceedance frequencies (i.e., intensities). Hazard curves include explicit consideration of ground motion uncertainty.

The following procedure should be used to determine analysis intensities, and to select and scale ground motions for time-based assessments:

Step 1 – Select Intensity Range. An appropriate range of ground motion exceedance frequencies and corresponding spectral response accelerations, $S_a(\bar{T})$, must be selected for the building under consideration. A range of exceedance frequencies is considered appropriate if it is associated with a range of spectral acceleration intensities that would be expected to cause building damage ranging from negligible to complete loss. For new buildings designed in accordance with ASCE/SEI 7-10, an appropriate range of exceedance frequencies is:

- Minimum mean annual frequency of exceedance corresponding to $S_a(\bar{T}) = S_a^{min} = 0.05\text{g}$ for $\bar{T} \le 1$ second, and $S_a^{min} = 0.05/\bar{T}\,\text{g}$ otherwise.
- Maximum mean annual frequency of exceedance taken as 0.0002, with S_a^{max} taken as $S_a(\bar{T})$ at this exceedance frequency.

Older, non-ductile buildings are more likely to experience damage at low levels of shaking, and collapse at moderate levels of shaking, than modern code-conforming buildings. For weak or otherwise damageable buildings, the range of exceedance frequencies suggested above should be modified. Specifically the lower bound should be adjusted so that the corresponding spectral acceleration at that level does not result in damage to structural or nonstructural components. The upper bound should be adjusted to a level at which no more than two intensities of shaking within the range trigger collapse.

Step 2 – Select Analysis Intensities and Scale Motions. Structural analysis will be performed at a series of intensities spanning the range of intensities selected in Step 1, above. Intensities should be determined, and ground motions should be selected and scaled, as follows:

1. Develop a seismic hazard curve for $S_a(\bar{T})$.
2. Compute the range of spectral accelerations S_a^{min} and S_a^{max} per Step 1, above.
3. Split the range of spectral acceleration, S_a^{min} to S_a^{max}, into *m* intervals (*m* = 8 is recommended); identify the midpoint spectral acceleration and the mean annual frequency of exceedance at each end of the interval (see Figure 4-3).
4. From the hazard curve, extract the mean annual frequency of exceedance of the midpoint spectral acceleration for each interval. Calculate the mean annual probability of occurrence, which is used to determine

average annual losses. The mean annual probability of occurrence of ground motions within an interval, $\Delta\lambda_i$, is the difference between the mean annual frequencies of exceedance at the end points of the interval.

5. Develop a target spectrum for each interval, using the mean annual frequency of exceedance of each midpoint spectral acceleration. This can be done using tools on the Open Seismic Hazard Analysis website, http://www.opensha.org/, or the USGS website at http://www.usgs.gov/.

6. For each target spectrum, select and scale suites of *n* ground motion pairs using Steps 2 through 4 for intensity-based assessments, above.

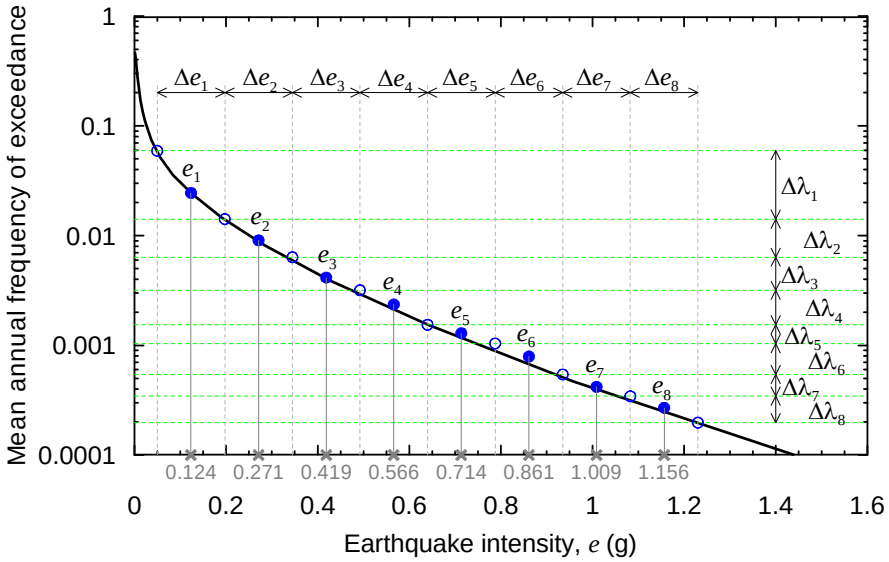

Figure 4-3 Example hazard characterization for time-based assessments showing intensity intervals, midpoint spectral accelerations, mean annual frequencies of exceedance, and mean annual probabilities of occurrence.

4.5 Simplified Analysis

This section provides procedures for earthquake hazard characterization for use in the simplified analysis procedure described in Chapter 5.

4.5.1 Intensity-Based Assessments

For intensity-based assessments, earthquake intensity is defined by any 5% damped, elastic, horizontal acceleration response spectrum. The simplified analysis procedure uses spectral response accelerations at the fundamental period of translational response in each of two orthogonal directions, T_1^X and T_1^Y, derived from that spectrum.

4.5.2 Scenario-Based Assessments

In scenario-based assessments using the simplified analysis procedure, earthquake hazard should be characterized as follows:

1. Select the magnitude and site-to-source distance for the scenario event.
2. Select an appropriate ground motion prediction equation for the region, site soil type, and source characteristics.
3. Determine the median values of the spectral response acceleration at the periods of the first translational mode along each axis of the building, T_1^X and T_1^Y.

4.5.3 Time-Based Assessments

Time-based assessments make use of site-specific seismic hazard curves. Guidance on selecting an appropriate range of intensities is provided in Section 4.4.2. In time-based assessments using the simplified analysis procedure, earthquake hazard should be characterized as follows:

1. Develop a seismic hazard curve for $S_a(\overline{T})$.
2. Compute the spectral accelerations S_a^{min} and S_a^{max}.
3. Split the range of spectral acceleration, S_a^{min} to S_a^{max}, into *m* intervals; (*m* = 8 is recommended); identify the midpoint spectral acceleration and the mean annual frequency of exceedance at each end of the interval (see Figure 4-3).
4. From the hazard curve, extract the mean annual frequency of exceedance of the midpoint spectral acceleration for each interval. Calculate the mean annual probability of occurrence, which is used to determine average annual losses. The mean annual probability of occurrence of ground motions within an interval, $\Delta\lambda_i$, is the difference between the mean annual frequencies of exceedance at the end points of the interval.
5. Develop a spectrum (e.g., UHS, CMS, or CS) for each mean annual frequency of exceedance of Step 3.
6. For each of the *m* spectra, determine the values of the spectral response acceleration at the periods of the first translational mode along each axis of the building, T_1^X and T_1^Y.

Chapter 5
Analyze Building Response

5.1 Introduction

Structural analysis is used to evaluate building response to earthquake shaking and produce estimated median values of structural response parameters that are predictive of structural and nonstructural damage. Key response parameters include floor accelerations, floor velocities, story drift ratios, and residual drift ratios.

Structural analysis is used to provide median estimates of key response parameters that are predictive of structural and nonstructural damage.

This chapter presents two alternative analysis procedures that can be used to predict peak values and estimate dispersion in structural response. Section 5.2 provides guidance on using nonlinear response history analysis to predict median response and dispersion. Section 5.3 describes a simplified analysis procedure for predicting median response and dispersion using linear static analysis and the yield strength of the structure. Section 5.4 presents equations for calculating residual drift ratios based on nonlinear response history analysis or simplified analysis results.

Analysis procedures include nonlinear response history and simplified analysis.

The procedures in the chapter are not suitable for evaluation of building collapse. The procedures of Chapter 6 should be used for estimating the collapse capacity of a structure.

5.2 Nonlinear Response History Analysis

Nonlinear response history analysis can be used to assess performance of any structure at any ground shaking intensity. Nonlinear response history analysis is used to generate sets of demands, such as story drift ratios, floor accelerations, and floor velocities, which are predictive of performance. These sets are used to develop statistics including median values and dispersions for each demand parameter of interest, and to derive correlations between different demands in the set.

The following sections provide limited guidance on nonlinear modeling for performance assessment. Comprehensive guidance on nonlinear simulation of building response is beyond the scope of this report. More detailed information can be found in NIST GCR 10-917-5, *Nonlinear Structural Analysis for Seismic Design: A Guide for Practicing Engineers* (NIST, 2010a), PEER/ATC-72-1, *Modeling and Acceptance Criteria for Seismic Design and Analysis of Tall Buildings* (ATC, 2010), and FEMA P-440A,

Effects of Strength and Stiffness Degradation on Seismic Response (FEMA, 2009c).

5.2.1 Modeling

Buildings should be modeled, analyzed, and assessed as three-dimensional assemblies of components, including all elements that provide measurable strength and stiffness.

Buildings should be modeled, analyzed, and assessed as three-dimensional assemblies of components, including the foundation, and considering soil-structure interaction effects, as necessary. All structural framing and nonstructural components that contribute significantly to the strength or stiffness of the building should be explicitly included in the analytical model.

Modeled components should typically include nonlinear representation of force-deformation behavior. Elastic component representations should only be substituted for nonlinear component models if elastic response is confirmed for the ground motion intensities under consideration. Components can be modeled using a variety of techniques, ranging from frame elements with concentrated plastic hinges, to detailed finite element and fiber element representations. Strength and stiffness degradation should be considered to the extent that these behaviors are expected to influence structural response at the intensities under consideration. Component modeling parameters should be verified against test data, or appropriate idealized backbone response curves, such as those recommended in PEER/ATC-72-1 and ASCE/SEI 41-06, *Seismic Rehabilitation of Existing Buildings* (ASCE, 2007), should be used.

The goal of an analysis used for performance assessment is to generate an estimate of the expected response of the building, and its components, to earthquake shaking. Median values of modeling parameters (e.g., initial stiffness, yield strength, plastic deformation limits) should be used, if known. However, mean values are more commonly available than median values, and can be used where insufficient information is available to accurately characterize the median and distribution of modeling parameters.

Component Force-Deformation Relationships

Nonlinear component behavior is typically characterized by an initial stiffness, yield strength, peak strength, plastic deformation capacity, and residual strength.

Element and component models are characterized by force-deformation relationships like those shown in Figure 5-1, with a single force parameter (e.g., axial load, shear, or moment), Q, plotted against a characteristic displacement (or rotation) parameter, Δ. Force-deformation behavior is typically characterized by an initial stiffness, yield strength, peak strength, plastic deformation capacity, and residual strength. The characteristic strength and deformation quantities shown in the figure are useful indices for calibration, validation, or comparison of component models.

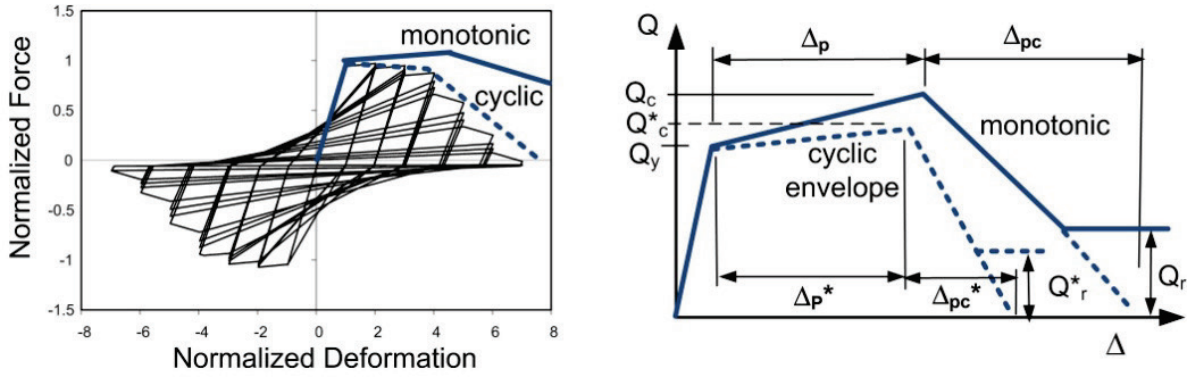

Figure 5-1 Generalized component force-deformation behaviors.

Historically, the term "backbone curve" has referred to many different things, and component backbone relationships can be envelopes of monotonic or cyclic loading response (FEMA, 2009c). The maximum strength that a component can develop at a given level of deformation is termed the force-displacement capacity boundary, and is generally equal to the response of the component to monotonic loading. A force-deformation curve that envelopes the hysteretic behavior of a component is termed the cyclic envelope. Cyclic envelopes are not unique, and they depend on the loading protocol used in component testing. Deformation capacities, peak strength, and residual strength parameters typically degrade under repeated cyclic loading.

Historically, the term "backbone curve" has referred to many different things, and component backbone relationships can be envelopes of monotonic or cyclic loading response.

Force-deformation relationships such as those presented in ASCE/SEI 41-06 (Figure 5-2), are defined based on a cyclic envelope curve to approximately capture cyclic degradation effects that are not explicitly included in the analytical model. In Figure 5-2, the "a", "b" and "c" parameters of ASCE/SEI 41-06 nonlinear force-deformation relationships are comparable to the Δ_p*, Δ_{pc}* and Q_r* parameters of Figure 5-1.

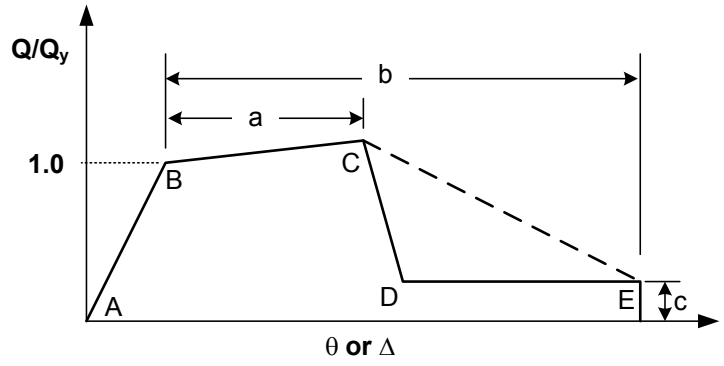

Figure 5-2 Generalized force-deformation relationship adapted from ASCE/SEI 41-06 (ATC, 2010).

The choice of backbone curve (monotonic or cyclic) depends on the capabilities of the analytical model.

The choice of backbone curve (monotonic or cyclic) depends on whether the analytical model is capable of explicitly simulating cyclic degradation or not. Direct modeling of cyclic degradation begins with a monotonic backbone curve, and degrades this relationship as the analysis proceeds, considering the cyclic loading history that is imposed on the component. Indirect modeling of cyclic degradation utilizes a cyclic envelope to define the component backbone curve, and additional cyclic deterioration is ignored. Although it is desirable to employ direct modeling of cyclic degradation, few commercial software packages have elements capable of doing so, and indirect modeling is most often used.

The envelope of component force-deformation behavior has a significant effect on overall building response (FEMA, 2009c). Types of degradation include cyclic degradation and in-cycle degradation, as illustrated in Figure 5-3. Cyclic degradation is characterized by loss of strength and stiffness occurring in subsequent cycles. In-cycle degradation is characterized by loss of strength and negative stiffness occurring within a single cycle. Studies have shown that components exhibiting cyclic degradation can have stable dynamic response, but components exhibiting in-cycle degradation are prone to dynamic instability (i.e., collapse). Differences are less significant for ductile components where imposed deformations do not exceed the peak strength (less than Δ_p or Δ_p* in Figure 5-1).

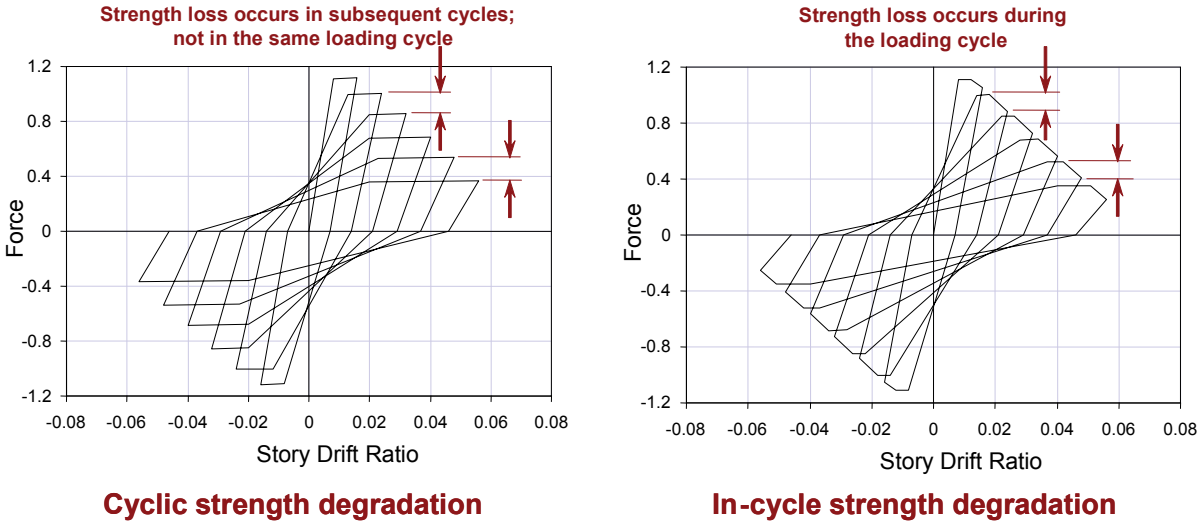

Figure 5-3 Comparison of cyclic versus in-cycle degradation of component response (FEMA, 2009c).

Ideally, the cyclic envelope should be determined based on tests conducted using several different loading protocols. One such protocol is given by ATC-24, *Guidelines for Cyclic Seismic Testing of Components of Steel Structures* (ATC, 1992), which represents the loading demands of a

characteristic earthquake. Further guidance on modeling component force-deformation behavior is provided in PEER/ATC-72-1, FEMA P-440A, and Ibarra et al. (2005).

Geometric Nonlinear Effects

P-delta effects can significantly increase displacements and internal member forces in the post-yield response of a structure. *P*-delta effects should, therefore, be accounted for in nonlinear analysis, even when elastic design provisions would otherwise allow them to be neglected.

Gravity Loads

Gravity loads based on expected dead and live loading should be considered in the analysis, along with the entire seismic mass of the structure. Expected live loads typically include about 25% of the unreduced design live load.

Damping

In nonlinear response history analysis, most energy dissipation is modeled directly through the hysteretic response of structural components. Therefore, equivalent viscous damping assigned in the analytical model should be limited to energy dissipation that is not otherwise captured by element hysteresis. Generally, this includes: (1) energy dissipation associated with components that are modeled as elastic but are expected to experience limited cracking or yielding; (2) architectural cladding, partitions and finishes, that are not modeled; and (3) interaction between the soil and foundation, when soil-structure interaction effects are not modeled. Equivalent viscous damping should typically be assigned in the range of 1% to 5% of critical damping in the predominant vibration modes of the structure. Values of 3% or less should be used for tall buildings and other structures where damping effects associated with foundations and nonstructural cladding are small relative to the structural hysteretic effects.

Most energy dissipation is explicitly modeled through the hysteretic response of structural components. Equivalent viscous damping assigned in the analytical model should be limited to 5% or less in typical buildings, and 3% or less in tall buildings.

When energy dissipation devices (e.g., dampers) are installed in a structural system, these components should be modeled explicitly using appropriate component models, including velocity terms to capture viscous effects and nonlinear springs to capture hysteretic effects. Additional guidance on modeling of damping is provided in PEER/ATC-72-1.

Diaphragms

Diaphragms should be modeled using appropriate stiffness assumptions. A diaphragm can be classified as rigid if the maximum in-plane lateral deformation of the diaphragm is less than one half of the average drift in the

stories above and below the subject diaphragm for the same intensity of shaking. Diaphragms that do not meet this criterion, and diaphragms in which significant shear transfer occurs between vertical lines of resistance (i.e., out-of-plane offset discontinuities), should be modeled explicitly using finite elements. Mass should be distributed across the floor (and roof) to capture torsional and in-plane response. If the diaphragms will not remain elastic at the ground motion intensities under consideration, a nonlinear representation should be used.

Soil-Structure Interaction

Where compliance at the soil-foundation interface will significantly alter the dynamic characteristics of the structure, or change the pattern of deformation response, soil-structure interaction effects should be modeled.

Foundations likely to uplift or slide at the ground motion intensities under consideration should be modeled to capture these effects. Where compliance at the soil-foundation interface will significantly alter the dynamic characteristics of the structure, or change the pattern of deformation response, this should also be modeled.

Soil-structure interaction effects will generally be most significant for stiff buildings founded on soft soils. NIST GCR 12-917-21, *Soil-Structure Interaction for Building Structures* (NIST, 2012), introduced the structure-to-soil stiffness ratio, $h/(V_sT)$, as a test for the significance of soil-structure interaction effects. In this equation, h is the effective height of the structure, taken as to-thirds of the modeled building height, V_s is the average effective overburden-corrected shear wave velocity of the soil profile below the site, and T is the fixed-base period of the building in the direction under consideration. Values of $h/(V_sT)$ exceeding 0.1 indicate that soil-structure interaction effects are likely to be significant. See NIST GCR 12-917-21 for detailed guidance on the calculation and interpretation of the structure-to-soil stiffness ratio.

Appendix B provides limited guidance on modeling soil-foundation-structure systems together with a discussion on the likely impact of soil-structure interaction on foundation input motions. NIST GCR 12-917-21 provides detailed guidance on procedures that can be used to model soil-foundation springs and dashpots, together with example applications. Alternatively, approximate methods of soil-structure interaction analysis found in FEMA 440, *Improvement of Nonlinear Static Seismic Analysis Procedures* (FEMA, 2005), can also be used.

Foundation Embedment

Depending on the site characteristics and the dynamic properties of the building, foundation input motions (i.e., the ground motions imparted at the base of a structure) can be substantially different from free-field ground

motions. Known as kinematic interaction effects, differences between free-field and foundation input motions are another result of soil-structure interaction effects. For structures with basements exceeding one story in depth, consideration should be given to modifying free-field motions to derive foundation input motions for analysis of the structure. Site-specific response analysis can be used for this purpose. Approximate procedures can also be used to reduce the amplitude of the target response spectrum. Appendix B and NIST GCR 12-917-21 provide more detailed guidance on this topic.

Non-Simulated Deterioration and Failure Modes

Ideally, all significant modes of component deterioration (and failure) should be incorporated directly into the analytical model. In new building designs that employ ductile detailing provisions and capacity design concepts, nonlinear analysis can often simulate the complete response of the building because nonlinear behavior is controlled in components with predictable deterioration characteristics. In certain structural systems, however, components do not have well-defined post-yield behaviors, and there can be rapid, non-ductile, strength and stiffness degradation that cannot be simulated in a nonlinear analysis. For example, premature shear failures in concrete columns or walls, torsional-flexural buckling of laterally unbraced steel members, or connection and splice failures are all behaviors that are difficult to include in an analytical model.

Non-simulated failure modes involve the selection of criteria beyond which the response of an individual component, or the overall model, cannot be trusted to be a reliable indicator of building response.

In such cases, steps should be taken to assure that modeling does not overestimate the available structural resistance when failure modes have not been explicitly simulated. Particular attention should be given to failure modes that might trigger building collapse. One technique involves the definition of non-simulated failure criteria, beyond which the response of an individual component, or the overall model, cannot be trusted to be a reliable indicator of building response.

Foundations are rarely included in building models, but can be damaged by earthquake shaking. Damage to vulnerable foundation components can be treated as non-simulated failure modes, but appropriate fragility and consequence functions will need to be assigned to include these impacts in loss calculations. For buildings with vulnerable foundation components, analyses that produce failure-level demands should not be considered valid for purpose of developing response statistics and generation of realizations.

5.2.2 Number of Analyses

The number of ground motion pairs necessary to obtain valid estimates of median response was discussed in Chapter 4. It depends on how well the geomean spectral shape of the scaled motions matches the shape of the target spectrum in the period range T_{min} to T_{max}. When ground motions are selected without consideration of spectral shape, analyses using 11 pairs of properly scaled motions can provide a reasonable estimate of median response, defined as 75% confidence of being within plus or minus 20% of the median (Huang et al., 2011). Limited study suggests that when a good match between the spectral shape of the selected motions and the target spectrum is obtained, use of fewer records can provide a reasonable prediction of median response. Regardless of the goodness of fit, a minimum of 7 ground motion pairs is recommended because of extremely poor prediction of record-to-record variability obtained in small suites of ground motions.

The number of analyses required for each scenario or intensity level depends on the match to the shape of the target spectrum. When the match is good, at least 7 pairs of motions should be used. When the match is poor, 11 pairs of motions, or more, are recommended.

For time-based assessments, nonlinear analyses are conducted at m different intensity levels representing intervals along the seismic hazard curve. A value of $m = 8$ is recommended, although it may be possible to use fewer intervals for some structures and seismic hazard environments. At each intensity level, at least 7 ground motion pairs should be used. If the selected motions do not have a good match to the spectral shape of the target spectrum, 11 or more motions may be necessary.

When performing nonlinear response history analysis at values of ground shaking intensity, $S_a(\overline{T})$, that approach the median collapse capacity of the structure, it is likely that one or more of the n sets of ground motion pairs will result in prediction of structural collapse, as evidenced by solution instability, predicted story drift ratios exceeding the range of validity of the analytical model, or predicted demands that suggest the onset of one or more non-simulated collapse modes. Although it is possible to obtain additional ground motions pairs and perform additional analyses to replace the motions that produce collapse, this is not always necessary, and for shaking intensities where the collapse probability is high, it is impractical to do.

The following procedures are recommended when analytically predicted collapse is encountered in q or more sets of the n ground motion pairs at a given ground motion intensity:

- Simulated demands sets used for loss calculation are conditioned on the non-collapsed state of the structure. Therefore, analysis results from any ground motion pair that results in prediction of collapse, either simulated or non-simulated, should not be included in the suites of analytical results used to generate simulated demands sets. These analyses,

however, can useful in developing the collapse fragility of the structure, as described in Chapter 6.

- If the remaining number of ground motion pairs for which collapse did not occur (n-q) is greater than or equal to 7, it is acceptable to use the results from the remaining (n-q) analyses to obtain estimates of demand at this ground motion intensity. No further analyses are required at this intensity level.
- If the remaining number of ground motion pairs for which collapse did not occur (n-q) is less than or equal to 7, then additional ground motion pairs should be selected until at least 7 analyses that do not predict collapse are obtained. It is important to note that if the ground shaking intensity at which analysis is performed is associated with a collapse probability greater than 0.5, a very large number of analyses may be necessary to obtain 7 runs that do not predict collapse. At such ground motion intensities, building performance will be dominated by the probability of collapse. Therefore, it is recommended that ground motion intensities associated with collapse probabilities greater than 0.5 not be used to determine demand. Chapter 6 provides information on determining the collapse probability at different ground motion intensities.

5.2.3 Floor Velocity and Floor Acceleration

Typical output from nonlinear response history analysis includes peak values of displacement, nonlinear deformation demands, and component forces. Although some component fragility functions use component force or deformation demand as the predictive demand parameter, most fragility functions are based on story drift ratio, floor acceleration or floor velocity. Most structural analysis software does not directly provide results in these forms, so some post-processing may be needed to obtain these quantities. Drift ratio is the difference in displacement at adjacent floor levels divided by the story height. Floor velocity can be calculated by numerical differentiation, which consists of dividing the difference in floor displacements at adjacent time steps by the size of the time step. If floor acceleration is not directly available, it can be obtained by taking a second numerical differential, which consists of dividing the difference in computed floor velocities at adjacent time steps by the size of the time step.

5.2.4 Quality Assurance

Nonlinear analysis is a complex process. To assure meaningful results, models should be carefully checked to establish their reliability.

Nonlinear analysis is a complex process. To assure meaningful results, models should be carefully checked to establish their reliability. The following steps are suggested:

- Results of linear dynamic (response spectrum) analyses should be compared to results of nonlinear response history analyses to assess the degree of nonlinearity in the structure under various ground motion intensities, and to confirm that under low intensity motions, the nonlinear model is behaving in a manner that is consistent with the linear model.
- Nonlinear static analyses under lateral and gravity loading should be used to interrogate inelastic mechanisms, plastic deformations, and inelastic force redistributions, to confirm these with expected behavior.
- Nonlinear analyses should be run both with and without *P*-delta effects to establish the sensitivity of the results to gravity loads and large deformations.
- Plots of the hysteretic response of selected components should be reviewed for conformance with the modeled component force-deformation behavior.

5.2.5 Uncertainty

It is usually impractical to perform a sufficient number of analyses to obtain statistically reliable estimates of dispersion and correlation in calculated response quantities.

Nonlinear response history analysis is used to provide estimates of median response. If a sufficient number of nonlinear analyses are performed on a sufficient number of models with varying modeling assumptions, it is possible to explicitly calculate uncertainties in demand associated with modeling assumptions, and the relationships (or correlations) between demand parameters. However, it is usually impractical to perform a sufficient number of analyses to obtain statistically valid information on dispersion or correlation in calculated response quantities. In this methodology, demand parameter dispersions are estimated based on judgment regarding the uncertainty inherent in response calculation. Because of probable inaccuracies in dispersion and correlation that would be observed in small suites of analyses, use of assumed values of uncertainty is considered the best available information.

Three sources of demand parameter uncertainty are considered: (1) modeling uncertainty; (2) record-to-record variability; and (3) ground motion variability. These are discussed below. Chapter 7 and Appendix G describe how the computed variability in response is augmented to account for modeling uncertainty and, in the case of scenario-based assessments, ground

motion variability, in the generation of simulated demand sets for loss computations.

Modeling Uncertainty

The demand distributions for selected ground motion intensities are characterized by median values and dispersions. These can be obtained through probabilistic analysis of a large family of building models in which component mechanical properties are random variables with user-specified distributions. However, the computational effort required to do this would be very large. Therefore, best-estimate analytical models are used for analysis, and calculated dispersions are augmented by judgmentally determined values accounting for modeling uncertainty.

Modeling uncertainty, β_m, results from inaccuracies in component modeling, damping, and mass assumptions. These uncertainties have been associated with the level of building definition and construction quality assurance, β_c, and the quality and completeness of the nonlinear analysis model, β_q.

Modeling uncertainty, β_m, results from inaccuracies in component modeling, damping, and mass assumptions. For the purpose of estimating β_m, these uncertainties have been associated with the level of building definition and construction quality assurance, β_c, and the quality and completeness of the nonlinear analysis model, β_q. The total modeling dispersion can be estimated as follows:

$$\beta_m = \sqrt{\beta_c^2 + \beta_q^2} \qquad (5\text{-}1)$$

Building definition and construction quality assurance, β_c. This component of modeling uncertainty accounts for the possibility that the actual properties of structural elements (e.g., material strength, section properties, and details such as rebar location) might be different than those otherwise believed to exist. Values of β_c are assigned based on the quality and confidence associated with building definition. For existing buildings, this will depend on the quality of the available drawings documenting the as-built construction, and the level of field investigation performed to verify their accuracy. For new buildings, this will be determined based on assumptions regarding how well actual construction will match the design. Table 5-1 provides recommended values for β_c under representative conditions. Judgment is necessary when selecting values from the table.

Quality and completeness of the analytical model, β_q. This component of modeling uncertainty recognizes that hysteretic models may not accurately capture the behavior of structural components, even if the details of construction are precisely known. Values of β_q are assigned based on the completeness of the mathematical model and how well the component deterioration and failure mechanisms are understood and implemented. Dispersion should be selected based on an understanding of how sensitive response predictions are to key structural parameters (e.g., strength, stiffness,

deformation capacity, in-cycle versus cyclic degradation) and the likely degree of inelastic response. Table 5-2 provides recommended values for β_q.

Table 5-1 Values of Dispersion for Construction Quality Assurance, β_c

Building Definition and Construction Quality Assurance	β_c
Superior Quality, New Buildings: The building is completely designed and will be constructed with rigorous construction quality assurance, including special inspection, materials testing, and structural observation. *Superior Quality, Existing Buildings*: Drawings and specifications are available and field investigation confirms they are representative of the actual construction, or if not, the actual construction is understood. Material properties are confirmed by extensive materials testing.	0.10
Average Quality, New Buildings: The building design is completed to a level typical of design development; construction quality assurance and inspection are anticipated to be of limited quality. *Average Quality, Existing Buildings:* Documents defining the building design are available and are confirmed by visual observation. Material properties are confirmed by limited materials testing.	0.25
Limited Quality, New Buildings: The building design is completed to a level typical of schematic design, or other similar level of detail. *Limited Quality, Existing Buildings*: Construction documents are not available and knowledge of the structure is based on limited field investigation. Material properties are based on default values typical for buildings of the type, location, and age of construction.	0.40

Table 5-2 Values of Dispersion for Quality of the Analytical Model, β_q

Quality and Completeness of the Analytical Model	β_q
Superior Quality: The numerical model is robust over the anticipated range of response. Strength and stiffness deterioration and all likely failure modes are explicitly modeled. Model accuracy is established with data from large-scale component tests through failure. *Completeness*: The mathematical model includes all structural components and nonstructural components in the building that contribute to strength or stiffness.	0.10
Average Quality: The numerical model for each component is robust over the anticipated range of displacement or deformation response. Strength and stiffness deterioration is fairly well represented, though some failure modes are simulated indirectly. Accuracy is established through a combination of judgment and large-scale component tests. *Completeness*: The mathematical model includes most structural components and nonstructural components in the building that contribute significant strength or stiffness.	0.25
Limited Quality: The numerical model for each component is based on idealized cyclic envelope curves from ASCE/SEI 41-06 or comparable guidelines, where strength and stiffness deterioration and failure modes are not directly incorporated in the model. *Completeness*: The mathematical model includes structural components in the seismic-force-resisting system.	0.40

Selection of β_q values should be guided by the expected degree of inelastic response and likelihood of component failure or building collapse. For example, component models in a building that are expected to remain elastic (i.e., no structural damage) need not address component deterioration, failure modes need not be simulated, and a value of $\beta_q = 0.1$ is likely appropriate. Conversely, if collapse simulations are being performed, robust numerical models are required for all components expected to suffer significant damage. If such models have not been validated by large-scale testing, the model confidence should be low, and a value of β_q in the range of 0.3 to 0.5 is likely appropriate.

Regardless of the relative values of β_c and β_q derived using Table 5-1 and Table 5-2, the total uncertainty computed using Equation 5-1 should not be taken greater than 0.5.

Record-to-Record Variability

In structures experiencing nonlinear response, or response in multiple modes, each record will produce somewhat different predictions of peak response quantities, resulting in record-to-record variability. Use of a small number of ground motion pairs will either underestimate or overestimate true record-to-record variability in each response quantity as well as the correlation between response quantities.

This methodology assumes that record-to-record response variability and demand correlation coefficients computed using small numbers of ground motions are sufficiently accurate for performance assessment.

Unless a very large number of ground motion pairs are used (on the order of 30 or more), values of dispersion obtained from limited suites of analyses will generally be inaccurate. This methodology, however, assumes that record-to-record response variability and demand correlation coefficients computed using small numbers of ground motions are sufficiently accurate for performance assessment, as augmented for other sources of uncertainty.

Ground Motion Variability

For scenario-based assessment, it is necessary to account for uncertainty in the shape and amplitude of the target spectrum. Table 5-3 lists suggested values for ground motion spectral demand dispersion, β_{gm}, based on uncertainty in attenuation relationships in widely accepted ground motion prediction equations for Western North America (WNA), the Central and Eastern United States (CEUS), and the Pacific North West (PNW). Values of β_{gm} appropriate to the specific ground motion prediction equations used to derive the target spectrum should be substituted for these, when known.

Table 5-3 Default Values of Dispersion for Ground Motion Uncertainty, β_{gm}

$\bar{T}$, T_1 (sec)	β_{gm}		
	WNA	CEUS	PNW
<0.20	0.60	0.53	0.80
0.35	0.60	0.55	0.80
0.5	0.61	0.55	0.80
0.75	0.64	0.58	0.80
1.0	0.65	0.60	0.80
1.50	0.67	0.60	0.85
≥2.0	0.70	0.60	0.90

5.3 Simplified Analysis

Simplified analysis uses linear structural models and the lateral yield strength of the structure to estimate median values of response parameters.

The simplified analysis procedure uses linear models, static analyses, and an estimate of the lateral yield strength of the structure to generate median values of demands that are predictive of damage. Structures are assumed to have independent translational response in each of two horizontal axes, denoted *X* and *Y*, and separate analyses are performed along each axis. The effects of vertical earthquake shaking, torsion, and soil-structure interaction are neglected.

The simplified analysis procedure is limited in its ability to estimate nonlinear response. Assumptions underlying the simplified analysis procedure include:

- The framing systems are independent along each horizontal axis of the building, response along each axis is uncoupled, and torsional response can be ignored.
- The building is regular in plan and elevation (i.e., there are no substantial discontinuities in strength and stiffness).
- Story drift ratios do not exceed 4 times the corresponding yield drift ratio, excessive degradation in strength and stiffness does not occur, and assumptions of bilinear elastic-plastic component behavior are reasonable.
- Story drifts ratios are limited to 4%, below which *P*-delta effects can be considered insignificant.
- The building is less than 15 stories tall, and higher mode contributions to response are not considered significant.

Simplified analysis of buildings that do not conform to these assumptions may not be reliable. Even for buildings that do conform to these assumptions, simplified analysis will entail greater uncertainty as to the true value of medians and dispersions associated with the calculated demands. As a result, use of the simplified analysis procedure will result in performance impacts and calculated losses that are somewhat different from those computed using nonlinear analysis methods.

5.3.1 Modeling

Mathematical models for simplified analysis should appropriately represent the distribution of mass and stiffness throughout the building. All elements that contribute significantly to lateral strength or stiffness should be included in the model, whether or not they are considered to be structural or nonstructural, or part of the seismic-force-resisting system. ASCE/SEI 41-06 provides guidance for modeling the strength and stiffness of typical building components appropriate for use in simplified analysis.

The mathematical model is used to establish the fundamental period and first mode shape in each of two orthogonal directions. These periods and mode shapes are used to compute pseudo lateral forces that are applied in a static analysis of the model to determine story drift ratios. This information, together with estimates of peak ground acceleration, peak ground velocity, and the yield strength of the structure, is used to compute median estimates of peak story drift ratio, peak floor acceleration, and peak floor velocity in each orthogonal direction.

The yield strength of the structure can be estimated using plastic analysis concepts, nonlinear static analysis in accordance with ASCE/SEI 41-06, or the response modification coefficient, R, and the overstrength factor, Ω_0, specified in ASCE/SEI 7-10, *Minimum Design Loads for Buildings and Other Structures* (ASCE, 2010). Use of R and Ω_0 is only appropriate when minimal information is available on the actual design of the structure, as may occur during schematic or preliminary design phases. In such cases, the yield strength can be taken in the range given by:

$$\frac{1.5S_a(T)W}{R/I} \le V_y \le \frac{\Omega_o S_a(T)W}{R/I} \qquad (5\text{-}2)$$

where $S_a(T)$ is the design spectral response acceleration evaluated at the fundamental period in the direction under consideration, and R, Ω_o, and I are the elastic design coefficients for structural system and occupancy of the building, as defined in ASCE/SEI 7-10.

5.3.2 Simplified Analysis Procedure

Figure 5-4 defines the floor level, story level, and floor height designation numbering system used in the simplified analysis procedure.

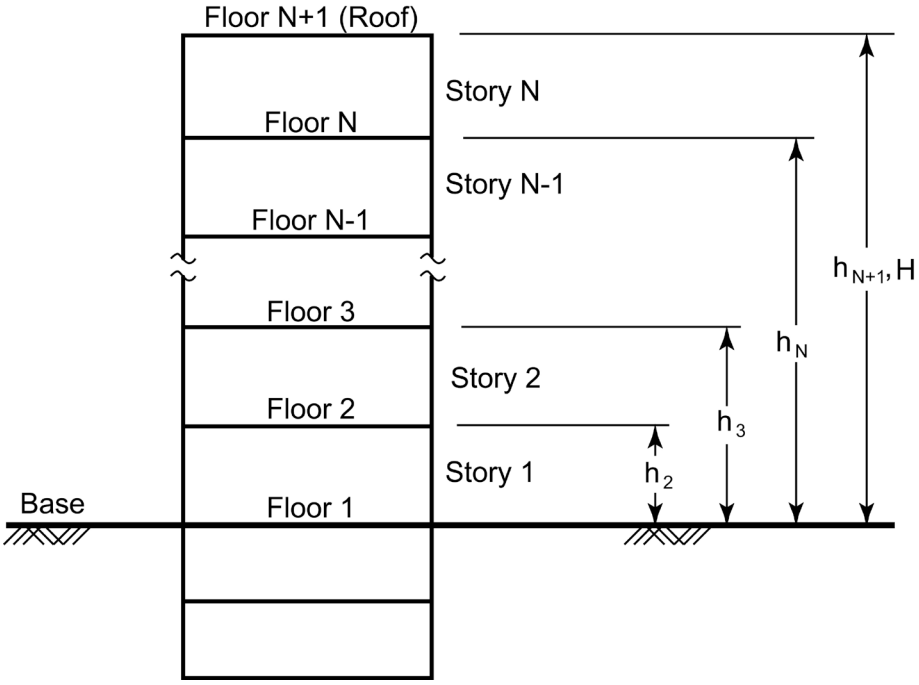

Figure 5-4 Definition of floor levels, story numbers, and floor heights used in the simplified analysis procedure.

Pseudo Lateral Force

In each direction, a pseudo lateral force, V, is used to compute story drift ratios, velocities, and accelerations. The force, V, in each direction is computed as:

$$V = C_1 C_2 S_a(T_1) W_1 \tag{5-3}$$

where C_1 is an adjustment factor for inelastic displacements; C_2 is an adjustment factor for cyclic degradation; $S_a(T_1)$ is the 5% damped spectral acceleration at the fundamental period of the building, in the direction under consideration, for the selected level of ground shaking; and W_1 is the first modal effective weight in the direction under consideration, taken as not less than 80% of the total weight, W. If building response is elastic, coefficients C_1 and C_2 are set equal to 1.0.

The first mode effective weight, W_1, can be calculated as:

$$W_1 = \frac{\left(\sum_{j=2}^{N+1} w_j \phi_{j1}\right)^2}{\sum_{j=2}^{N+1} w_j \phi_{j1}^2} \tag{5-4}$$

where w_j is the lumped weight at floor level j, ϕ_{j1} is the jth floor ordinate of the first mode deflected shape, N is the number of floors in the building above the base, and floor levels are as defined in Figure 5-4. Alternatively, W_1 can be taken as $C_m W$, where C_m is as defined in ASCE/SEI 41-06.

The adjustment factor, C_1, is computed as:

$$\begin{aligned} C_1 &= 1 + \frac{S-1}{0.04a} && \text{for } T_1 \le 0.2\,\text{sec} \\ &= 1 + \frac{S-1}{aT_1^2} && \text{for } 0.2 < T_1 \le 1.0\,\text{sec} \\ &= 1 && \text{for } T_1 > 1.0\,\text{sec} \end{aligned} \tag{5-5}$$

where T_1 is the fundamental period of the building in the direction under consideration, a is a function of the soil site class (taken as 130, 130, 90, 60, and 60 for ASCE/SEI 7-10 site classes A, B, C, D and E, respectively) and S is a strength ratio given by:

$$S = \frac{S_a(T_1)W}{V_{y1}} \tag{5-6}$$

where V_{y1} is the estimated yield strength of the building in first mode response, and W is the total weight. The estimated yield strength, V_{y1}, should be determined by a suitable nonlinear static analysis procedure, such as that contained in ASCE/SEI 41-06. If S has a value less than or equal to 1.0, then C_1 is taken as unity.

When the value of S is less than or equal to 1.0, C_2 is also taken as unity. When S is greater than 1.0, C_2 is computed as:

$$\begin{aligned} C_2 &= 1 + \frac{(S-1)^2}{32} && \text{for } T_1 \le 0.2\,\text{sec} \\ &= 1 + \frac{1}{800}\frac{(S-1)^2}{T_1^2} && \text{for } 0.2 < T_1 \le 0.7\,\text{sec} \\ &= 1 && \text{for } T_1 > 0.7\,\text{sec} \end{aligned} \tag{5-7}$$

If the building incorporates viscous or viscoelastic damping devices, the 5% damped spectral acceleration ordinate should be replaced by the value that corresponds to the first mode damping in the building. The procedures of

ASCE/SEI 41-06 can be used to estimate the damping in a building equipped with viscous or viscoelastic energy dissipation devices, and to adjust the response spectrum for the effects of damping other than 5%.

Median Estimates of Demand

Median estimates of story drift ratio, Δ_i^*, floor acceleration, a_i^*, and floor velocity, v_i^*, from the simplified analysis procedure are computed using the following steps, as further described below:

1. Determine vertical distribution of forces by distributing the pseudo lateral force, V, over the height of the building.
2. Apply the lateral forces to the linear static model to compute floor displacements and uncorrected story drifts. Divide story drifts by story height to obtain story drift ratios.
3. Correct story drift ratios to account for inelastic behavior and higher mode effects.
4. Estimate peak floor acceleration at each floor from peak ground acceleration.
5. Estimate peak floor velocity at each floor from peak ground velocity.

Step 1 – Determine vertical distribution of forces. The pseudo lateral force, F_x, at floor level x, is given by:

$$F_x = C_{vx} V \tag{5-8}$$

where, C_{vx} is a vertical distribution factor given by:

$$C_{vx} = \frac{w_x h_x^k}{\sum_{i=2}^{N+1} w_i h_i^k} \tag{5-9}$$

and w_i is the lumped weight at floor level i; h_i (or h_x) is the height above the effective base of the building to floor level i (or x); and k is equal to 2.0 for a first mode period greater than 2.5 seconds, or equal to 1.0 for a first mode period less than or equal to 0.5 seconds (linear interpolation can be used for intermediate periods).

Step 2 – Compute floor displacements and uncorrected story drift ratios. The lateral forces, F_x, at each level are simultaneously applied to the linear static analysis model. The displacement of each floor relative to the base is computed. The uncorrected story drift ratio at each level, Δ_i, is determined as the difference between the lateral displacements of the floor levels immediately above and below the story, divided by the story height.

Step 3 – Correct story drift ratios to account for inelastic behavior and higher mode effects. Estimates of median story drift ratio, Δ_i^*, at each level *i*, are calculated as:

$$\Delta_i^* = H_{\Delta i}\left(S, T_1, h_i, H\right) \times \Delta_i \tag{5-10}$$

where $H_{\Delta i}\left(S, T_1, h_i, H\right)$ is the drift correction factor for story *i* computed from:

$$\ln\left(H_{\Delta i}\right) = a_0 + a_1 T_1 + a_2 S + a_3 \frac{h_{i+1}}{H} + a_4 \left(\frac{h_{i+1}}{H}\right)^2 + a_5 \left(\frac{h_{i+1}}{H}\right)^3 \tag{5-11}$$

$$\text{for } S \geq 1,\ i = 1 \text{ to } N$$

and the values of the coefficients a_0 through a_5 are obtained from Table 5-4 for structures less than 9 stories in height, and Table 5-5 for structures 10 to 15 stories in height; *S* is the strength ratio previously defined; T_1 is the first mode period; and *H* is the total building height above the base, as defined in Figure 5-4.

Step 4 – Estimate peak floor acceleration from peak ground acceleration. At the base of the building, peak floor acceleration is taken as equal to the peak ground acceleration. At other floor levels, *i*, the estimated median peak floor acceleration, a_i^*, relative to a fixed point in space, is derived from the peak ground acceleration using:

$$a_i^* = H_{ai}\left(S, T, h_i, H\right) \times PGA \qquad \text{for } i = 2 \text{ to } N+1 \tag{5-12}$$

where *PGA* is the peak ground acceleration; $H_{ai}\left(S, T, h_i, H\right)$ is the acceleration correction factor for floor *i* computed from:

$$\ln\left(H_{ai}\right) = a_0 + a_1 T_1 + a_2 S + a_3 \frac{h_i}{H} + a_4 \left(\frac{h_i}{H}\right)^2 + a_5 \left(\frac{h_i}{H}\right)^3 \tag{5-13}$$

$$\text{for } S \geq 1,\ i = 2 \text{ to } N+1$$

and the values of the coefficients a_0 through a_5 are obtained from Table 5-4 for structures less than 9 stories in height, and Table 5-5 for structures 10 to 15 stories in height. If the building response is elastic, *S* is taken as 1.0.

Step 5 – Estimate peak floor velocity from peak ground velocity. At the base of the building, peak floor velocity is taken as equal to the peak ground velocity, *PGV*. Peak ground velocity can be calculated by seismic hazard analysis for intensity- or time-based assessments, or by using a ground motion prediction equation for a scenario-based assessment. If detailed information on peak ground velocity is not available, *PGV* can be estimated along each building axis by dividing the spectral velocity at a period of one

second, $S_v(1.0\text{ s})$, by a factor of 1.65 (Newmark and Hall, 1982; Huang et al., 2012).

Table 5-4 Correction Factors for Story Drift Ratio, Floor Velocity, and Floor Acceleration for 2-Story to 9-Story Buildings

Demand	Frame Type	a_0	a_1	a_2	a_3	a_4	a_5
Story drift ratio	Braced	0.90	-0.12	0.012	-2.65	2.09	0

Table 5-5 Correction Factors for Story Drift Ratio, Floor Velocity, and Floor Acceleration for 10-Story to 15-Story Buildings

Demand	Frame Type	a_0	a_1	a_2	a_3	a_4	a_5
Story drift ratio	Braced	1.91	-0.12	-0.077	-3.78	6.43	-3.42
	Moment	0.67	-0.044	-0.098	-1.37	1.71	-0.57
	Wall	0.86	-0.036	-0.076	-4.58	6.88	-3.24
Floor velocity	Braced	0.086	-0.10	0.041	0.45	-2.89	2.57
	Moment	-0.020	-0.068	0.034	0.32	-1.75	1.53
	Wall	-0.11	-0.085	0.11	0.87	-4.07	3.27
Floor acceleration	Braced	0.44	-0.27	-0.052	3.24	-9.71	6.83
	Moment	0.34	-0.25	-0.062	2.86	-7.43	5.10
	Wall	-0.13	-0.15	-0.10	7.79	-17.52	11.04

Spectral velocity at a period of 1 second can be derived from spectral acceleration at a period of one second using the formula:

$$S_v(1.0\text{ s}) = \frac{S_a(1.0\text{ s})}{2\pi} g \tag{5-14}$$

where $S_a(1.0\text{ s})$ is the spectral acceleration at 1 second period. Peak ground velocity can then be approximated as:

$$PGV = \frac{S_v(1.0\text{ s})}{1.65} \tag{5-15}$$

At other floor levels, i, the estimated median peak floor velocity, v_i^*, relative to a fixed point in space, is computed from the peak ground velocity using the formula:

$$v_i^* = H_{vi}\left(S, T, h_i, H\right) \times v_{si} \qquad \text{for } i = 2 \text{ to } N+1 \tag{5-16}$$

where $H_{vi}\left(S, T, h_i, H\right)$ is computed from:

$$\ln\left(H_{vi}\right) = a_0 + a_1 T_1 + a_2 S + a_3 \frac{h_i}{H} + a_4 \left(\frac{h_i}{H}\right)^2 + a_5 \left(\frac{h_i}{h}\right)^3 \tag{5-17}$$

$$\text{for } S \geq 1,\ i = 2 \text{ to } N+1$$

and the values of the coefficients a_0 through a_5 are obtained from Table 5-4 for structures less than 9 stories in height, and Table 5-5 for structures 10 to 15 stories in height. The reference floor velocity, v_{si}, is determined from:

$$v_{si} = PGV + 0.3 \frac{T_1}{2\pi} \left(\frac{V_{y1}}{W_1 / g} \Gamma_1\right) \left(\frac{\delta_i}{\delta_r}\right) \tag{5-18}$$

where T_1 is the first mode period; V_{y1} is the effective yield strength in first mode response; W_1 is the first modal effective weight in the direction under consideration, taken as not less than 80% of the total weight; Γ_1 is the first mode participation factor; δ_i is the uncorrected displacement of floor i; δ_r is the uncorrected roof displacement with respect to the base, and all other terms are as previously defined.

Dispersions in Response Calculations

Simplified analysis yields discrete values of median estimates of response quantities. To conduct performance assessments using simplified analysis, it is necessary to develop distributions of story drift, floor acceleration, and floor velocity, where the distributions capture uncertainty in ground motion intensity (β_{gm}), analysis record-to-record variability ($\beta_{a\Delta}$, β_{aa}, β_{av}), and modeling (β_m). Table 5-6 lists default values of dispersion to be used with simplified analysis results. Linear interpolation can be used to estimate values of β for intermediate values of T_1 and S.

To conduct performance assessments using simplified analysis, it is necessary to develop distributions of story drift, floor acceleration, and floor velocity to capture uncertainty.

For intensity-based and time-based assessments, separate values of total dispersion for drift, β_{SD}, floor acceleration, β_{FA}, and floor velocity, β_{FV}, are needed. These are calculated based on Table 5-6 values for analysis record-to-record dispersion for drift, $\beta_{a\Delta}$, acceleration, β_{aa}, and velocity, β_{av}, respectively, as follows:

$$\beta_{SD} = \sqrt{\beta_{a\Delta}^{\ 2} + \beta_m^{\ 2}} \tag{5-19}$$

$$\beta_{FA} = \sqrt{\beta_{aa}{}^2 + \beta_m{}^2} \tag{5-20}$$

$$\beta_{FV} = \sqrt{\beta_{av}^2 + \beta_m^2} \tag{5-21}$$

Table 5-6 Default Dispersions for Record-to-Record Variability and Modeling Uncertainty for use with Simplified Analysis

T_1 (sec)	$S = \frac{S_a(T_1)W}{V_{y1}}$	$\beta_{a\Delta}$	β_{aa}	β_{av}	β_m
0.20	≤1.0	0.05	0.10	0.50	0.25
	2	0.35	0.10	0.51	0.25
	4	0.40	0.10	0.40	0.35
	6	0.45	0.10	0.37	0.50
	≥8	0.45	0.05	0.24	0.50
0.35	≤1.0	0.10	0.15	0.32	0.25
	2	0.35	0.15	0.38	0.25
	4	0.40	0.15	0.43	0.35
	6	0.45	0.15	0.38	0.50
	≥8	0.45	0.15	0.34	0.50
0.5	≤1.0	0.10	0.20	0.31	0.25
	2	0.35	0.20	0.35	0.25
	4	0.40	0.20	0.41	0.35
	6	0.45	0.20	0.36	0.50
	≥8	0.45	0.20	0.32	0.50
0.75	≤1.0	0.10	0.25	0.30	0.25
	2	0.35	0.25	0.33	0.25
	4	0.40	0.25	0.39	0.35
	6	0.45	0.25	0.35	0.50
	≥8	0.45	0.25	0.30	0.50
1.0	≤1.0	0.15	0.30	0.27	0.25
	2	0.35	0.30	0.29	0.25
	4	0.40	0.30	0.37	0.35
	6	0.45	0.30	0.36	0.50
	≥8	0.45	0.25	0.34	0.50
1.50	≤1.0	0.15	0.35	0.25	0.25
	2	0.35	0.35	0.26	0.25
	4	0.40	0.30	0.33	0.35
	6	0.45	0.30	0.34	0.50
	≥8	0.45	0.25	0.33	0.50
≥2.0	≤1.0	0.25	0.50	0.28	0.25
	2	0.35	0.45	0.21	0.25
	4	0.40	0.45	0.25	0.35
	6	0.45	0.40	0.26	0.50
	≥8	0.45	0.35	0.26	0.50

For scenario-based assessments, the values of total dispersion must also include uncertainty in ground motion attenuation, β_{gm}, obtained from Table 5-3. Total dispersion for drift, floor acceleration, and floor velocity including uncertainty in ground motion attenuation, β_{gm}, are given by:

$$\beta_{SD} = \sqrt{\beta_{a\Delta}{}^2 + \beta_m{}^2 + \beta_{gm}{}^2} \tag{5-22}$$

$$\beta_{FA} = \sqrt{\beta_{aa}{}^2 + \beta_m{}^2 + \beta_{gm}{}^2} \tag{5-23}$$

$$\beta_{FV} = \sqrt{\beta_{av}^2 + \beta_m^2 + \beta_{gm}^2} \tag{5-24}$$

5.4 Residual Drift

Nonlinear analysis using standard production software and typical component modeling techniques does not result in accurate assessments of residual drift.

Residual drift predicted by nonlinear analysis is highly sensitive to component modeling assumptions related to post-yield hardening/softening slope and unloading response. Accurate statistical simulation of residual drift requires the use of advanced component models, careful attention to cyclic hysteretic response, and a large number of ground motion pairs.

Since the requirements for direct simulation of residual drift are computationally complex and not practical for general implementation in design, the following equations were developed to estimate the median residual drift ratio, Δ_r, as a function of the peak transient response of the structure:

$$\begin{aligned} \Delta_r &= 0 && \text{for } \Delta \le \Delta_y \\ \Delta_r &= 0.3\left(\Delta - \Delta_y\right) && \text{for } \Delta_y < \Delta < 4\Delta_y \\ \Delta_r &= \left(\Delta - 3\Delta_y\right) && \text{for } \Delta \ge 4\Delta_y \end{aligned} \tag{5-25}$$

where Δ is the median story drift ratio calculated by analysis, and Δ_y is the median story drift ratio calculated at yield. Appendix C provides background information on the development of these relationships.

The yield drift ratio, Δ_y, is associated with significant yielding in the structure. In steel concentrically braced frame systems, the yield drift ratio can be calculated as the story drift ratio associated with story shear forces equal to the expected yield strength of the braces. In low aspect ratio shear wall systems, it is the drift ratio associated with the expected shear strength of the walls. In slender shear wall systems dominated by flexural behavior, it is the drift ratio associated with the expected flexural strength of the walls under a lateral load distribution consistent with the dynamic response of the building.

In moment frame systems, the yield drift ratio can be calculated as the story drift associated with story shear forces related to: (1) beams or columns reaching their expected plastic moment capacity, including the effect of axial forces in the members; or (2) the beam-column connection panel joints reaching their expected yield strength. The distribution of forces in the story under consideration can be calculated based on equivalent lateral forces, or alternatively, by applying a shear force at the floor above the story being evaluated with a lateral support imposed at the floor below the story being evaluated.

When nonlinear response history analysis is used, the residual drift ratio, Δ_r, can be calculated at each level using Equation 5-25 and the story drift ratios calculated from the suite of analysis results. When simplified analysis is used, the residual drift, Δ_r, can be calculated at each level using a value of median transient drift, Δ_t^*, calculated using the procedures of Section 5.3.

The dispersion in the residual drift is generally larger than that of the story drift. When simplified analysis is used, the total dispersion in the residual drift due to both record-to-record variability, β_a, and modeling, β_m, should be set equal to 0.8 (Ruiz-Garcia and Miranda, 2005). When response history analysis is used, the dispersion in residual drift, β_{RD}, can be determined from the equation:

$$\beta_{RD} = \sqrt{\beta_a^2 + \beta_{ARD}^2} \tag{5-26}$$

where β_a is the dispersion in residual drift obtained from the suite of analyses, and β_{ARD} is set equal to 0.2.

Chapter 6
Develop Collapse Fragility

6.1 Introduction

Assessment of collapse-induced earthquake casualties requires the development of a building collapse fragility, which is a relationship that defines the probability of incurring structural collapse as a function of ground motion intensity.

Building collapse is the principle cause of earthquake casualties. Assessment of collapse-induced earthquake casualties requires the development of a building collapse fragility, which is a relationship that defines the probability of incurring structural collapse as a function of ground motion intensity. The probability of collapse is expressed as a lognormal distribution of spectral acceleration at the first mode period, defined by a median value, $\hat{S}_a(T)$, and dispersion, β. This chapter presents several alternative procedures for establishing building-specific collapse fragility functions for input into a building performance model.

The present state-of-the-art for collapse assessment is described in FEMA P-695, *Quantification of Building Seismic Performance Factors* (FEMA, 2009b). The procedures in FEMA P-695 are based on the concept of incremental dynamic analysis (IDA), which is a computationally intensive procedure that is rarely practical in non-research applications. Use of incremental dynamic analysis for the development of a collapse fragility function is described in Appendix J.

A more practical alternative, also described in FEMA P-695, is to perform limited suites of nonlinear response history analyses at key intensity levels that produce collapse predictions, and to develop collapse fragility functions from the resulting collapse statistics. Collapse fragility functions for low-rise buildings can be approximated using a simplified procedure based on nonlinear static (pushover) analysis. Collapse fragilities for buildings conforming to the requirements of recent building codes can be inferred based on the target collapse resistance inherent in the building code.

6.2 Nonlinear Response History Analysis

Nonlinear response history analysis is the most reliable method of establishing collapse fragility functions. The basic process entails performing large suites of analyses at multiple intensity levels ranging from intensities that produce near linear response to intensities that cause collapse. A smooth lognormal distribution is fit to the fraction of ground motions at each intensity level that result in collapse.

6.2.1 Definition of Collapse

Building collapse is generally associated with local or global loss of vertical-load carrying capacity, or failure of the gravity-load carrying system. Analytically, collapse is evidenced by numerical instability, large lateral drift response, or demands exceeding the failure capacity of gravity-load carrying components.

Collapse is defined as sidesway failure (lateral dynamic instability), loss of vertical-load carrying capacity, or exceedance of non-simulated failure criteria.

Aside from soil or foundation (e.g., pile) failures, there are few examples of building collapse due to overturning. Excessive lateral displacement, which can lead to a near-complete loss of lateral stiffness, can also trigger failure of vertical-load carrying components. In this methodology, collapse is defined as:

- Sidesway failure (lateral dynamic instability), characterized by loss of lateral stiffness, and development of *P*-delta instability.
- Loss of vertical-load carrying capacity in gravity or seismic-force-resisting components due to earthquake-induced drifts.
- Exceedance of non-simulated failure criteria, consisting of force or deformation limits beyond which components can no longer continue to reliably resist load.

Simulation of collapse requires explicit solution techniques that are available in few commercial software packages. Typical analytical software used in engineering offices employ implicit solution techniques, which are unable to do so. As a result, collapse is assumed when numerical instability occurs, when lateral displacements exceed the range of model validity, or when non-simulated failure criteria are exceeded. Loss of vertical-load carrying capacity is predicted by excessive strength or deformation demands on gravity-load carrying components.

6.2.2 Mathematical Models

In general, three-dimensional mathematical models should be used for collapse assessment. Two-dimensional (planar) models may be sufficient in cases where buildings have regular configurations, the translational response in each orthogonal direction is independent, and torsional response is not significant. When two-dimensional models are used, the median collapse capacity, $\hat{S}_a(T)$, should be taken as the smaller of the values obtained in each direction.

Best-estimate mechanical properties should be used for each component in the mathematical model. Best-estimate models use median values for all component force-deformation parameters, such as yield strength, yield

deformation, post-yield stiffness, maximum strength, and deformation corresponding to maximum strength. If median values are unavailable, mean values can be used. Chapter 5 provides additional information, and resources for additional guidance, on modeling component force-deformation behavior.

Ideally, nonlinear models should simulate all possible modes of component deterioration and failure (e.g., axial, flexure, axial-flexure interaction, shear, and shear-flexure interaction). If a mode of deterioration or failure is not included in the model, its effect on collapse must be accounted for indirectly, through the use of non-simulated failure criteria. Some vertical-load carrying components (e.g., gravity columns) may not be included in the mathematical model, but must be checked for possible failure to ensure that they do not result in a collapse condition at the force or deformation demands predicted in the analysis.

Ideally, nonlinear models should simulate all possible modes of deterioration or failure. Failure modes that are not directly simulated in the model must be checked for possible collapse at the force or deformation demands predicted in the analysis.

Most energy dissipation is modeled directly through the hysteretic force-deformation response of the structural components. Equivalent viscous damping assigned in the mathematical model should, therefore, be limited. For typical buildings, equivalent viscous damping should be in the range of 1% to 5% of critical damping in the predominant vibration modes of the structure. Values of 3% or less should be used for tall buildings and other structures where damping effects are small relative to structural hysteretic effects. Chapter 5 provides additional guidance on consideration of damping in structural analysis.

6.2.3 Incremental Dynamic Analysis

In incremental dynamic analysis (IDA), a large number of nonlinear response history analyses are performed using ground motions that are systematically scaled to increasing earthquake intensities until collapse occurs. Incremental dynamic analysis yields a distribution of results at varying intensities that can be used to generate a collapse fragility.

Because this method involves a large suite of suitable ground motion pairs (on the order of 20 or more), each of which is incrementally scaled to many different intensity levels, and nonlinear response history analysis is conducted for each pair at each intensity, the level of effort is computationally intensive and the method is seldom used in practice. The resulting data, however, are comprehensive, as illustrated in Figure 6-1. Use of incremental dynamic analysis for generation of a building-specific collapse fragility is described in Appendix J.

Incremental dynamic analysis is computationally intensive and seldom used in practice, but the resulting collapse data are comprehensive.

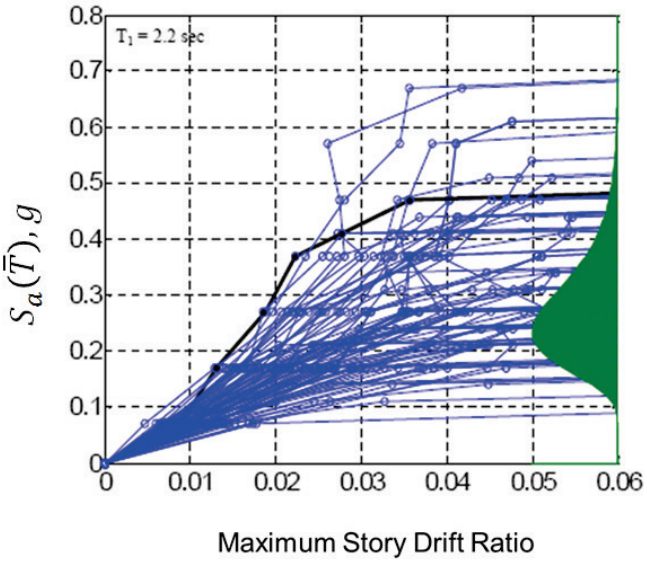

Figure 6-1 Sample incremental dynamic analysis results showing the distribution of collapse statistics for a hypothetical building.

6.2.4 *Limited-Suite Nonlinear Analysis*

In this approach, nonlinear response history analyses are performed at a number of intensity levels, some of which result in collapse. Such analyses will be an inherent part of time-base assessments when nonlinear response history analysis is used. At each intensity level, I, an estimated conditional probability of collapse, $P(C|I)$ is obtained from the equation:

$$P(C|I) = \frac{n}{N} \tag{6-1}$$

where n is the number of analyses at intensity, I, for which collapse is predicted, and N is the total number of analyses performed at intensity, I. A plot of the estimated conditional probability of collapse can be developed as a function of intensity, using an appropriate estimate of dispersion, and a lognormal distribution can be fitted to the data as shown in Figure 6-2.

When fitting a lognormal distribution to the data obtained from such analyses, it is best to anchor the fitted curve to data near the median collapse point, as small suites of analyses will be unreliable when only a small fraction of the analyses predict collapse. A dispersion of not less than 0.6 is recommended when this procedure is used. A companion *Collapse Fragility Tool*, which is an Excel workbook application designed to assist in fitting lognormal curves to limited sets of collapse data, is provided as part of *Volume 3 – Supporting Electronic Materials and Background Documentation*.

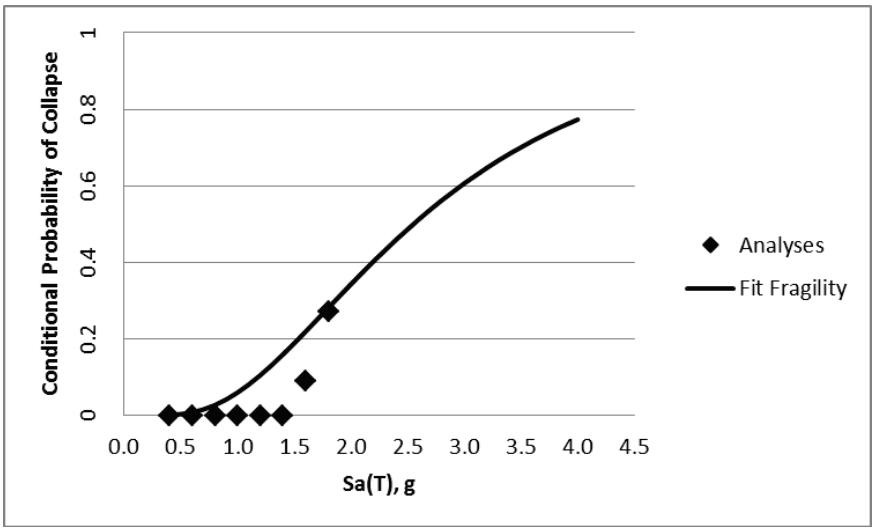

Figure 6-2 Illustration of collapse fragility estimated using nonlinear analysis at several intensity levels.

Figure 6-2 illustrates this approach for a hypothetical structure in which a time-based assessment is performed using suites of 10 nonlinear response history analyses at values of $S_a(\bar{T})$ equal to 0.4 g, 0.6 g, 0.8 g, 1.0 g, 1.2 g, 1.4 g, 1.6 g, and 1.8 g. In this example, analysis predicted three collapses at $S_a(\bar{T}) = 1.8$ g, one collapse at 1.6 g, and no collapses at lower intensities. A lognormal distribution has been fitted to these data with a judgmentally selected median of 2.6 g and a dispersion of 0.6.

To obtain reliable estimates of collapse fragility, a large number of ground motions (on the order of 20) should be used. However, it is worth noting that collapse fragility estimates obtained with as few as 7 ground motions per intensity level are likely to be of comparable quality to those obtained using the other approximate methods described in this chapter.

6.3 Simplified Nonlinear Analysis

SPO2IDA can be used to convert static pushover curves into approximate incremental dynamic analysis results for generating collapse fragilities.

From empirical relationships for characteristic segments of IDA curves for many systems, Vamvatsikos and Cornell (2006) suggested that static pushover curves could be used to estimate nonlinear dynamic response. The open source software tool, *Static Pushover 2 Incremental Dynamic Analysis* (SPO2IDA), was created as a product of that research. This tool, which is an Excel workbook application designed to convert static pushover curves into approximate incremental dynamic analysis results, is provided as part of *Volume 3 – Supporting Electronic Materials and Background Documentation*.

Approximate incremental dynamic analysis results derived from SPO2IDA can be used to generate collapse fragilities. Use of SPO2IDA should be

limited to low-rise buildings that are regular in both plan and elevation, dominated by first mode translational behavior, with independent response along each principal axis, and negligible torsion.

To use SPO2IDA, a pushover analysis, similar to the nonlinear static procedure described in ASCE/SEI 41-06*, Seismic Rehabilitation of Existing Buildings* (ASCE, 2007), is performed, and a normalized force-displacement relationship for the global behavior is generated. The global base-shear, V, versus roof displacement, Δ, relationship is transformed into a normalized spectral acceleration versus global displacement ductility relationship, as shown in Figure 6-3.

Figure 6-3 Normalized spectral acceleration versus global ductility relationship used in SPO2IDA.

The spectral acceleration is computed as $S_a = V / \left(C_m W / \mathrm{g}\right)$, with all terms as defined in Chapter 5. The spectral acceleration is normalized by S_y, which is equal to S_a at the first control point (i.e., $S_a / S_y = 1$). The global displacement ductility, μ, is the ratio of the roof displacement, Δ, to the roof yield displacement. The coordinate of the first control point (yield point) in SPO2IDA space is $(\mu, S_a / S_y)$, or (1, 1).

Figure 6-4 presents sample output from SPO2IDA, which is based on the static pushover curve shown in Figure 6-3 as input. Results include the 16th, 50th (median) and 84th percentile estimates of normalized spectral acceleration at collapse. Since a best-estimate model is used to derive the static pushover curve and the resulting fractiles for collapse, the total dispersion used to derive the collapse fragility curve should be computed considering record-to-record variability and modeling uncertainty. A

minimum default dispersion of 0.6 is recommended for deriving collapse fragility functions based on SPO2IDA results.

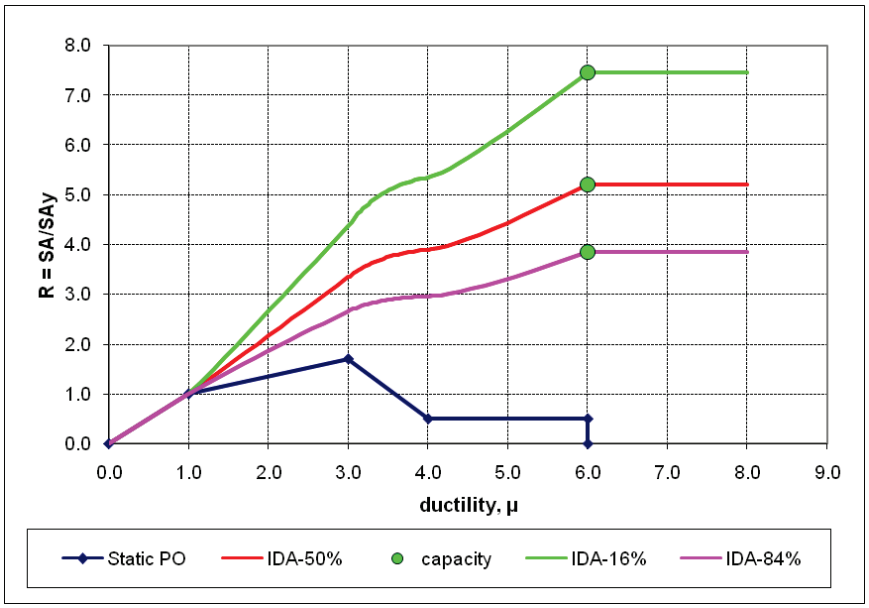

Figure 6-4 Sample SPO2IDA results and fractile estimates of normalized spectral acceleration at collapse for the static pushover curve shown in Figure 6-3.

6.4 Judgment-Based Collapse Fragility

Seismic design procedures contained in ASCE/SEI 7-10, *Minimum Design Loads for Buildings and Other Structures* (ASCE, 2010), are intended to provide less than a 10% chance that structures conforming to the requirements for Risk (or Occupancy) Category II will collapse when subjected to Maximum Considered Earthquake shaking, as defined in that standard. Studies have shown that conforming structures generally meet this criterion (FEMA, 2009b; NIST, 2010b). As a result, collapse fragility curves can be developed using engineering judgment based on the expected collapse capacity of code-conforming structures.

Judgment based on the collapse resistance inherent in code-conforming buildings can be used to estimate collapse fragility, but this should not be regarded as a reliable measure of the collapse resistance of an individual building.

This approach entails significantly greater uncertainty than the other methods described in this chapter. As with any exercise of engineering judgment, the resulting performance assessments will be limited by the accuracy and uncertainty inherent in the judgment used to develop the fragility. Available collapse studies have generally considered well-configured, regular structures. Some structural systems have easily met the intended collapse criterion, while others have not. It should be expected that somewhat irregular structures with unfavorable structural configurations will not provide equivalent collapse performance as more favorable configurations permitted in ASCE/SEI 7-10.

The following procedure should be used along each principal axis of the building, and the lowest value of median collapse capacity $\hat{S}_a(\overline{T})$ should be used as the basis for the collapse fragility:

Step 1. Determine the highest value of base shear, V, calculated per ASCE/SEI 7-10, for which the structure just satisfies the applicable seismic design criteria within ASCE/SEI 7-10.

Step 2. Determine the effective value of the design spectral acceleration at the fundamental period, S_{aD}, at which the structure satisfies all applicable seismic design criteria of ASCE/SEI 7-10 from the equation:

$$S_{aD} = \frac{V}{W} R \tag{6-2}$$

where V is the base shear determined in Step 1, W is the seismic weight, and R is the response modification coefficient for the structure, as defined in ASCE/SEI 7-10.

Step 3. Compute the inferred median collapse capacity, $\hat{S}_a(T)$, at the fundamental period, T, using Equation 6-3, Equation 6-4, or Equation 6-5, as applicable:

$$\hat{S}_a(T) = 4S_{aD}, \text{ for } T \geq 0.6 \text{ seconds} \tag{6-3}$$

$$\hat{S}_a(T) = 4S_{aD}\left[5(1-C_4)T + 3C_4 - 2\right], \text{ for } 0.4 < T < 0.6 \text{ seconds} \tag{6-4}$$

$$\hat{S}_a(T) = 4C_4 S_{aD}, \text{ for } T \leq 0.4 \text{ seconds} \tag{6-5}$$

where:

$$C_4 = \frac{\sqrt{2R-1}}{R} \tag{6-6}$$

Step 4. Convert the computed median collapse capacity at the fundamental period, $\hat{S}_a(T)$, to that at the average period, $\hat{S}_a(\overline{T})$, using:

$$\hat{S}_a(\overline{T}) = \frac{T}{\overline{T}} S_a(T), \text{ for } T \geq 0.6 \text{ seconds} \tag{6-7}$$

$$\hat{S}_a(\overline{T}) = S_a(T), \text{ for } T < 0.6 \text{ seconds} \tag{6-8}$$

Step 5. For regular, well-configured structures, assume a dispersion, β, of 0.7. For irregular structures, or structures with configuration issues that are otherwise unfavorable for good seismic performance, assume a dispersion, β, of 0.8, or higher.

If the building under consideration has been analyzed using nonlinear response history analysis, and the judgment-based collapse fragility is not in reasonable agreement with the number of collapses predicted at different ground shaking intensities, re-examination of the analysis results or the derived collapse fragility is recommended. In the case of archaic construction (i.e., not currently permitted under ASCE/SEI 7-10), the median spectral acceleration value at collapse can be estimated on the basis of past experience, and a dispersion of $\beta = 0.6$, or higher, should be assumed.

6.5 Collapse Modes

In addition to determining the likelihood of collapse (i.e., collapse fragility), it is also necessary to describe: (1) the potential collapse mode(s), along with the probability of occurrence of each, given that collapse occurs; (2) the extent of collapse in each mode at each story in the form of collapse area ratios; and (3) the respective probabilities that people occupying the areas of potential collapse will become fatalities or experience serious injuries. Collapse modes define the ways in which a building would be expected to collapse, ranging from partial to complete collapse. Possible collapse modes include single-story collapse, multi-story collapse, or total collapse. Collapse floor area ratios indicate the portion of floor area at each level that will be subjected to debris from collapse of the levels above. In some cases, collapse of one story on top of another might be expected to result in a cascading collapse of the lower stories. This should be considered when generating collapse modes.

Collapse area ratios indicate the percent of floor area at each level that is subject to collapse in each mode.

For example, a hypothetical 4-story building might be expected to experience five possible modes of collapse:

- Mode 1 – total collapse in all stories
- Mode 2 – collapse in the 1st story (i.e., collapse of floor 2 onto floor 1)
- Mode 3 – collapse in the 2nd story (i.e., collapse of floor 3 onto floor 2)
- Mode 4 – collapse in the 3rd story (i.e., collapse of floor 4 onto floor 3)
- Mode 5 – collapse in the 4th story (i.e., collapse of the roof onto floor 4).

The corresponding collapse modes are shown in Table 6-1. In this example, it has been assumed that each mode has an equal chance of occurring (i.e., each has a collapse mode probability of 0.2), and that collapse at one level does not cause a cascading effect in the levels below. Note that the sum of the conditional probabilities that each collapse mode will occur must be equal to 1.0.

For each collapse mode, the table also shows the collapse floor area ratio at each level. The collapsed floor area ratio identifies the total floor area that will be subjected to debris from the floors above. In this example, it has been assumed that if a story collapses, the entire floor level associated with that story will be subjected to debris, as indicated by a collapse area ratio of 1.0 in the table. It is possible to indicate partial collapse within a story by specifying a collapse area ratio less than 1.0.

Table 6-1 Sample Collapse Modes, Collapse Floor Area Ratios, and Probabilities of Fatalities and Serious Injuries for a Hypothetical Building

Collapse Modes					
	Mode 1	**Mode 2**	**Mode 3**	**Mode 4**	**Mode 5**
Probability of Collapse Mode	0.2	0.2	0.2	0.2	0.2
Probability of Fatality	1.0	0.9	0.9	0.9	0.9
Probability of Serious Injury	0	0.1	0.1	0.1	0.1
Collapse Floor Area Ratios					
Roof	1.0	0	0	0	0
Floor 4	1.0	0	0	0	1.0
Floor 3	1.0	0	0	1.0	0
Floor 2	1.0	0	1.0	0	0
Floor 1	1.0	1.0	0	0	0

Collapse predicted by analysis will be sensitive to modeling assumptions, relative strengths between floor levels, and the frequency content, amplitude and duration of the input ground motions. In general, it is not possible to reliably determine the range of possible collapse modes that might occur in a building on the basis of a limited suite of analyses. Therefore, information obtained from analysis must be supplemented with judgment regarding the viability of each mode for a particular structure, the appropriate floor area ratio at each floor level for each mode, and the probability of occurrence of each mode, given that collapse occurs.

In addition, it is necessary to specify the likelihood that persons in areas affected by collapse will become fatalities or will incur serious injuries. Based on casualty data from past earthquakes, the likelihood of fatality or serious injury can be related to the type and quality of the construction of the

building. Available historic data are not robust, and judgment is necessary in assigning these probabilities.

For example, data from past U.S. earthquakes suggest that most people occupying unreinforced masonry bearing wall buildings with wood floors and roofs survive a building collapse. In this type of construction, heavy debris falls away from the building rather than into it, and casualties most commonly occur as a result of falling hazards outside of the building. Casualty rates for this type of construction might be on the order of 10% (i.e., 0.1) for fatalities and 30% (i.e., 0.3) for serious injuries. Conversely, collapse of reinforced concrete structures has typically resulted in significant numbers of fatalities among people occupying floors impacted by collapse. Casualty rates for reinforced concrete construction might be on the order of 90% (i.e., 0.9) for fatalities and 10% (i.e., 0.1) for serious injuries. Additional information can be found in FEMA P-58/BD-3.7.8, *Casualty Consequence Function and Building Population Model Development*, provided as part of *Volume 3 – Supporting Electronic Materials and Background Documentation*.

Chapter 7
Calculate Performance

7.1 Introduction

This chapter outlines the procedures that are used to calculate building performance in the assessment process. These include generation of simulated demands, assessment of collapse, determination of damage, and computation of losses in the form of casualties, repair cost, and repair time, and unsafe placarding. Calculation procedures are presented for intensity-based assessment. Calculations for scenario-based assessments are performed in a similar manner. Calculations for time-based assessments are performed as a series of intensity-based assessments that are weighted based on frequency of occurrence.

Performance calculation includes generation of simulated demands, assessment of collapse, determination of damage, and computation of losses.

To assess uncertainty and explore variability in building performance, this process would ideally involve performing a large number of structural analyses, using a large suite of input ground motions, and analytical models with properties that have been randomly varied. Models would include all structural and nonstructural components and systems, and would be able to explicitly predict damage to each component of each system as it occurs. The results of each single analysis would represent one possible outcome, and the results of the large suite (thousands) of analyses would produce a smoothed distribution for probabilistic evaluation of earthquake consequences.

Given the current state of modeling capability, such an approach would be impractical for implementation in practice. Instead, a Monte Carlo procedure is used to assess a range of possible outcomes given a limited set of inputs. In this procedure, limited suites of analyses are performed to derive a statistical distribution of demands from a series of building response states for a particular intensity of motion. From this distribution, statistically consistent demand sets are generated representing a large number of possible building response states. These demand sets, together with fragility and consequence functions, are used to determine a building damage state and compute consequences associated with that damage.

A Monte Carlo procedure is used to assess a range of possible outcomes given a limited set of inputs.

Each unique performance outcome, in terms of a building damage state and consequences given one simulated demand set, is termed a realization. Many realizations are generated, each considering a single random combination of

Each realization represents one possible performance outcome. Many realizations are used to produce a distribution of losses for probabilistic assessment of earthquake performance.

possible values of each uncertain factor, to produce a distribution of losses for probabilistic assessment of earthquake performance. This approach, while lacking the precision of large suites of analyses explicitly assessing uncertainty and variability at each step in the process, is computationally efficient and better suited for practical use at this time.

The flowchart in Figure 7-1 illustrates the performance calculation process used to assess damage and consequences in each realization. The steps are described in the sections that follow.

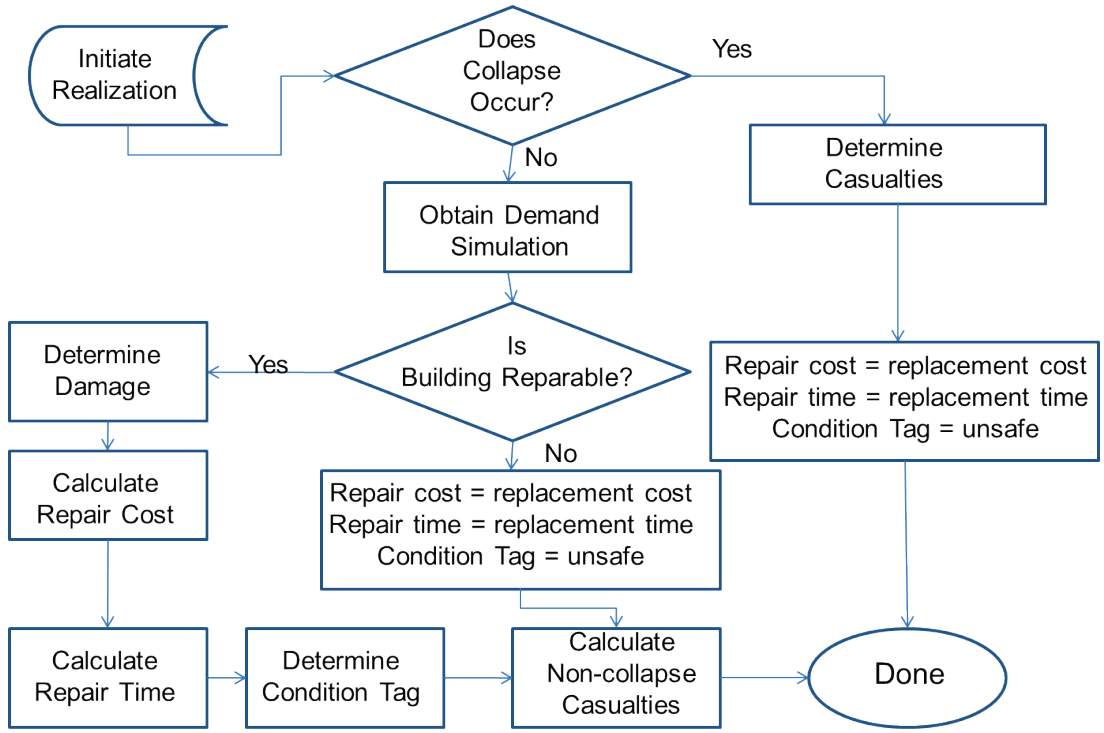

Figure 7-1 Flowchart for performance calculation in each realization.

7.2 Demand Simulation

Generation of simulated demand sets occurs prior to initiation of realizations.

Not shown in the flowchart, and prior to the initiation of realizations, is the generation of simulated demand sets. For mathematical convenience, this step is conducted ahead of the actual realizations. Appendix G describes the process used to generate the hundreds to thousands of demand sets (one demand set is used per realization) needed to assess the distribution of possible building damage states for a ground motion intensity level. This process depends on whether nonlinear response history analysis or the simplified analysis procedure has been used to develop the set of initial demands.

7.2.1 *Nonlinear Response History Analysis*

Nonlinear response history analysis produces a suite of initial demand vectors, assembled into a matrix.

Nonlinear response history analysis generates a suite of initial demand sets, one for each input ground motion. The results are assembled into a vector containing the values of each of the demand parameters (e.g., peak floor acceleration, peak floor velocity, peak story drift ratio, and residual story drift ratio at each level in each direction) for each analysis. These vectors are assembled into a matrix, with each row representing the results from one analysis, and each column representing the values of one demand parameter. The entries in the matrix are assumed to be a jointly lognormal distribution, and are manipulated to compute a vector of median demands (assumed to be the median vector derived from the suite of analyses), variances (or dispersion), and a correlation matrix that indicates how each demand parameter varies with respect to the other demand parameters in the set.

Once this manipulation has occurred, the terms of the diagonal dispersion matrix are augmented using a square-root-sum-of-squares approach to account for additional modeling uncertainty and ground motion uncertainty (in the case of scenario-based assessments). The resulting simulated demand sets will be statistically consistent with the initial demand set, but will more closely represent the range of possible responses that the building could experience at a particular ground motion intensity level. Figure 7-2 illustrates the potential variation in simulated displacement demands associated with nonlinear response history analysis of a hypothetical structure. The resulting response profile can vary in amplitude and shape from simulation to simulation.

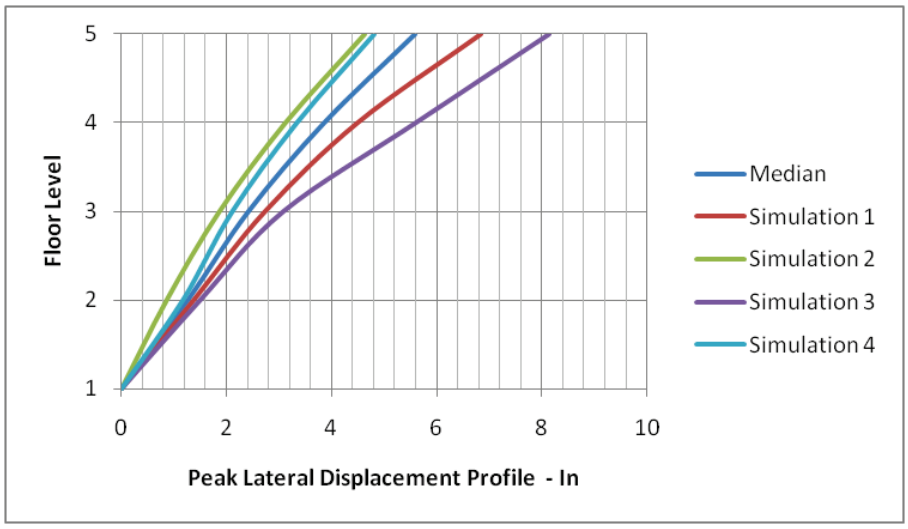

Figure 7-2 Potential variability in simulated drift demands associated with nonlinear response history analysis of a hypothetical building.

7.2.2 *Simplified Analysis*

Simplified analysis produces a single set of median demands and default estimates of dispersion associated with each demand parameter.

The simplified analysis procedure results in a single vector of estimated median values of each demand parameter (e.g., peak floor acceleration, peak floor velocity, peak story drift ratio, and residual story drift ratio at each level in each direction). It also utilizes default estimates of the dispersion associated with each parameter.

For each realization, a number between 1 and 100 is randomly generated, representing the percentile, within the lognormal distribution, for determination of demands for this realization using the default estimate of dispersion for each response quantity. This approach assumes that the building maintains the same response profile at a given intensity of ground motion, but with different amplitude. If one value of simulated demand is higher than the median by a particular measure, all are equally higher. In essence, it is assumed that there is perfect correlation between the various demands when using the simplified analysis procedure.

Figure 7-3 illustrates the potential variation in simulated displacement demands associated with simplified analysis of a hypothetical structure. The resulting response profile can vary in amplitude, but not shape. Use of the simplified analysis will result in more uniformity in response than nonlinear response history analysis, which is a less realistic treatment of potential variability.

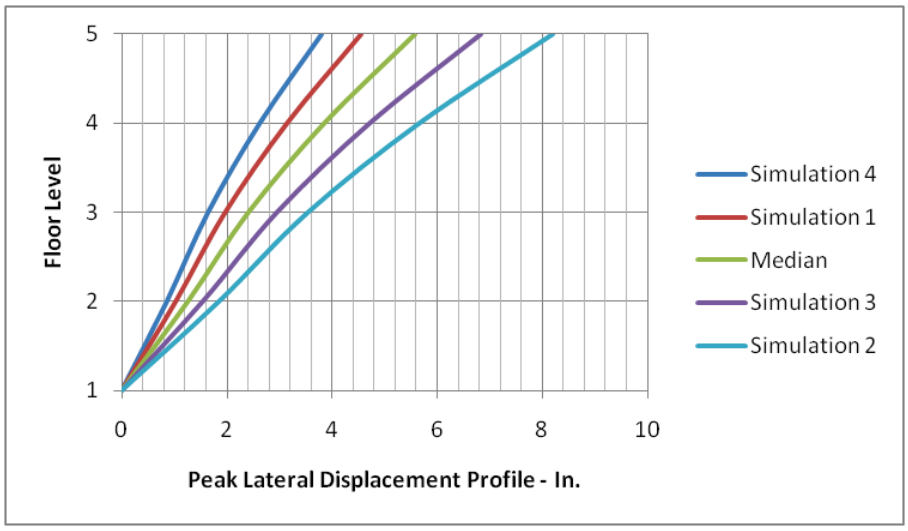

Figure 7-3 Potential variability in simulated drift demands associated with simplified analysis of a hypothetical building.

7.3 Realization Initiation

Each realization initiates with determination of the time of day, and day of the year at which the earthquake is assumed to occur. This information is used, together with the population model, to determine the number of people present in the building in a given realization.

7.4 Collapse Determination

For each realization, a determination is made as to whether or not collapse has occurred. The possibility of collapse is assessed using the collapse fragility function described in Chapter 6. Figure 7-4 shows a collapse fragility function for a hypothetical building.

For each realization, a determination is made as to whether or not collapse has occurred.

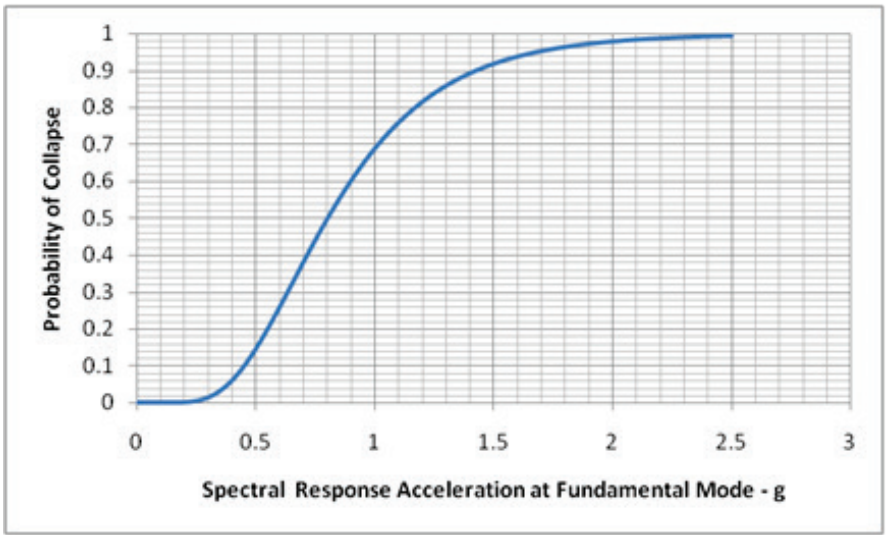

Figure 7-4 Collapse fragility function for a hypothetical building.

As an example, at a ground motion intensity level with a spectral acceleration of 0.5 g at the fundamental period of the building, Figure 7-4 indicates that there is a 15% probability of collapse. To determine if collapse has occurred in each realization, a number between 1 and 100 is randomly generated. If the random number is less than or equal to the value of conditional probability of collapse factored by 100 (i.e., 0.15×100 = 15), collapse is deemed to occur in this realization. If the number is greater than 15, collapse is deemed not to occur.

7.4.1 Collapse Mode

As described in Chapter 6, a building can collapse in one of several modes ranging from partial collapse to total collapse. Given that collapse is predicted to occur, the mode of collapse must be determined to estimate casualties. Development of the collapse fragility function includes

identification of the possible collapse modes and the conditional probability of occurrence of each mode, given that collapse occurs, as well as the fraction of each floor subject to collapse debris.

The collapse mode probabilities are assembled into an array ranging from 1 to 100, with n_i sequential numbers assigned to each mode, where n_i is the conditional probability of occurrence for mode "*i,*" factored by 100. To determine which collapse mode has occurred in a realization, a number between 1 and 100 is randomly generated. The range of the array in which this number falls indicates the collapse mode that has occurred.

For example, if a two story building has three potential collapse modes, consisting of first story collapse (50% probability), second story collapse (25% probability), and complete collapse (25%), these probabilities would be used to construct the array. Numbers 1 through 50 would be assigned to collapse mode 1; numbers 51 to 75 would be assigned to collapse mode 2; and numbers 76 to 100 would be assigned to collapse mode 3. A random number of 64 would indicate that collapse mode 2 occurred in this realization.

7.4.2 Casualties

Using a random number generator and a time-dependent population model appropriate for the building occupancy, along with the randomly generated day and time, the number of people present in the area of collapse is determined. Given that collapse has occurred and the collapse mode has been determined, the number of casualties is estimated based on the building population assumed present at the time of the realization, the associated fraction of floor area at each level subject to collapse, and additional building-specific casualty information.

For each collapse mode, user-defined mean fatality and injury rates are assigned. Based on building type and limited data from past earthquakes, these rates describe the percent of occupants that will suffer fatality or injury in an area impacted by collapse. These probabilities are factored by the ratio of floor area subject to debris, and the population present in the building, to estimate the resulting injuries and fatalities in each realization.

7.4.3 Repair Cost and Repair Time

If collapse has occurred, repair cost and repair time for the realization are set equal to the building replacement values.

Given that collapse has occurred, repair cost and repair time for the realization are set equal to the building replacement values.

7.5 Damage Calculation

If collapse has not occurred, the damage sustained by each component is calculated. To determine damage for each realization in which collapse has not occurred, one vector of simulated demands is obtained, and a damage state is determined utilizing the fragility functions assigned to each performance group. The overall building damage state for the realization is the aggregate of the damage states in each performance group.

Random number generation is used to determine the damage state for each component based on the assigned fragility function. For correlated damage states, each component in a performance group is assumed to have the same damage state, and the process is performed only one time for the performance group. For uncorrelated damage states, each component in a performance group can have a different damage state, and the process must be performed *n* times, where *n* is the number of components in the group.

For correlated damage states, every element in a performance group is assumed to have the same damage state. For uncorrelated damage states, each element in a performance group can have a different damage state.

7.5.1 Sequential Damage States

Sequential damage states must occur in sequential order, with one state occurring before another is possible. Each sequential damage state represents a progression to higher levels of damage as demand increases. Figure 7-5 illustrates hypothetical fragility functions for three sequential damage states and a hypothetical realization demand of 0.25 g.

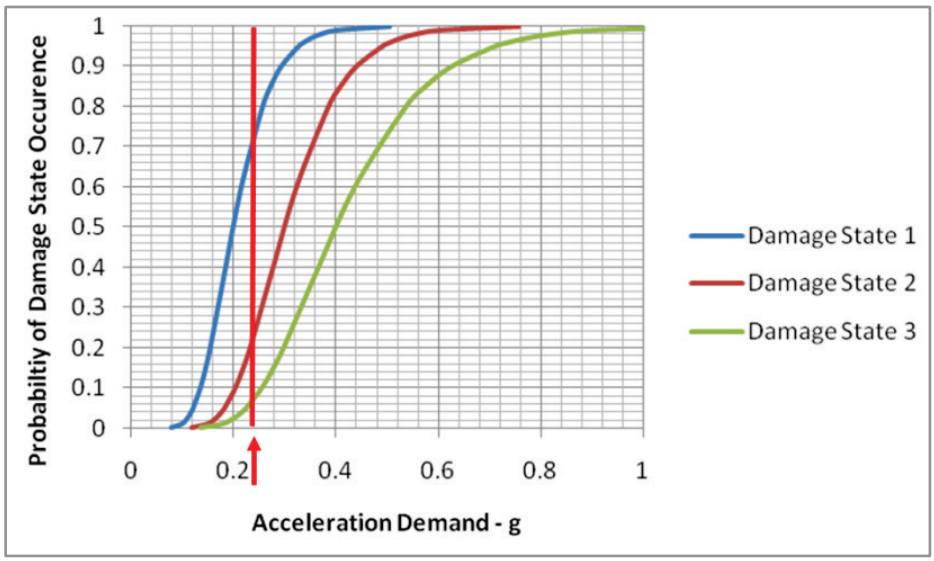

Figure 7-5 Hypothetical fragility functions for three sequential damage states.

Each sequential damage state is assigned a range of numbers. For example, DS1 ranging from ($P_1 \times 100$) to ($P_2 \times 100$), and DS2 ranging from ($P_2 \times 100+1$) to ($P_3 \times 100$), where P_i is the inverse probability of incurring damage state "*i*"

at the demand level for the realization, as indicated by the fragility assigned to the performance group. A random number below ($P_1 \times 100$) indicates that no damage has occurred; a random number between ($P_i \times 100$) and ($P_{i+1} \times 100$) indicates damage state P_i has occurred.

In this example, the probability of not incurring DS1 or higher is $P_1 = 1 - 0.75 = 0.25$; the probability of not incurring DS2 or higher is $1 - P_2 = 1 - 0.23 = 0.77$; and the inverse probability of not incurring DS3 is $P_3 = 1 - 0.06 = 0.94$. Therefore, the range of numbers assigned to no damage would be 1 to 25; the range assigned to DS1 would be 26 to 77; the range assigned to DS2 would be 78 to 94; and the range assigned to DS3 would be 95 to 100. A random number of 97 would indicate that a component has incurred DS3 for the realization.

When two or more sequential damage states have different dispersions, the fragility curves may cross, especially at the tails. In such cases, the probabilities are adjusted to avoid nonsensical negative probabilities of occurrence. For example, if the curve for DS2 crossed the curve for DS1 at a probability of 0.1 (which corresponds to an acceleration of 0.13 g), the probability of incurring DS1 is set equal to 0 for levels of acceleration less than 0.13 g, and the probability of incurring DS2 is obtained directly from the fragility curve for DS2.

7.5.2 Mutually Exclusive Damage States

Mutually exclusive damage states exist when the occurrence of one damage state precludes the occurrence of another damage state. Each mutually exclusive damage state must have a conditional probability of occurrence, given that the component is damaged, and the sum of the conditional probabilities must add up to 1.0.

Mutually exclusive damage states are each assigned a range of numbers, with DS1 assigned a range from 1 to ($P(DS_1) \times 100$); DS2 assigned a range from ($P(DS_1) \times 100+1$) to ($P(DS_1) + P(DS_2)) \times 100$, and so on. A random number is then generated between 1 and 100, and the range in which it falls determines the type of damage that occurs in the realization.

For example, if a hypothetical component that has three mutually exclusive damage states, DS1, DS2 and DS3, with conditional probabilities of occurrence equal to 20%, 30% and 50%, respectively, the range of numbers assigned to DS1 would be 1 to 20; the range assigned to DS2 would be 21 to 50; and the range assigned to DS3 would be 51 to 100. A random number of 42 would indicate that a component has incurred DS2 for the realization.

7.5.3 Simultaneous Damage States

Simultaneous damage states involve a series of potential damage states that are independent and unrelated in that they can occur, but need not necessarily occur, at the same time. Each simultaneous damage state is assigned a conditional probability of occurrence, given that the component is damaged. To identify the occurrence of damage, an initial random number is selected to determine whether damage has occurred or not. If the random number is less than the probability of incurring damage, then damage of some type is deemed to occur in the realization.

Given that damage has occurred, a second random number is selected for each possible damage state to determine if one or more of the simultaneous damages states have occurred. Unless one of the possible damage states has a conditional probability of occurrence equal to 1.0, there will be some small possibility that the random number generation will determine none of the simultaneous damage states has occurred. When this happens, the process is repeated until at least one damage state is deemed to occur for the realization.

7.6 Loss Calculation

If collapse has not occurred, losses are calculated based on the damage sustained by each component and the consequence functions assigned to each performance group. The aggregate of the losses in each performance group is the overall performance outcome for the realization.

In each realization, calculated losses include consideration of economies of scale and efficiencies in construction for repair actions at the performance group level. However, in aggregating losses to determine the overall performance outcome, global efficiencies of scale are not taken into account at the realization level.

A determination is made as to whether or not the building is repairable. The maximum residual drift ratio is used, together with a building repair fragility, to determine if repair is practicable. As with collapse determination, a random number generator is used to select an integer between 1 and 100. If this number is equal to or less than the probability of irreparability, as determined by the building repair fragility at the residual drift ratio for the realization, then the building is deemed irreparable for that realization. If the building is deemed irreparable, then the computed repair costs and repair times are discarded and the total replacement cost and replacement times are assigned to the realization.

If the maximum residual drift ratio renders a building irreparable, then the computed repair costs and repair times are discarded and the total replacement cost and replacement times are assigned to the realization.

Loss distributions are developed by repeating the calculation of damage and loss for a large number of realizations.

Loss distributions are developed by repeating the calculation of damage and loss for a large number of realizations, and sorting the values in ascending (or descending) order to enable the calculation of the probability that total loss will be less than a specific value for a given intensity of shaking. For example, if loss calculations are performed for 1,000 realizations, and the realizations are assembled in ascending order, the repair cost with a 90% chance of exceedance will be the repair cost calculated for the realization with the 100th largest cost, as 90% of the realizations will have had a higher computed cost.

Figure 7-6 shows a hypothetical cumulative loss distribution of repair costs for an intensity-based or scenario-based assessment. In the figure, each point represents the repair cost determined in a single realization. The smooth curve is a lognormal distribution that has been fitted to the data.

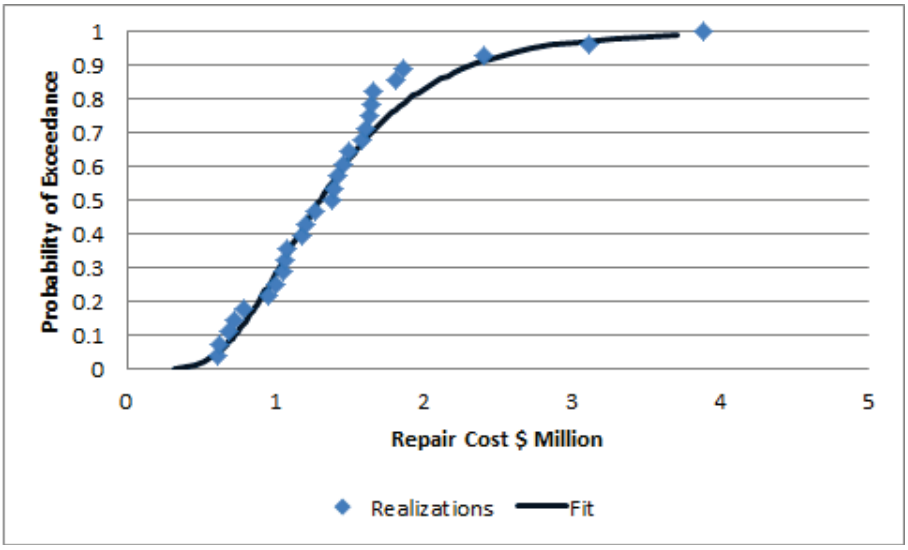

Figure 7-6 Hypothetical cumulative loss distribution of repair costs for an intensity-based or scenario-based assessment.

Any value of total loss can also be de-aggregated into the losses associated with a specific performance group by summing, on a realization basis, the sources of the loss. Figure 7-7 shows a hypothetical de-aggregation of repair costs across six performance groups. Results for other consequences can be similarly de-aggregated. Casualties can be de-aggregated across different building collapse modes, as well as those caused by falling hazards associated with different performance groups.

7.6.1 Unsafe Placard Loss Calculation

For each realization, and for each performance group with damage states that can result in unsafe placarding, a determination is made as to the number of components within a performance group that would need to be damaged to

trigger posting of an unsafe placard. The damage state calculated for each component is evaluated to determine if the triggering percentage has been exceeded for the group. If the number of components damaged to a given damage state exceeds the triggering percentage in any performance group, the building is assigned an unsafe placard. The probability of obtaining an unsafe placard is then calculated as the number of realizations in which an unsafe placard is assigned, divided by the total number of realizations for the particular intensity.

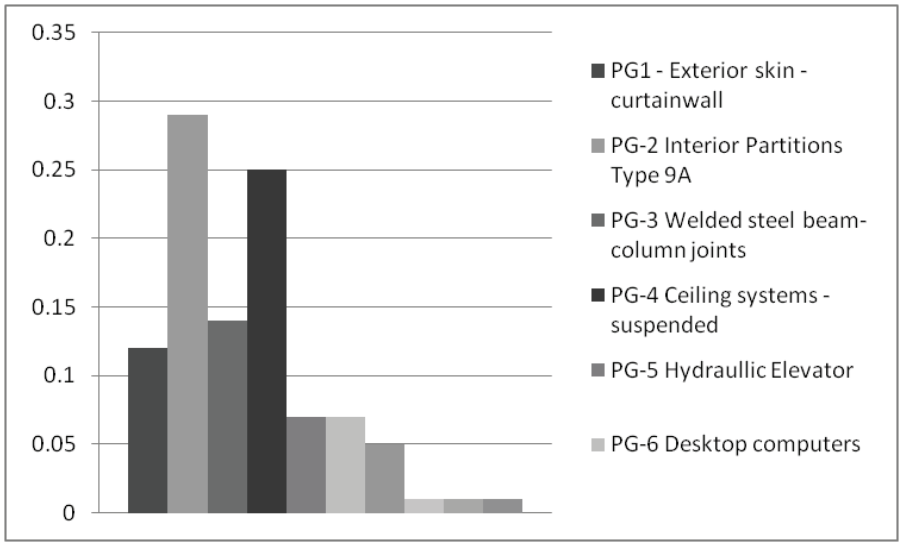

Figure 7-7 Hypothetical de-aggregation of repair costs by performance group.

7.7 Time-Based Assessments

Time-based assessments produce a loss curve of the type shown in Figure 7-8, which plots the total value of a loss (e.g., repair cost, repair time, or casualties), as a function of the annual rate of exceeding that loss. The curve shown in Figure 7-8 is constructed using the results of a series of intensity-based assessments that are weighted based on the frequency of occurrence, as indicated by a seismic hazard curve for the site.

Figure 7-9 shows a representative seismic hazard curve, where the annual frequency of exceeding earthquake intensity, $\lambda(e)$, is plotted against the earthquake intensity, e. Typically, earthquake intensity is measured as spectral acceleration at the first mode period of the building.

The hazard curve for the site is used with Equation 7-1 to calculate the annual probability that the loss, L, will exceed a value, l:

$$P(L > l) = \int_{\lambda} P(L > l \,|\, E = e)\, d\lambda(e) \qquad (7\text{-}1)$$

where the term $P\left(L > l \middle| E = e\right)$ is the loss curve obtained from an intensity-based assessment for intensity, e.

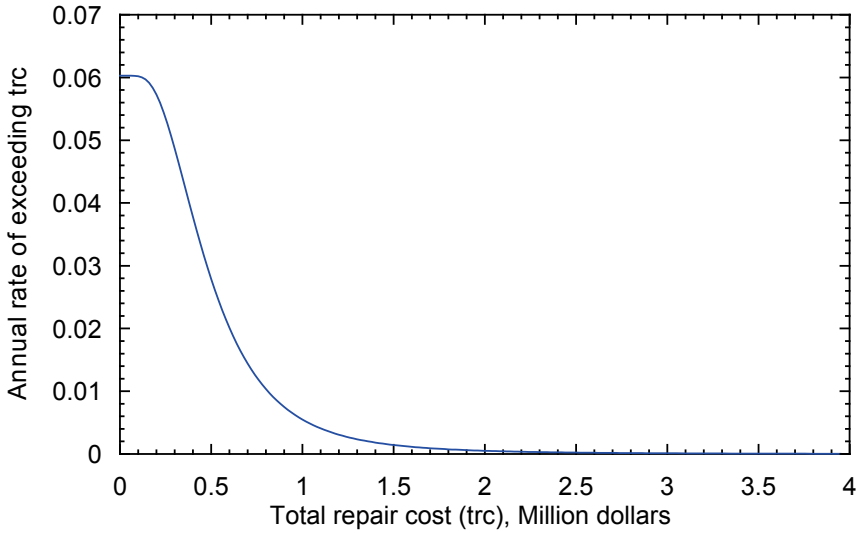

Figure 7-8 Distribution of mean annual total repair cost.

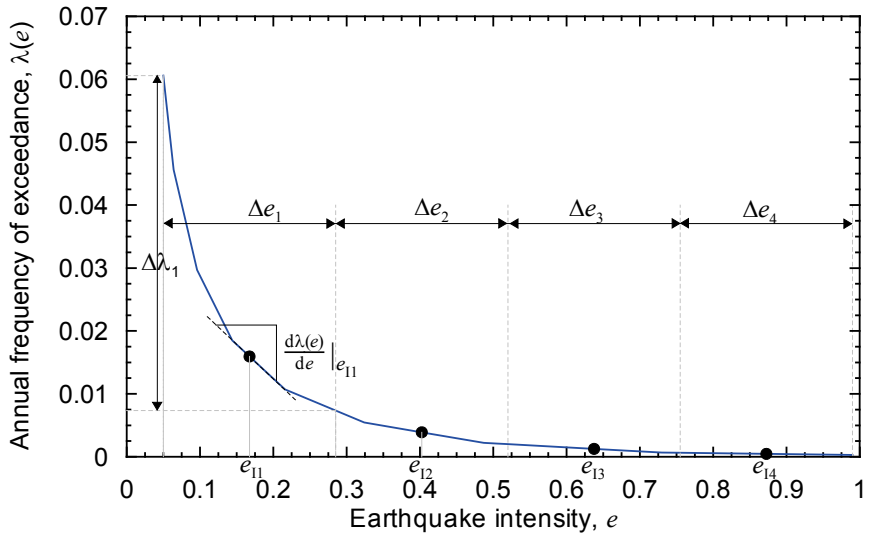

Figure 7-9 Seismic hazard curve and intervals used for time-based loss calculations.

Equation 7-1 is solved by numerical integration. To perform this integration, the spectral range of interest is divided into n intervals, Δe_i. The spectral range of interest will typically range from a very low intensity, resulting in no damage, to a very high intensity, resulting in a high likelihood of collapse. The midpoint intensity in each interval is e_{Ii}, and the annual frequency of occurrence for earthquakes with an intensity in the range of Δe_i is $\Delta\lambda_i$, where the parameters are as defined in Figure 7-9, for $n = 4$. Note that in most

time-based assessments, a larger number of intensities, n, will typically be necessary.

The intensity at e_{I1} is assumed to represent all earthquake shaking in the interval Δe_i. The number of intensities, n, required to implement time-based assessments will vary, and will depend on the slope of the hazard curve and the ability of the structure to survive a wide range of ground shaking intensities. An intensity-based assessment is performed at each of the midpoint intensities, e_{I1} through e_{In}. The product of the n intensity-based assessments is n loss curves of the type shown in Figure 7-10.

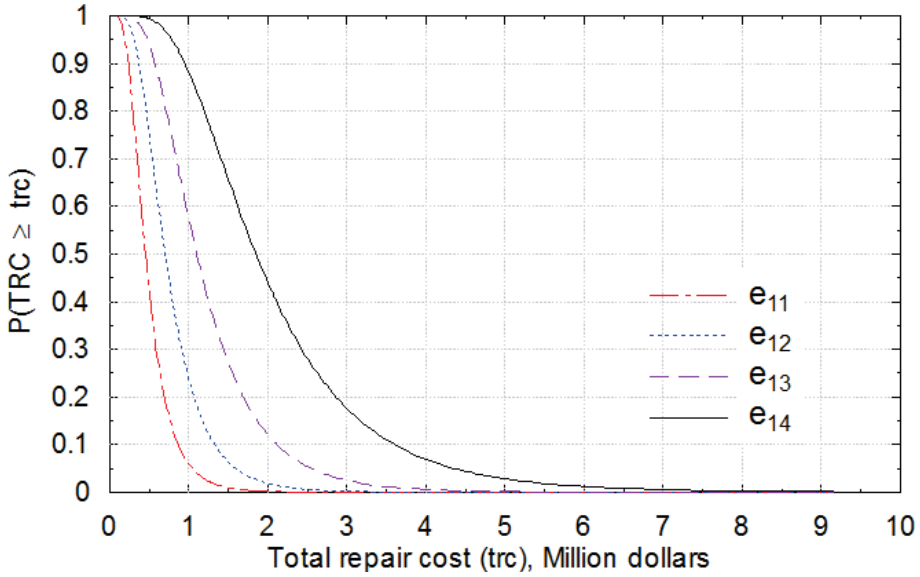

Figure 7-10 Cumulative probability distributions of total repair cost for a hypothetical building at four ground motion intensities.

The annual probability of occurrence, $\Delta\lambda_i$, for shaking intensity e_{Ij}, is calculated from the seismic hazard curve as the difference between the annual frequencies of exceedance at each end of the interval, Δe_i. Figure 7-10 is constructed by: (1) multiplying each loss curve by the annual frequency of occurrence in the interval corresponding to the earthquake intensity used to construct the curve; and (2) summing the annual frequencies for a given value of the loss.

Chapter 8
Decision Making

8.1 Introduction

Performance assessment can provide useful information for many decisions associated with real property. These include:

- Demonstrating equivalence of alternative design approaches.
- Selecting appropriate design criteria for new buildings.
- Determining if an existing building constitutes an acceptable risk for a particular planned use, whether or not it should be upgraded, and if so, to what level.
- Performing benefit-cost studies to determine a reasonable investment for improved seismic resistance in a building.
- Determining whether or not insurance is a cost-effective risk management technique.

This chapter illustrates how data obtained from performance assessments can be used to aid in the planning and design decision-making process.

8.2 Code Equivalence

For many years, building codes have permitted alternative designs and construction techniques that do not conform to the prescriptive seismic design criteria contained within the code. This permission is subject to the building official's satisfaction that the proposed design or construction technique is capable of providing performance that is equivalent to what is expected of code-conforming buildings. The performance assessment process can be used to demonstrate that an alternative design is capable of providing equivalent performance.

Commentary to Section 1.3 of ASCE/SEI 7-10, *Minimum Design Loads for Buildings and Other Structures* (ASCE, 2010), establishes the intended minimum safety-related seismic performance of building structures conforming to any of four Risk (or Occupancy) Categories. This performance is quantified in terms of acceptable probabilities of collapse, given that a structure is subjected to Maximum Considered Earthquake (MCE) shaking. The procedures of Chapter 6 can be used to assess collapse

Code safety-related seismic performance is quantified in terms of acceptable probabilities of collapse, given MCE shaking.

behavior and to develop a collapse fragility for a specific building or alternative design. This can be used to determine directly, the probability of collapse given MCE shaking, a specific earthquake scenario of interest, or considering all earthquake hazards affecting a site on a time-basis.

Intensity-based assessments can be used to indicate probable building performance for Design Earthquake shaking or MCE shaking, as defined in the building code.

It is envisioned that future building codes will likely include quantitative criteria that address performance issues in a broader context and more direct manner. Rather than considering the probability of collapse alone, it is possible that future codes could set safety-related goals in terms of the risk of casualties, rather than collapse. It is also possible that additional performance measures, such as the potential for loss of beneficial use, and damage to critical functionality-related equipment might be considered and quantified. With criteria so defined, intensity-based assessment procedures can be used to indicate probable building performance for Design Earthquake shaking or MCE shaking, as defined in the building code, or for any other target response spectrum.

8.3 Use of Scenario-Based Assessment Results

Scenario-based assessments can be useful to decision-makers with buildings located close to major active faults.

Scenario-based assessments evaluate the probable performance of a building assuming that it is subjected to an earthquake scenario consisting of a specific magnitude earthquake occurring at a specific location relative to the building site. Scenario-based assessments can be useful to decision-makers with buildings that are located close to a major active fault, and who believe that a particular magnitude earthquake might occur on this fault within a time period that is meaningful to them, often ranging from 10 to 30 years.

Scenario-based assessments will provide direct information regarding the probable repair costs for such an occurrence, the potential for life loss, and the potential for long term loss of use. These impacts are quantified in the form of performance curves indicating the probability that losses will exceed a certain value, over the full range of possible values. Decision-makers may be uncomfortable with, or unable to use this type of probabilistic-based information, and might want a more specific answer regarding how big the losses could be. One way to provide this type of information is in the form of an expected performance, together with possible upper and lower bounds.

Probabilistic results can be communicated in the form of an expected performance, together with possible upper and lower bounds

Expected performance can be mathematically derived from performance curves through numerical integration. Figure 8-1 illustrates this process, showing a scenario-based performance curve for a hypothetical performance measure. In the figure, the performance curve has been divided into five stripes, each with an equal probability of occurrence of 20%, given that the earthquake scenario has occurred. The probability of occurrence is equal to

the difference between the probabilities of non-exceedance at each end of the stripe. Within each stripe, the central value of the performance measure has been identified by reading horizontally from the middle of the stripe, and then reading vertically from the intersection point on the performance curve. The expected performance can be taken as the mean value of the performance measure, $\overline{PM}$, given by:

$$\overline{PM} = \sum_{i=1}^{k} P(i)\, PM_i \qquad (8\text{-}1)$$

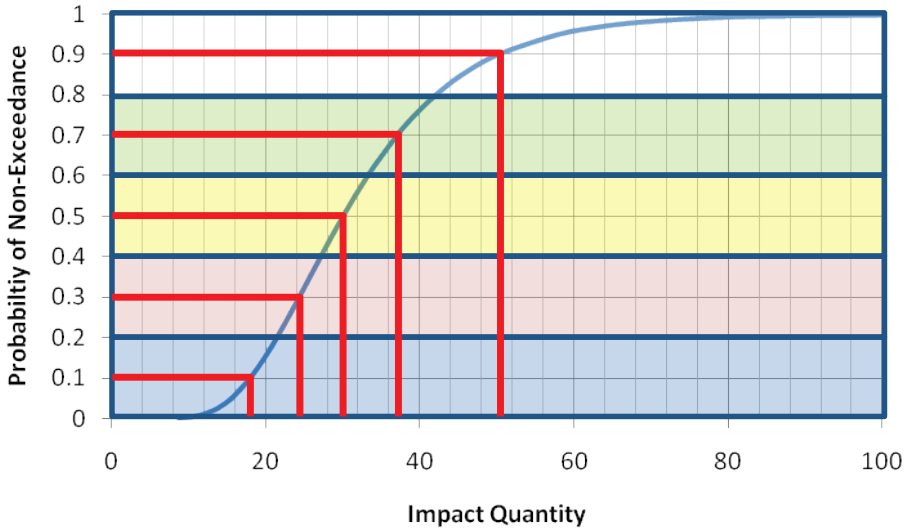

Figure 8-1 Hypothetical scenario-based peformance curve and striping for numerical integration of the mean value of a performance measure.

where $P(i)$ is the probability of occurrence for performance measure values within stripe i; PM_i is the central value of the performance measure for stripe i; and k is the number of stripes. For the case illustrated in the figure, the mean value, $\overline{PM}$, is given by 0.2 (19 + 24 +30 + 38 + 50) = 32. It should be noted that this value is slightly larger than the median value (i.e., the value corresponding to 50% probability of non-exceedance), which in this case has a value of 30. As the skew in a distribution increases, so does the difference between the mean and median values, with the mean being larger than the median. Any number of stripes can be used in the numerical integration process, and the stripes do not need to be uniform in size (i.e., the probability of occurrence need not be equal for each stripe). As the number of stripes increases, the accuracy of numerical integration also increases.

An alternative method of determining the mean value is to assume that the performance curve is approximated by a lognormal distribution, with median value, PM_{50}, and dispersion, β. The median value is the value with a 50%

probability of non-exceedance (i.e., the value exceeded 50% of the time), which is 30. The dispersion, β, can be approximated as:

$$\beta = 0.43\left(\frac{PM_{50}}{PM_{10}} - 0.782\right) \tag{8-2}$$

where, PM_{50} and PM_{10} are the 50th and 10th percentile values from the loss curve. The mean value can then be determined as:

$$\overline{PM} = PM_{50}e^{\beta^2/2} \tag{8-3}$$

where all terms are as previously defined. For the performance curve of Figure 8-1, these equations yield β = 0.34 and $\overline{PM}$ = 31.8, which compares well with the value of 32 computed by numerical integration.

When providing expected (or mean) performance to decision-makers, it is also important to provide bounds on this performance so there is some understanding of the chance that performance will be superior or inferior to the mean. Often, PM_{10} (i.e., the value that is not exceeded 10% of the time) and PM_{90} (i.e., the value that is not exceeded 90% of the time) are appropriate bounds to communicate along with the mean.

8.4 Use of Time-Based Assessment Results

Time-based assessments provide the average annual value of a performance measure, which is useful in cost-benefit analyses.

Time-based assessments evaluate the probable performance of a building over a specified period of time (e.g., 1 year, 30 years, or 50 years) considering all earthquakes that could occur in that time period, and the probability of occurrence associated with each earthquake. Time-based assessments can be used to provide the average annual value of a performance measure. Average annual values are useful in benefit-cost studies, and for determining reasonable insurance premiums on a property.

The average annual value of a performance measure is the mean value obtained from a time-based performance curve, such as that shown in Figure 8-2. It can be derived by numerical integration using Equation 8-1, as described for scenario-based performance curves in the previous section. For the hypothetical annual performance curve shown in Figure 8-2, the computed mean annual value of the performance measure is 0.2 (0.05 + 0.07 + 0.1 + 0.14 + 0.19) = 0.11 per year. If, for example, the performance measure was casualties, this value would indicate an average annual casualty rate of 0.11. If the performance measure was repair cost (in millions of dollars), this would indicate an average annual repair cost of $110,000.

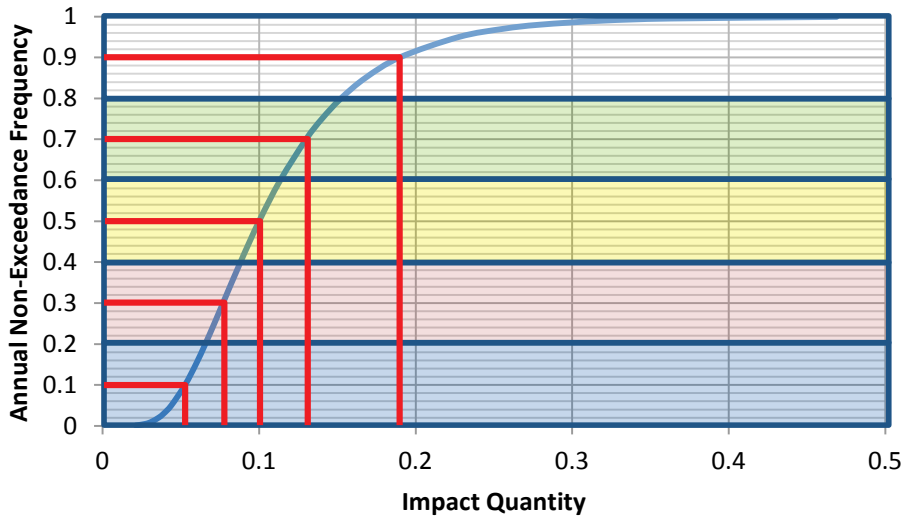

Figure 8-2 Hypothetical annual performance curve and striping for numerical integration of the mean annual value of a performance measure.

Earthquake losses, however, do not occur in annual increments. Over a period of many years, the average annual loss should approximate the total loss in a period of time, divided by the number of years in that period. If the performance measure is repair cost, the average annual repair cost is a reasonable measure of the insurance premium that a decision-maker might pay to insure against possible future earthquake repair costs. If the performance measure is expanded to include probable costs associated with loss of use, this can also indicate a reasonable value of insurance premiums to cover occupancy interruption costs.

Average annual repair costs are a good measure of the insurance premium that a decision-maker might pay to insure against possible future earthquake repair costs.

Average annual values of a performance measure can also be an input to benefit-cost studies used to determine a reasonable investment for improved seismic resistance in a building. Benefit-cost studies involve a comparison between the net present value of average annual costs that are avoided through enhanced seismic resistance, versus the costs associated with providing the enhanced seismic resistance. The net present value, *NPV*, of a stream of equal annual future expenditures (or avoided expenditures) is given by:

Net present value of average annual costs can be used to perform benefit-cost studies.

$$NPV = A\left\{\frac{1-\frac{1}{(1+i)^t}}{i}\right\} \tag{8-4}$$

where A is a stream of equal annual expenditures (or avoided expenditures), t is the period of time in years, and i is the internal rate of return (or interest rate). The value of i represents the interest rate one would expect to pay if

capital was borrowed from others, or it represents the rate of return on investment that would be expected.

For decisions regarding property with an anticipated life of more than 40 years, the average annual cost (or savings) can be considered an annuity with an infinite term. In this case, Equation 8-4 reduces to the simpler form:

$$NPV = \frac{A}{i} \tag{8-5}$$

As an example, consider a hypothetical company with operations in a single building in an earthquake-prone region. A performance assessment of the existing building indicates that it poses negligible risk for casualties, but potential earthquake damage could result in average annual repair costs of $150,000, and an average annual repair time of 5 days. Costs associated with each day of downtime are estimated to be $100,000 in lost profit.

The cost for seismic upgrade of the building, including design fees and internal costs, is estimated to be $3,000,000. A performance assessment of the upgraded building indicates that average annual repair costs will be reduced to $50,000, and the average annual repair time will be reduced to 3 days. The internal rate of return on investment is assumed to be 7%. Time-based assessment results can be used to determine if the upgrade is a reasonable investment if the company expects to remain in the building for 10 years, or if it expects to remain in the building indefinitely.

The average annual benefit of performing the upgrade is the average annual avoided repair cost ($150,000 - $50,000 = $100,000) plus the avoided loss in profit per year ((5 days - 3 days) x ($100,000) = $200,000), which results in a total reduction in average annual loss equal to $300,000. The net present value of the avoided average annual loss over a 10-year period and an indefinite period are given by:

$$NPV_{10\ years} = \$300,000\left[\frac{1-\frac{1}{1.07^{10}}}{0.07}\right] = \$2,108,000 \tag{8-6}$$

$$NPV_{indefinite} = \frac{\$300,000}{0.07} = \$4,290,000 \tag{8-7}$$

Since the net present value of losses avoided over a 10-year period is less than the cost of the seismic upgrade, there is not an economic benefit for this upgrade over a 10-year return period. However, if the company anticipated remaining in the building indefinitely, there would be a net benefit for investing in the upgrade.

In the above example, it is possible, although unlikely, that within 10 years of deciding not to upgrade the building, a damaging earthquake could occur resulting in real losses that are substantially in excess of the $3,000,000 cost of the upgrade.

Time-based assessments provide a means to determine the maximum loss likely to occur within in a specified time period.

Risk-averse decision-makers might want to avoid the realistic possibility of such a scenario. They might prefer to base decisions on a loss with a specific anticipated probability of occurrence, or return period, such as 10-year, 50-year, or 100-year losses. Time-based assessments can be used to provide this type of information.

Return period is the reciprocal of the annual frequency of exceedance. Thus, if a decision-maker is interested in a 50-year loss, one could read from the time-based performance curve the loss at an annual probability of exceedance of 1/50 years = 2%, and determine the 50-year loss directly. A risk-averse decision-maker might be willing to invest an amount up to the value of this loss in the form of seismic upgrades to avoid incurring the loss at some future point during the time period.

8.5 Probable Maximum Loss

Many commercial lenders and real estate investors use a measure of seismic risk known as Probable Maximum Loss (PML). Such decision-makers will either not invest in a property, or will require the purchase of earthquake insurance, when the projected PML exceeds a certain threshold value, which is often 20%.

Intensity-based assessments can be used to determine Probable Maximum Loss and other scenario loss measures used in real estate investment decisions.

ASTM E-2026, *Standard Guide for Seismic Risk Assessment of Buildings* (ASTM, 2007a) and ASTM E-2557, *Standard Practice for Probable Maximum Loss (PML) Evaluations for Earthquake Due-Diligence Assessments* (ASTM, 2007b) set standard procedures for seismic evaluations and the development of PMLs for use by the financial industry. These standards define several different measures including:

- **Scenario Expected Loss (SEL).** Scenario Expected Loss represents the mean repair cost, expressed as a percentage of building replacement value, for a particular intensity of ground motion, typically defined as a ground motion having a 475-year return period.
- **Scenario Upper Loss (SUL).** Scenario Upper Loss represents the 90th percentile repair cost, expressed as a percentage of building replacement value, for a particular intensity of ground motion, typically defined as a ground motion having a 475-year return period.

- **Probable Loss (PL).** Probable Loss represents the loss having a specific probability of exceedance, over a specified number of years.

Both Scenario Expected Loss and Scenario Upper-Bound Loss values can be determined by performing intensity-based assessments for response spectra having the specified return period. The Scenario Expected Loss is obtained by computing the mean repair cost for the assessment. The Scenario Upper Loss is determined directly from the performance curve for repair cost at the 90^{th} percentile loss.

Probable loss can be derived directly from a time-based assessment using an appropriate return period for the assessment. The return period for a loss, P_R, can be derived from the desired probability of exceedance, P_{EY}, in Y years, using the formula:

$$P_R = \frac{-Y}{ln\left(1 - P_{EY}\right)} \tag{8-8}$$

Once the return period for the loss is known, it is possible to compute the annual frequency of exceedance of the loss, as $1/P_R$, and then determine the corresponding probable loss for the frequency of exceedance directly from the annual performance curve.

Appendix A
Probability, Statistics, and Distributions

A.1 Introduction

This appendix provides a brief tutorial on probability and statistics including methods of expressing probabilities in the form of statistical distributions. It is intended to provide readers that are unfamiliar with these topics the basic information necessary for understanding the procedures used to account for uncertainties in performance assessment. Interested readers can obtain additional information in textbooks on probability and statistics, and structural reliability theory, such as Benjamin and Cornell (1970).

A.2 Statistical Distributions

Statistical distributions are mathematical representations of the probability of experiencing a specific outcome given a set of possible outcomes. The set representing all possible outcomes is termed a *population*. There are generally two broad types of populations considered in statistical studies. The first is a finite population of discrete outcomes, and the second is an infinite population of possible outcomes. Each is discussed separately, below.

A.2.1 Finite Populations and Discrete Outcomes

A *finite population* of outcomes occurs when each possible outcome has a discrete value representing one of a finite number of possible occurrences. Consider the classic case of a coin tossed in the air to determine an outcome. One of two possible outcomes will occur each time the coin is tossed. One is that the coin will land "heads-up" and the other is that it will land "heads-down." Which way the coin will land on a given toss is a function of many factors, including which way the coin is held before the toss, the technique used to toss the coin, how hard or high the coin is tossed, how much rotation it is given, and how it lands. It is not possible to precisely simulate each of these factors, and therefore, the occurrence of a "heads-up" or "heads-down" outcome in a given coin toss appears to be a random phenomenon that is not predictable. There is an equal chance that the coin will land "heads-up" or

"heads-down," and it is not known which way the coin will land before the toss is made.

If a coin is tossed in the air one time, there are two possible outcomes. These two outcomes ("heads-up" and "heads-down") completely define all possibilities for a single coin toss and, therefore, the probability that the coin will land either "heads-up" or "heads-down" is 100%. In essence, this illustrates the total probability theorem in that the sum of the probabilities of all possible outcomes will be 100%, also expressed as 1.0.

The probability that the coin will land "heads-up" is 50%, or 0.5. The probability that it will land "heads-down" is the inverse of this, calculated as one minus the probability of "heads-up," 1 – 0.5 = 0.5, or 50%.

If a coin is tossed in the air many times, a "heads-up" outcome would be expected in half of the tosses, and a "heads-down" outcome would be expected in the other half. This does not mean that every second toss of the coin will have a "heads-up" outcome. Several successive "heads-up" or "heads-down" outcomes might occur; however, over a large number of tosses, there should be approximately the same number of each possible outcome.

A.2.2 Combined Probabilities

A *combined probability* is the probability of experiencing a specific combination of two or more independent outcomes. The combined probability of two independent events ($A + B$) is calculated as the product of the probability of outcome A and the probability of outcome B:

$$P(A + B) = P(A) \times P(B) \tag{A-1}$$

To illustrate this, if a coin is tossed into the air two times, there is a 50% chance that the coin will land "heads-up" each time. The chance that the coin will land "heads-up" both times is calculated, using Equation A-1, as the probability of landing "heads-up" the first time (0.5) multiplied by the probability that it will land "heads-up" the second time (0.5), or (0.5 × 0.5) = 0.25, or 25%.

This probability means that if a coin is tossed into the air twice in succession a large number of times, and record the number of "heads-up" outcomes, in each pair of tosses, approximately 25% of the total number of pairs of tosses will have two successive "heads-up" outcomes. This does not mean that every fourth time a pair of coin tosses is made two successive "heads-up" outcomes will occur. There is some possibility that two successive "heads-up" outcomes could occur several times in a row, and there is also a

possibility that more than four pairs of coin tosses will need to be made to obtain an outcome of two "heads-up" in any of the pairs of tosses. However, over a very large number of pairs of tosses, 25% of the pairs should be successive "heads-up" outcomes.

If a coin is tossed into the air three times, there is again a 50% chance on each toss that the coin will land "heads-up." The probability that the coin will land "heads-up" all three times is the probability that it will land "heads-up" the first two times (0.25) multiplied by the probability that it will land "heads-up" the third time (0.5), or $(0.25 \times 0.5) = 0.125$, or 12.5%. If this exercise is repeated with four coin tosses, the probability that all four will land "heads-up" will be the probability that the first three tosses will land "heads-up" (0.125) times the probability that the fourth toss will land "heads-up" or $(0.125 \times 0.5 = 0.0625)$ or 6.25%. That is, there is approximately a 6% chance that on four coin tosses there will be four successive "heads-up" outcomes.

A.2.3 Mass Distributions

A *probability mass distribution* is a plot of the probability of occurrence of each of the possible outcomes in a finite population of discrete outcomes, such as a coin landing either "heads-up" or "heads-down" a specified number of times in N throws.

In the case of four coin tosses, there is a 6.25% chance that all four coin tosses will land "heads-up." There is also a 6.25% chance that all four coin tosses will land "heads-down," which is the same as no tosses landing "heads-up." The chance that three of the four coin tosses will land "heads-up" is equal to the combined chance of any of the following series of outcomes: "T-H-H-H"; "H-T-H-H"; "H-H-T-H" or "H-H-H-T," where "H" indicates "heads-up" and "T" indicates "heads-down." The chance of each of these series of outcomes is equal to $(0.5 \times 0.5 \times 0.5 \times 0.5) = 0.0625$, or 6.25%. Therefore, the chance of exactly three out of four tosses landing "heads-up" is equal to the chance of "T-H-H-H," plus the chance of "H-T-H-H," plus the chance of "H-H-T-H," plus the chance of "H-H-H-T," or $0.0625 + 0.0625 + 0.0625 + 0.0625 = 0.25$, or 25%. Similarly, the probability that exactly three of the four tosses will be "heads-down," or that only one of the tosses will land "heads-up," is also 25%. Similar approaches can be used to show that the probability of exactly half of the tosses landing "heads-up" is 37.5%.

Figure A-1 shows a probability mass distribution for the chance of obtaining zero, one, two, three, or four "heads-up" outcomes in four coin tosses. The

horizontal axis is potential outcome, and the vertical axis is the probability of that outcome. For example, the plot shows the chance that all four tosses will land "heads-up" is 0.06, the chance that three of the four tosses will land "heads-up" is 0.25, and the chance that exactly half of the tosses will land "heads-up" is 0.375.

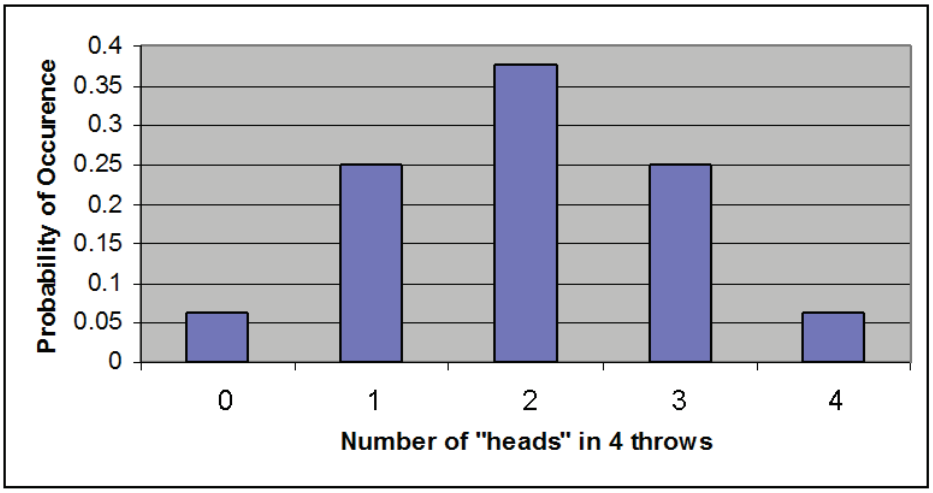

Figure A-1 Probability mass distribution indicating the probability of the number of "heads-up" outcomes in four successive coin tosses.

The probability of having not more than one "heads-up" outcome in four tosses is calculated as the sum of the probability of zero "heads-up", plus the probability of one "heads-up," which is 0.0625 + 0.25 = 0.3125, or 31.25%. Another way to say this is that the *probability of non-exceedance* for one "heads-up" in four coin tosses is 31.25%. The inverse of this is the cumulative probability of more than one "heads-up," which is 1 – 0.3125 = 68.75%. This could also be called the *probability of exceedance* of one "heads-up" in four tosses.

A.2.4 Infinite Populations and Continuous Distributions

The distribution of possible "heads-up" outcomes from a series of coin tosses is a finite population of discrete outcomes. In contrast, for many situations the range of possible outcomes is not finite or discrete, but rather a *continuous distribution* of an infinite number of possibilities.

One example of a continuous distribution is the possible compressive strength obtained from concrete cylinder tests taken from concrete using the same mix design. Such a distribution will have the form shown in Figure A-2, where the observed dispersion in strength can be attributed to minor variability in the relative proportions of cement and water, the strength of aggregates, the techniques used to cast and cure the cylinders, and other

factors. There are an infinite number of possible outcomes for the strength of any particular cylinder test. Such a plot is termed a *probability density function*.

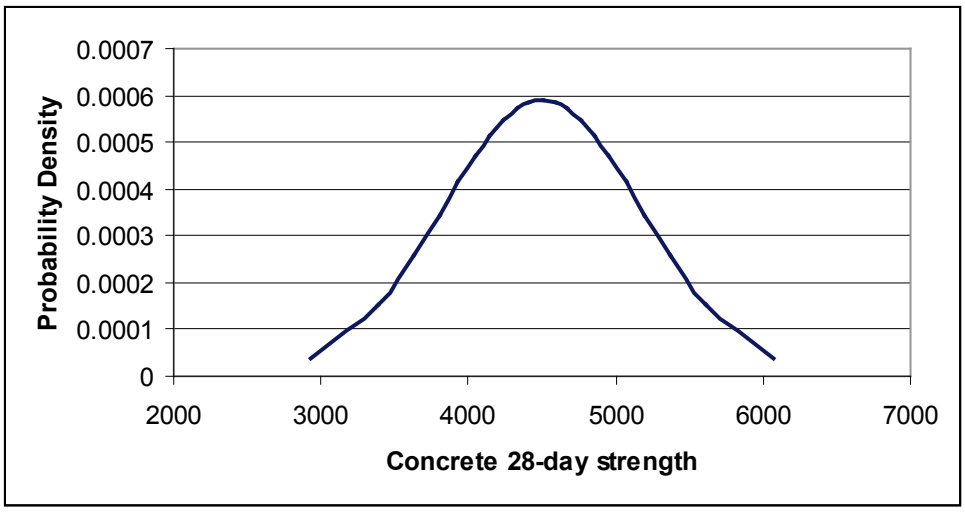

Figure A-2 Probability density function of possible concrete cylinder strengths for a hypothetical mix design.

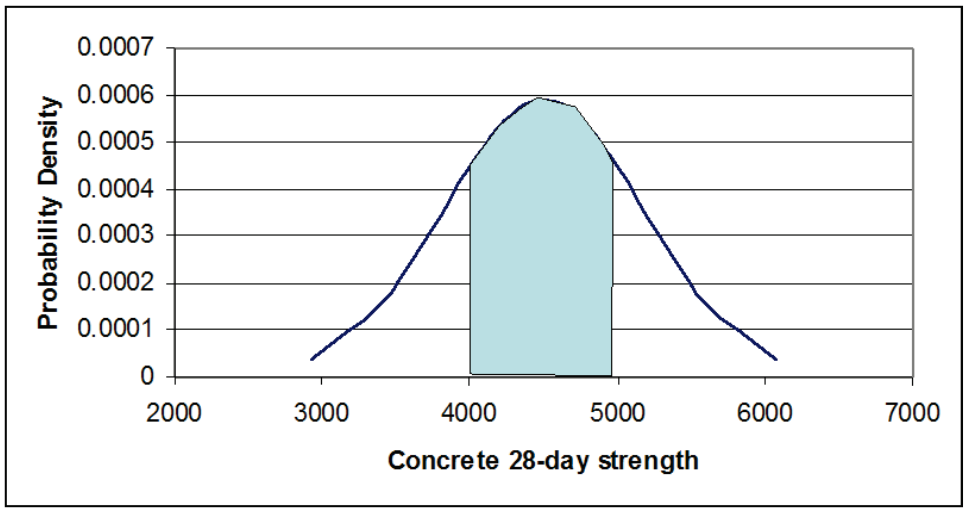

Figure A-3 Area under a probability density function indicating the probability that a member of the population will have a value within a defined range.

The area under a probability density function between any two points along the horizontal axis gives the probability that the value of any one member of the population will be within the range defined by the two points on the axis. In Figure A-3, the probability that a single cylinder test will have a compressive strength that is greater than 4,000 psi, but less than or equal to 5,000 psi, is given by the shaded area under the curve between 4000 psi and 5000psi, which in this case is equal to 54%. That is, there is a 54% chance

that any cylinder test in this population will have a compressive strength between 4,000 psi and 5,000 psi.

A.3 Common Forms of Distributions

A.3.1 Normal Distributions

The probability density function illustrated in Figure A-2 has a special set of properties known as a normal distribution. In a *normal distribution* the *median* outcome, which is the outcome that is exceeded 50% of the time, is also equal to the *mean* or average outcome, which is the total value of all possible outcomes, divided by the number of possible outcomes. In the concrete cylinder test example above, the median outcome is a compressive strength of 4,500 psi. The average strength of all cylinders tested is also 4,500 psi.

Normal distributions are also symmetric. That is, there is an equal probability of having a value at a defined measure above the mean (e.g., 1,000 psi above, or 5,500 psi), as there is of having a value at the same defined measure below the mean (e.g., 1,000 psi below, or 3,500 psi).

Two parameters uniquely define the characteristics of a normal distribution, namely, the mean value $\bar{x}$ and standard deviation, σ. Equation A-2 and Equation A-3 define these values for a random variable x (e.g., compressive strength of concrete as measured by cylinder testing):

$$\bar{x} = \frac{\sum_{i=1}^{N} x_i}{N} \tag{A-2}$$

$$\sigma = \sqrt{\frac{1}{N-1}\sum_{i=1}^{N}\left(x_i - \bar{x}\right)^2} \tag{A-3}$$

where N is the size of the population. If a parameter is normally distributed, having mean value, $\bar{x}$, and standard deviation, σ, it is possible to determine the value, x, of an outcome with a specific probability of exceedance, based on the number of standard deviations that the value lies away from the mean, $\bar{x}$. The number of standard deviations above or below the mean at a specified probability of exceedance is sometimes termed the *Gaussian variate*. Standard tables are available that provide the Gaussian variate. For example, there is a 97.7% chance that the value of any single outcome, x, will be greater than $\bar{x} - 2\sigma$, an 84.1% chance that the value will be greater than $\bar{x} - \sigma$, a 50% chance it will be greater than $\bar{x}$, a 15.8% chance it will be greater than $\bar{x} + \sigma$, and a 2.3% chance that it will be greater than $\bar{x} + 2\sigma$. Tables that provide values of the Gaussian variate are called *Gaussian tables*.

A.3.2 Cumulative Probability Functions

Figure A-4 plots probability density functions for different coefficients of variation. An alternative means of plotting probability distributions is the form of a cumulative probability function. Figure A-5 plots cumulative probability functions for the same normally distributed populations shown in Figure A-4. In both series of plots it can be observed that the larger the coefficient of variation, the greater the amount of scatter in the values of the possible outcomes.

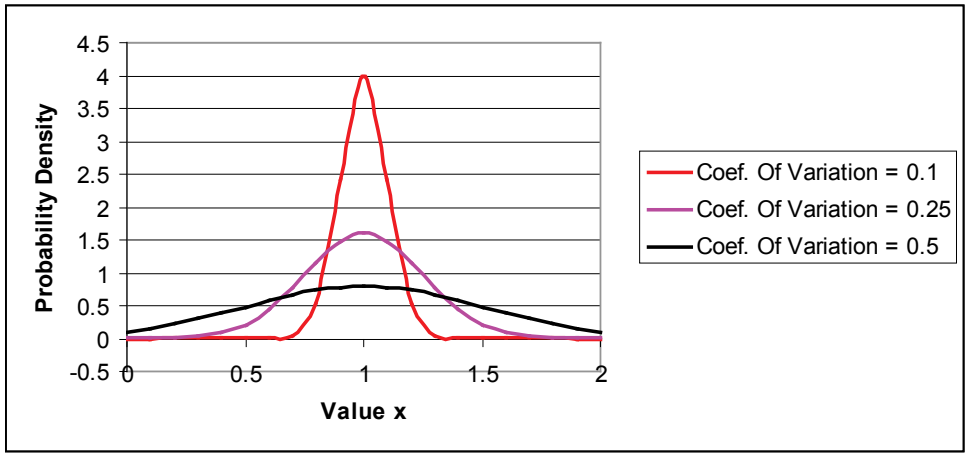

Figure A-4 Probability density plots of normal distributions with a mean value of 1.0 and coefficients of variation of 0.1, 0.25, and 0.5.

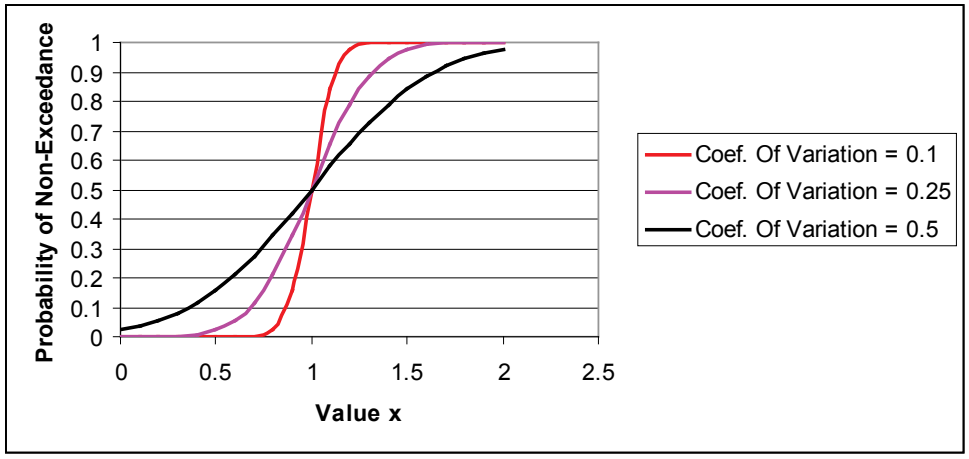

Figure A-5 Cumulative probability plots of normal distributions with a mean value of 1.0 and coefficients of variation of 0.1, 0.25, and 0.5.

Cumulative probability functions are obtained by integrating over the probability density function to determine the area under the curve between the lowest possible value of x and the specified value of x. A *cumulative probability function* gives the probability that an outcome in the population of possible outcomes will have a value that is less than or equal to the

specified value of x. This probability is sometimes termed the *probability of non-exceedance*. Table A-1 indicates representative values of the Gaussian variate for several commonly referenced probabilities of non-exceedance.

Table A-1 Values of the Gaussian Variate in Normal Distributions for Common Probabilities of Non-Exceedance

Probability of Non-Exceedance	Number of Standard Deviations below the Mean		Probability of Non-Exceedance	Number of Standard Deviations above the Mean
.02	-2.00		.60	0.25
.05	-1.64		.70	0.52
.10	-1.28		.80	0.84
.158	-1.00		.84	1.00
.20	-0.84		.90	1.28
.30	-0.52		.95	1.64
.40	-0.25		.98	2.00
.50	0.00			

A.3.3 Lognormal Distributions

Although normal distributions represent some random variables well, they do not represent all variables well. Some variables have skewed distributions. In skewed distributions, the mean value, $\bar{x}$, will be greater than or less than the median value. In structural reliability applications, such as performance assessment, it is common to use a specific type of skewed distribution known as a lognormal distribution. The skew inherent in lognormal distributions can reasonably represent the distributions observed in many structural engineering phenomena, such as the distribution of strength in laboratory test specimens.

A lognormal distribution has the property that the natural logarithm of the values of the population, $\ln(x)$, are normally distributed. The mean and the median of the natural logarithms of the population have the same value, equal to $\ln(\theta)$, where θ is the median value. The standard deviation of the natural logarithms of the population, $\sigma_{\ln(x)}$, is called the dispersion, and is represented by the symbol, β. For relatively small values of dispersion, the value of β is approximately equal to the coefficient of variation for the population. Together, the values of median, θ, and dispersion, β, completely define the lognormal distribution for a population.

Figure A-6 plots probability density functions for three lognormally distributed populations having a median value of 1.0 and dispersions of 0.1,

0.25 and 0.5. Figure A-7 plots cumulative probability functions for the same lognormally distributed populations shown in Figure A-6.

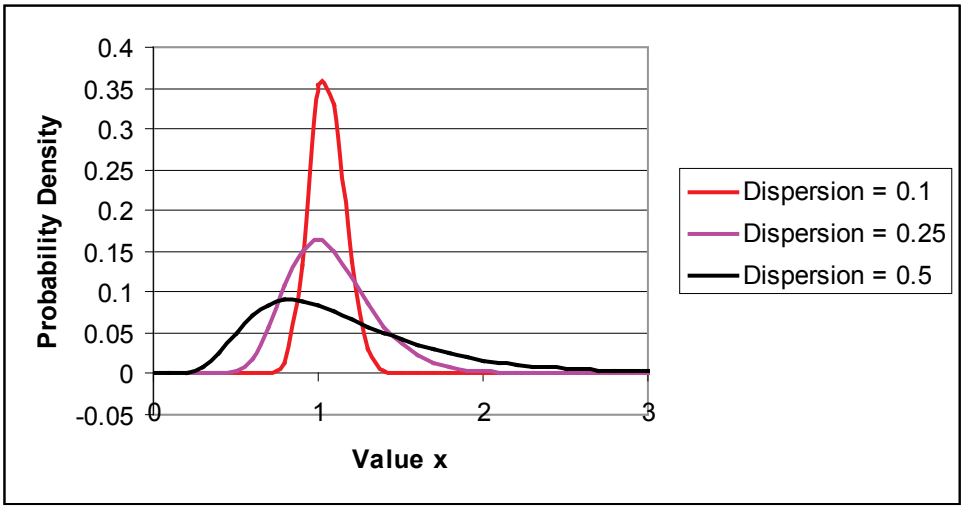

Figure A-6 Probability density plots of lognormal distributions with a median value of 1.0 and dispersions of 0.1, 0.25, and 0.5.

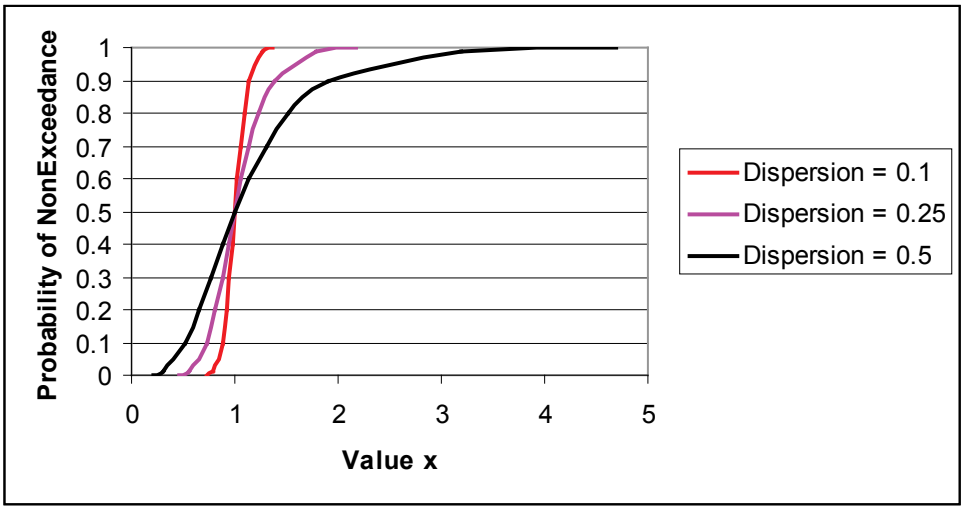

Figure A-7 Cumulative probability plots of lognormal distributions with a median value of 1.0 and dispersions of 0.1, 0.25, and 0.5.

In both series of plots, it can be observed that for small values of the dispersion, the distribution approaches the shape of the normal distribution. As the dispersion increases, the lognormal distribution becomes more and more skewed. This skew is such that extreme values above the median are substantially more probable than extreme values below the median, and there is zero probability of incurring a negative value in the distribution (because the natural logarithm of a negative number is positive).

Consider the distribution of possible actual yield strengths of various steel components, all conforming to a specific ASTM specification and grade.

Since a random variable like yield strength cannot take on values less than zero, a lognormal distribution with a median value and dispersion could be used to describe the variation in possible steel strengths. In this example, the median value of actual yield strengths will be substantially higher than the minimum specified value, which is intended to have a very low probability of non-exceedance by any steel component conforming to the specification (i.e., the actual yield strength of any one component in the population should have a high probability of exceeding the minimum specified yield strength of the ASTM specification).

The seismic performance assessment methodology uses lognormal distributions to represent many uncertain factors that affect performance including: (1) the distributions of intensity for a scenario earthquake; (2) the values of response parameters given an intensity; (3) the probability of incurring a damage state as a function of a response parameter, herein termed a fragility; and (4) the probability of incurring a specific level of consequences in terms of casualties, repair costs, repair time or other impacts, given the occurrence of a damage state. These lognormal distributions are derived in a variety of ways:

- Intensity distributions are obtained based on statistical analysis of actual ground motion data recorded from past earthquakes, and represented in the form of equations known as attenuation relationships or ground motion prediction equations.
- Response parameter distributions are obtained by performing suites of structural analyses for multiple ground motion recordings and using these results to generate large numbers of statistically consistent simulated demand sets considering modeling uncertainty and ground motion uncertainty.
- Fragility distributions are obtained primarily through laboratory testing or observation of actual damage in past earthquakes.
- Loss distributions are obtained through performing multiple calculations of loss, and varying the factors that affect the loss.

Regardless of how they are derived, these distributions are represented by the median value, θ, and dispersion, β.

The mean, m_Y, and standard deviation, σ_Y, of a lognormal distribution, Y, can be calculated from θ_Y and β_Y as follows:

$$m_Y = \theta_Y \exp\left(\frac{\beta_Y^2}{2}\right) \tag{A-4}$$

$$\sigma_Y^2 = m_Y^2\left[\exp\left(\beta_Y^2\right) - 1\right] \quad \text{(A-5)}$$

The coefficient of variation, ν_Y, is given by:

$$\nu_Y = \frac{\sigma_Y}{m_Y} = \sqrt{\exp(\beta_Y^2) - 1} \quad \text{(A-6)}$$

Many common spreadsheet applications have embedded functions that will automatically solve lognormal distribution problems. For example, in Excel, the LOGNORMDIST function will determine the cumulative probability of non-exceedance of any value in a population *Y*, based on input of the value, *y*, the natural logarithm of the median, $\ln(\theta_Y)$, and the dispersion, β_Y. The Excel input is of the form =LOGNORMDIST (y, $\ln(\theta_Y)$, β_Y). Similarly, the LOGINV function can be used to determine the value of *y*, at a given cumulative probability of non-exceedance, based on the desired probability, *p*, which must be less than 1.0, the natural logarithm of the median $\ln(\theta_Y)$, and the dispersion, β_Y. The Excel input is of the form =LOGINV (y, $\ln(\theta_Y)$, β_Y).

A.4 Probabilities over Time

Sometimes it is convenient to express the probability of the occurrence of an event conditioned on a specific period of time, such as a single year, the length of a lease, or the length of a mortgage loan. The probability that an event will occur in a single year is termed the *annual probability*. If the annual probability of the occurrence of an event, P_1, is known, it is possible to convert this into the probability, P_N, of the event occurring over any arbitrary length of time, *N*, using the formula:

$$P_N = 1 - \left(1 - P_1\right)^N \quad \text{(A-7)}$$

Appendix B
Ground Shaking Hazards

B.1 Introduction

This appendix presents supplemental information on characterization of ground shaking hazards and an alternate procedure for scaling ground motions for scenario-based assessments.

B.2 Ground Motion Prediction Equations

Ground motion prediction equations, sometimes termed attenuation relationships, relate ground motion parameters to the magnitude of an earthquake, distance between the site and the fault rupture, and other parameters (e.g., soil type and rupture directivity). Models have been established for many ground motion parameters including peak horizontal acceleration, velocity, displacement, and corresponding spectral terms.

Ground motion prediction equations are developed primarily by statistical evaluation of large sets of ground motion data. Relationships have been developed for different regions of the United States (and other countries) and different fault types (e.g., strike-slip, dip-slip, and subduction faults).

Ground motion predictive equations generally return a geometric mean, S_g, of two horizontal spectral ordinates. For a given pair of horizontal earthquake histories with spectral ordinates, S_x and S_y, the geometric mean is $S_{gm} = \sqrt{S_x S_y}$. Because the functional form of the attenuation relationship involves the natural log of the ground motion parameter, the geometric mean of the ordinates (which is equivalent to the arithmetic mean of the logs of the ordinates) is used instead of the arithmetic mean to characterize the pair of histories.

Table B-1 presents selected models for North American ground motion prediction. These models all use moment magnitude, M_W, to define earthquake magnitude, but many use different definitions of site-to-source distance and other parameters. Figure B-1 defines some of the distance parameters used.

Table B-1 Ground Motion Prediction Models

Model	Calculated[1]	Site Conditions[2]	Variables[3]	Ranges		
				T_n (seconds)	r (km)	M_W[4]
Western North America (WNA)						
Abrahamson and Silva, 2008	PHA, PHV, S_{ah}	$180 \le V_{S30} \le 2000$[5]	M, r_{rup}, r_{jb}, V_{S30}, F, H, B	0–10	0–200	5–8.5
Boore and Atkinson, 2008	PHA, PHV, S_{ah}	$180 \le V_{S30} \le 1300$	M, r_{jb}, V_{S30}, F			5–8
Campbell and Bozorgnia, 2008	PHA, PHV, S_{ah}	$150 \le V_{S30} \le 1500$	M, r_{rup}, r_{jb}, V_{S30}, F, H, B			4–8.5 (s) 4–8 (r) 4–7.5 (n)
Chiou and Youngs, 2008	PHA, PHV, S_{ah}	$150 \le V_{S30} \le 1500$	M, r_{rup}, r_{jb}, V_{S30}, F, H, B			4–8.5 (s) 4–8 (r,n)
Idriss, 2008	PHA, S_{ah}	$V_{S30} > 900$; $450 \le V_{S30} \le 900$	M, r_{rup}, F			4.5–8[5]
Central and Eastern North America (CENA)						
Atkinson and Boore, 1997	PHA, S_{ah}	Rock	M, r_{hypo}	0–2	10–300	4–9.5
Campbell, 2003	PHA, S_{ah}	Hard Rock	M, r_{rup}	0–4	1–1000	5–8.2
Toro et al., 1997	PHA, S_{ah}	Rock	M, r_{jb}	0–2	1–100	5–8
Subduction Zones						
Atkinson and Boore, 2003	PHA, S_{ah}	Rock to Poor Soil	M, r_{hypo}	0–3	10–300	5.5–8.3
Youngs et al., 1997	PHA, S_{ah}	Rock, Soil	M, r_{rup}, F, H	0–4	0–100	4–9.5

Notes: (1) PHA = peak horizontal ground acceleration; PHV = peak horizontal ground velocity; S_{ah} = horizontal spectral acceleration

(2) V_{S30} = average shear wave velocity in the upper 30 meters of sediments (m/s)

(3) r_{rup} = closest distance to the rupture surface; r_{jb} = closest horizontal distance to the vertical projection of the rupture; r_{hypo} = hypocentral distance; M = magnitude; F = fault type; H = hanging wall; B = three-dimensional basin response

(4) s = strike-slip faulting; r = reverse faulting; n = normal faulting

(5) Ranges are not specified but are estimated based on the datasets (Abrahamson and Silva, 2008; Idriss, 2008)

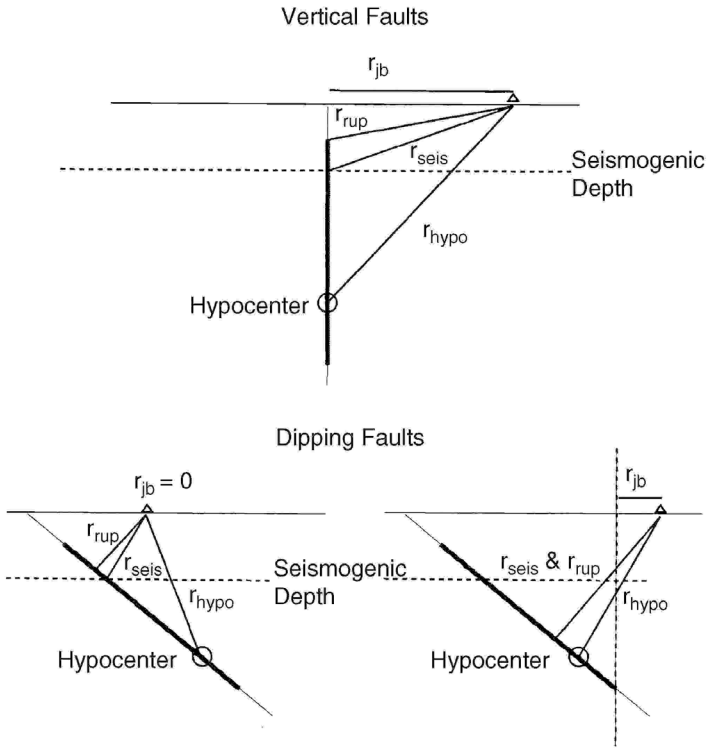

Figure B-1 Site-to-source distance definitions (Abrahamson and Shedlock, 1997).

B.3 Fault Rupture Directivity and Maximum Direction Shaking

Rupture directivity causes spatial variation in the amplitude and duration of ground motions in the vicinity of a fault. Propagation of rupture towards a site produces larger amplitudes of shaking, and shorter duration of strong-motions, than average directivity conditions at periods longer than 0.6 seconds. Somerville et al. (1997) developed modifications to the Abrahamson and Silva (1997) ground motion prediction equations to account for these variations. These and other equations at that time were constructed using strong motion databases that included few near-fault records, so spectral demands associated with near-fault shaking were not adequately represented.

Somerville et al. (1997) identified fault rupture directivity parameters θ and X for strike-slip faults, and ϕ and Y for dip-slip faults, as shown in Figure B-2. Ground motion parameters used to characterize directivity include: (1) *amplitude factor*, which is the bias in average horizontal response spectrum acceleration with respect to Abrahamson and Silva (1997); and (2) *fault-normal/average amplitude*, which is the ratio of fault normal to

average (directivity) horizontal response spectrum acceleration. Bounds were set on the range of applicability of the directivity model.

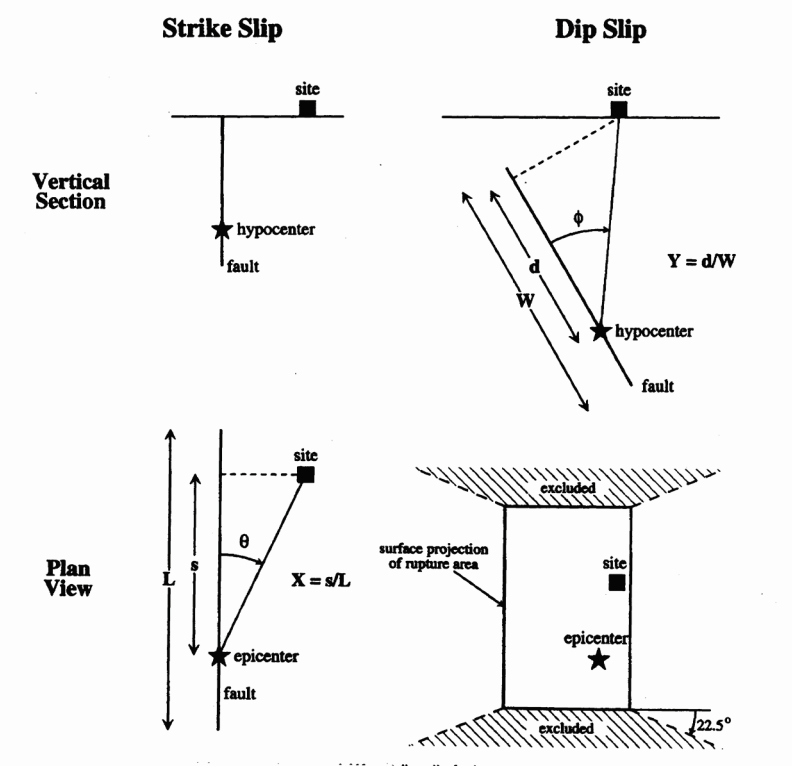

Figure B-2 Fault rupture directivity parameters (Somerville et al., 1997).

Next-Generation Attenuation (NGA) relationships for the Western United States were developed using a database that included many near-fault ground motion recordings. These relationships predict geomean spectral demand of recorded near-fault motions well, with little bias (Huang et al., 2008a, 2008b). Huang et al. (2008a, 2008b) also reported the median and 84th percentile ratios of maximum and minimum direction spectral demand to NGA-calculated geomean spectral demand for average directivity (i.e., all near-fault records) in the forward directivity region.

B.4 Probabilistic Seismic Hazard Assessment

Performance assessment can utilize site-specific characterization of ground shaking associated with different probabilities of exceedance. Such characterizations are routinely performed using probabilistic seismic hazard assessment (PSHA), described in the sections that follow, based on information from Kramer (1996), McGuire (2004) and Bozorgnia and Bertero (2004).

B.4.1 Probabilistic Seismic Hazard Assessment Calculations

In probabilistic seismic hazard assessment, probability distributions are determined for the magnitude of each possible earthquake on each source, $f_M(m)$, the location of each earthquake in or along each source, $f_R(r)$, and the prediction of the response parameter of interest $P(\text{pga} > \text{pga}' | m, r)$. Kramer (1996) describes this as a four-step process enumerated below and depicted in Figure B-3:

1. Identify and characterize geometry and potential M_W for all earthquake sources capable of generating significant shaking (i.e., $M_W \geq 4.5$) at the site. Develop the probability distribution of rupture locations within each source. Combine this distribution with the source geometry to obtain the probability distribution of source-to-site distance for each source.

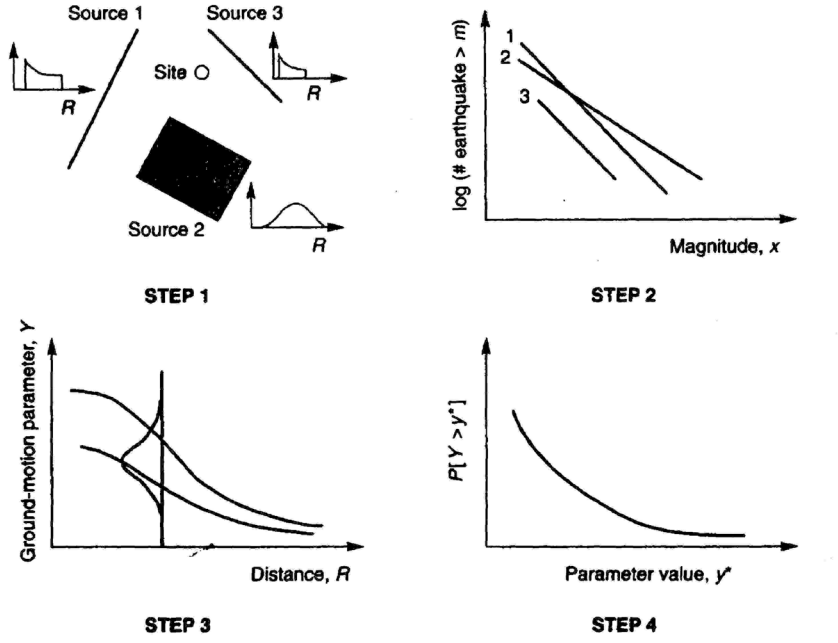

Figure B-3 Steps in probabilistic seismic hazard assessment (Kramer, 1996).

2. Develop a distribution of earthquake occurrence for each source using a recurrence relationship. This distribution can be random or time-dependent.

3. Using predictive models, determine the ground motion produced at the site (including uncertainty) for earthquakes of any possible magnitude, occurring at any possible point, in each source zone.

4. Combine the uncertainties in earthquake location, size, and ground motion prediction to obtain the probability that the ground motion parameter of interest (e.g., peak horizontal ground acceleration, spectral

acceleration) will be exceeded in a particular time frame (i.e., 10% chance of exceedance in 50 years).

Earthquake Source Characterization

Characterization of an earthquake source (there can be many sources for some sites) requires consideration of the spatial characteristics of the source, the distribution of earthquakes within that source, the distribution of earthquake size within that source, and the distribution of earthquakes over time. Each of these characteristics involves some degree of uncertainty, which is explicitly addressed in the process.

Spatial Uncertainty

Earthquake source geometries are typically characterized as shown in Figure B-4. Source zone geometries include: (1) point sources (e.g., volcanoes); (2) two-dimensional areal sources (e.g., a well-defined fault plane); and, (3) three-dimensional volumetric sources (e.g., areas where earthquake mechanisms are poorly defined such as the Central and Eastern United States). These representations can have varying levels of accuracy.

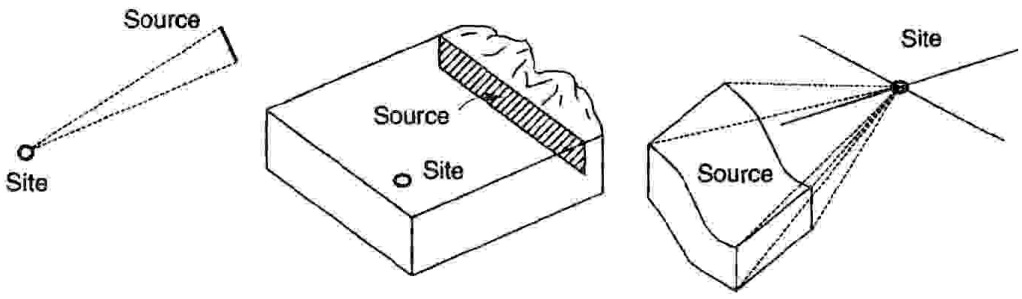

Figure B-4 Source zone geometries: (a) point sources; (b) two-dimensional areal sources; and (c) three-dimensional volumetric sources (Kramer, 1996).

Because attenuation relationships and other predictive models express ground motion parameters in terms of a measure of the source-to-site distance, the spatial uncertainty must be described with respect to the appropriate distance parameter. Uncertainty in source-to-site distance can be described by a probability density function, as shown in Figure B-5.

For a point source, the distance R is r_s. The probability that $R = r_s$ is 1.0, and the probability that $R \neq r_s$ is 0. For more complex source zones, it is easier to evaluate $f_R(r)$ by numerical integration. For example, the source zone in Figure B-5c is broken up into a large number of discrete elements of the

same area. A histogram that approximates $f_R(r)$ can be constructed by tabulating the values of R that correspond to the center of each element.

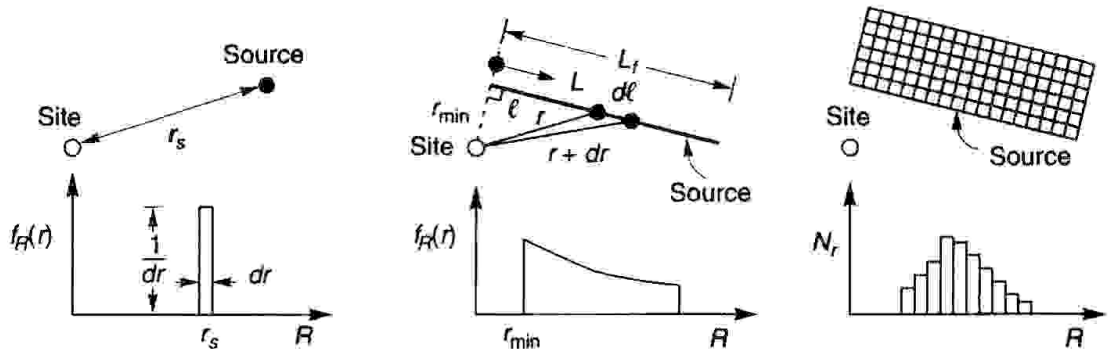

Figure B-5 Variations in site-to-source distance for three source zone geometries (Kramer, 1996).

Size Uncertainty

Recurrence laws describe the distribution of probable earthquake size over a period of time. One basic assumption is that past recurrence rates for a source are appropriate for the prediction of future seismicity. The best known recurrence law, Gutenberg and Richter (1944), is based on data collected from Southern California earthquakes over a period of years. Data were plotted according to the number of earthquakes that exceeded different magnitudes during that time period. The number of exceedances of each magnitude was divided by the length of the time period used to assemble the data, defining the mean annual rate of exceedance, λ_m, of an earthquake of magnitude, m. The reciprocal of the mean annual rate of exceedance for a particular magnitude is termed the return period for earthquakes exceeding that magnitude. Gutenberg-Richter (1944) plotted the logarithm of the annual rates of exceedance against magnitude and obtained the following linear regression relationship:

$$\log \lambda_m = a - bm \qquad \text{(B-1)}$$

where λ_m is as defined above, 10^a is the mean annual number of earthquakes with magnitude greater than or equal to magnitude m, and b describes the relative likelihood of large and small earthquakes. As the value of b increases, the number of larger magnitude earthquakes decreases relative to the number of smaller magnitude earthquakes. The mean rate of small magnitude earthquakes is often under-predicted because historical records are used to supplement the instrumental records, and larger magnitude events dominate the historical record.

The Guttenberg-Richter recurrence law was originally developed from regional data, and not for specific source zones. Paleoseismic studies over the past 30 years have indicated that individual points on faults (or fault segments) tend to move approximately the same distance in successive earthquakes. This suggests that faults repeatedly generate earthquakes of a similar size (within 0.5 magnitude), known as characteristic earthquakes, at or near their maximum capable magnitude. Geological evidence indicates that characteristic earthquakes occur more frequently than would be implied by extrapolation of the recurrence law from high exceedance rates (of low magnitude events) to low exceedance rates (of high magnitude events), resulting in a more complex recurrence law than that given in Equation B-1.

Attenuation Relationships

Scatter or randomness in the results obtained from predictive models is inevitable because of differences in site condition, path of travel, and fault rupture mechanics associated with the data set, and a lack of certainty as to the precise values of these parameters for any specific site. Scatter can be characterized by confidence limits, or by the standard deviation of the predicted parameter.

The probability that a ground motion parameter Y exceeds a certain value y for an earthquake of magnitude, m, occurring at a distance, r, is given by:

$$P[Y > y|m,r] = 1 - F_y(y) = 1 - \Phi\left(\frac{\ln y - \ln \theta}{\beta}\right) \qquad \text{(B-2)}$$

where $F_Y(y)$ is the value of the cumulative distribution function of Y at m and r, which is assumed to be lognormal in form; θ is the median value of Y; and β is the dispersion. Figure B-6 illustrates the conditional probability of exceeding a particular value of a ground motion parameter for a given combination of m and r.

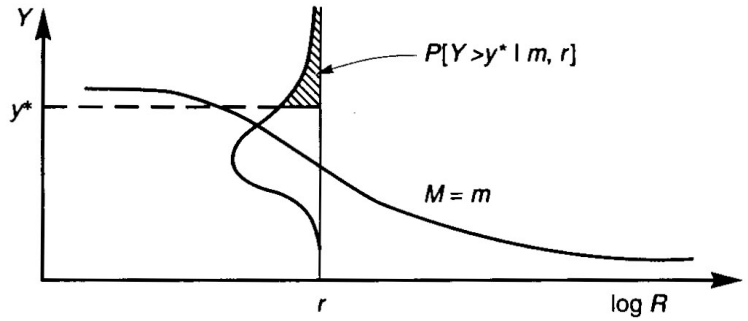

Figure B-6 Illustration of the conditional probability of exceeding a ground motion parameter (Kramer, 1996).

Temporal Uncertainty

The distribution of earthquake occurrence with time must be computed (or assumed) to calculate the probabilities of different earthquake magnitudes occurring in a given time period. Earthquakes are assumed to occur randomly with time, and the assumption of random occurrence permits the use of simple probability models.

The temporal occurrence of earthquakes is commonly described as a Poisson process, which is a process that yields values of a random variable describing the number of occurrences of a particular event during a given time interval (or spatial region). In a Poisson process, the number of occurrences in one time interval are independent of the number that occur in any other time interval; the probability of occurrence during a very short time interval is proportional to the length of the time interval; and the probability of more than one occurrence in a very short time interval is negligible. Events in a Poisson process occur randomly, with no memory of the time, size, or location of any preceding events. Cornell and Winterstein (1988) showed that the Poisson model is useful for probabilistic hazard analysis unless the hazard is dominated by a single source zone that produces characteristic earthquakes, and the time since the previous significant event exceeds the average time between events.

In a Poisson process, the probability of a random variable, N, representing the number of occurrences of a particular event in a given time period is given by:

$$P[N = n] = \frac{\mu^n e^{-\mu}}{n!} \tag{B-3}$$

where μ is the average number of occurrences of the event in the time period. To characterize the temporal distribution of earthquake recurrence for probabilistic seismic hazard analysis, the Poisson probability is normally expressed as:

$$P[N = n] = \frac{(\lambda t)^n e^{-\lambda t}}{n!} \tag{B-4}$$

where λ is the average rate of recurrence of the event, and t is the time period. When the event is the exceedance of a particular earthquake magnitude, the Poisson model can be combined with a suitable recurrence law to predict the probability of at least one exceedance in a period of t years by:

$$P[N \geq 1] = 1 - e^{-\lambda_m t} \tag{B-5}$$

Probability Computations and Seismic Hazard Curves

Seismic hazard curves identify the annual frequency of exceedance of different values of a selected ground motion parameter. Development of seismic hazard curves involves probabilistic calculations that combine the uncertainties in earthquake size, location, and frequency for each potential earthquake source that could impact shaking at the site.

Seismic hazard curve calculations are straightforward once the uncertainties in earthquake size, location, and frequency are established, but much bookkeeping is involved. The probability of exceeding a particular value y of a ground motion parameter, Y, is calculated for one possible source location, and then multiplied by the probability of that magnitude earthquake occurring at that particular location. The calculation is then repeated for all possible magnitudes and locations, and the probabilities of each are summed to compute the $P[Y > y]$ at the site. A summary of this process based on Kramer (1996) and McGuire (2004) is presented below.

For a given earthquake occurrence, the probability that a ground motion parameter, Y, will exceed a particular value y can be computed using the total probability theorem (Benjamin and Cornell, 1970) as:

$$P[Y > y] = P[Y > y|\mathbf{X}]P[\mathbf{X}] = \int P[Y > y|\mathbf{X}]f_x(\mathbf{X})\,dx \qquad \text{(B-6)}$$

where $\mathbf{X}$ is a vector of random variables that influence Y. In most cases, the quantities in $\mathbf{X}$ are limited to the magnitude, M, and distance, R. Assuming that M and R are independent, the probability of exceedance can be written as:

$$P[Y > y] = \iint P[Y > y|m,r]f_M(m)\,f_R(r)\,dm\,dr \qquad \text{(B-7)}$$

where $P[Y > y|m,r]$ is obtained from the predictive relationship, and $f_M(m)$ and $f_R(r)$ are the probability density functions for magnitude and distance, respectively.

If the site is in a region of N_s potential earthquake sources, each of which has an average threshold rate of exceedance $\nu_i = \exp(\alpha_i - \beta_i m)$, the total average exceedance rate for the region is given by:

$$\lambda_y = \sum_{i=1}^{N_s} P[Y > y|m,r]f_{Mi}(m)\,f_{Ri}(r)\,dm\,dr \qquad \text{(B-8)}$$

This equation is typically solved by numerical integration. One simple approach described by Kramer (1996) is to divide the possible ranges of

magnitude and distance into N_M and N_R segments, respectively. The average exceedance rate can then be calculated using the multi-level summation:

$$\begin{aligned}\lambda_y &= \sum_{i=1}^{N_s}\sum_{j=1}^{N_m}\sum_{k=1}^{N_R} \nu_i P[Y > y | m_j, r_k] f_{Mi}(m_j) f_{Ri}(r_k) \Delta m \Delta r \\ &= \sum_{i=1}^{N_s}\sum_{j=1}^{N_m}\sum_{k=1}^{N_R} \nu_i P[Y > y | m_j, r_k] P[M = m_j] P[R = r_k]\end{aligned} \tag{B-9}$$

where:

$$m_j = m_0 + (j - 0.5)(m_{\max} - m_0) / N_M$$

$$\Delta r = (r_{\max} - r_{\min}) / N_r$$

$$r_k = r_{\min} + (k - 0.5)(r_{\max} - r_{\min}) / N_R$$

$$\Delta m = (m_{\max} - m_0) / N_M$$

The above statement is equivalent to assuming that each source is capable of generating only N_M different earthquakes of magnitude, m_i, at only N_R different source-to-site distances of, r_k. The accuracy of this method increases with smaller segments and, thus, larger values of N_M and N_R.

Figure B-7 presents a sample seismic hazard curve for peak ground acceleration at a site in Berkeley, California. The figure shows contributions to the annual frequency of exceedance from nine different seismic sources.

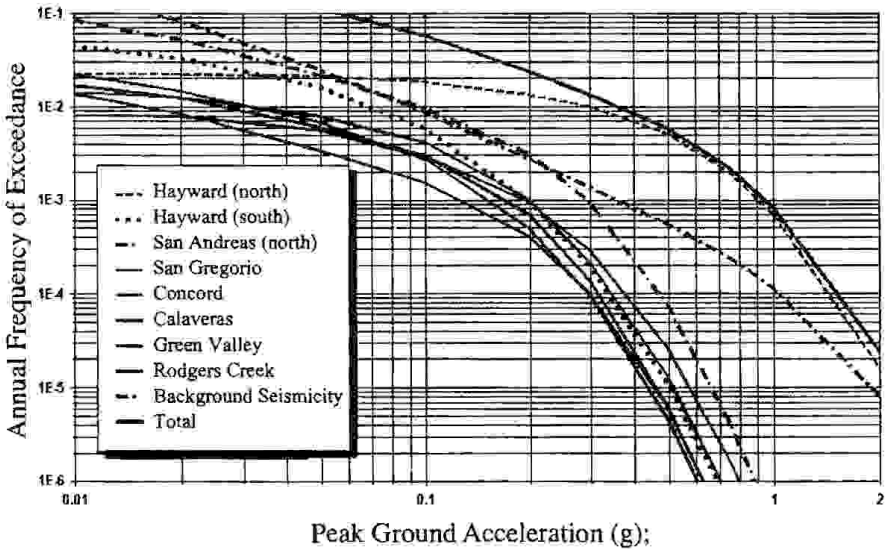

Figure B-7 Sample seismic hazard curve for Berkeley, California (McGuire, 2004).

Exceedance probabilities in a selected time period can be computed using seismic hazard curves combined with the Poisson model. The probability of exceedance for a value, y, in a time period, T, is:

$$P[Y_T > y] = 1 - e^{-\lambda_y T} \tag{B-10}$$

As an example, the probability that a peak horizontal ground acceleration of 0.10 g will be exceeded in a 50-year time period for a site characterized by the hazard curve in Figure B-7 is:

$$P[\text{PHA} > 0.1g \text{ in 50 years}] = 1 - e^{-\lambda_y T} = 1 - e^{-(0.060)(50)} = 0.950 = 95\% \tag{B-11}$$

where $\lambda_y = 0.06$ is read from the curve in the figure corresponding to the total for all nine sources. An alternative, often made, computation is the value of the ground motion parameter corresponding to a particular probability of exceedance in a given time period. For example, the acceleration that has a 10% probability of exceedance in a 50-year time period would be the acceleration corresponding to an annual frequency of exceedance calculated by rearranging Equation B-10:

$$\lambda_y = -\frac{\ln(1 - P[Y_T > y])}{T} = -\frac{\text{In}(1 - 0.10)}{50} = 0.00211 \tag{B-12}$$

Using the hazard curve from Figure B-7 for all nine sources, the corresponding zero-period spectral acceleration is approximately 0.75 g.

Hazard curves can be developed for specific periods of oscillation (0.2 s and 1.0 s are widely used periods), and the above calculations for probability of exceedance can be extended across the spectral domain. This permits development of probabilistic estimates of spectral demands for different probabilities of exceedance or return periods. Hazard curves have been developed for many different response quantities and characterizations of earthquake ground motion.

B.4.2 Inclusion of Rupture Directivity Effects

If the building site is located within 20 km of an active fault capable of generating an earthquake with magnitude M_w 6.5 or greater, rupture directivity effects should be considered. Average rupture directivity effects can be included directly in probabilistic seismic hazard analysis if the attenuation relationships are: (1) constructed using a database of recorded ground motions that include directivity effects (i.e., the NGA relationships described previously); or (2) corrected to account for rupture directivity in a manner similar to that described by Somerville et al. (1997) and Abrahamson (2000). The ratio of median maximum demand to geomean demand in the near-fault region is period-dependent, and can be as large as 2.0 (Huang et al., 2008a, 2008b).

B.4.3 Deaggregation of Seismic Hazard Curves and Epsilon

Probabilistic seismic hazard analysis enables calculation of annual rates of exceedance of ground motion parameters (e.g., spectral acceleration at a selected period) at a particular site based on aggregating the risks from all possible source zones. Therefore, the computed rate of exceedance for a given parametric intensity value is not associated with any particular earthquake magnitude, m, or distance, r.

For a given building site and hazard curve, it is possible to establish the combinations of magnitude, distance, and source that contribute most to particular values of an intensity. This process is termed deaggregation (or disaggregation). Hazard deaggregation requires expression of the mean annual rate of exceedance as a function of magnitude and distance in the form:

$$\lambda_y(m_j, r_k) = P[M = m_j]P[R = r_k]\sum_{i=1}^{N_s} \nu_i P[Y > y | m_j, r_k] \qquad \text{(B-13)}$$

McGuire (2004) provides detailed information on hazard deaggregation.

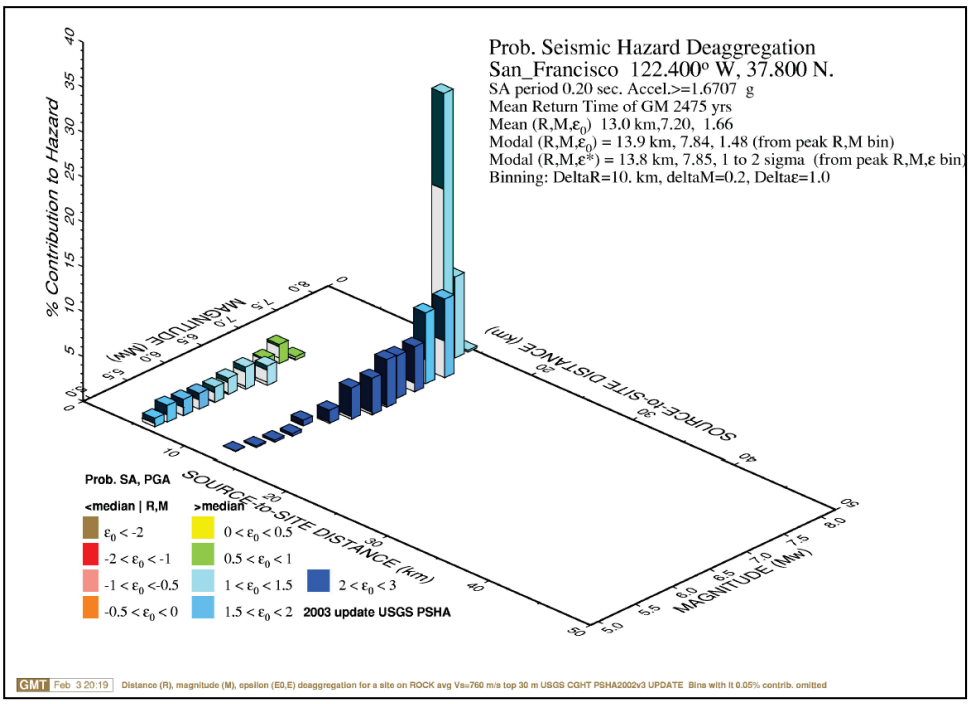
Figure B-8 shows sample deaggregation results for horizontal spectral acceleration at periods of 0.2 s and 1.0 s for a site in the Western United States, for a 2% probability of exceedance in 50 years. Figure B-8b shows contributions to the 1-second uniform hazard spectral ordinate as a function of moment magnitude and distance. Approximately 50% of the total 1-second seismic demand can be ascribed to a M_W 7.8 earthquake at a distance of 14 km. The [M, r] pair that dominates the 1-second spectral demand at this site is, therefore, [7.8, 14].

Figure B-8 also introduces another important ground motion variable, termed epsilon, ε. Epsilon can be defined as:

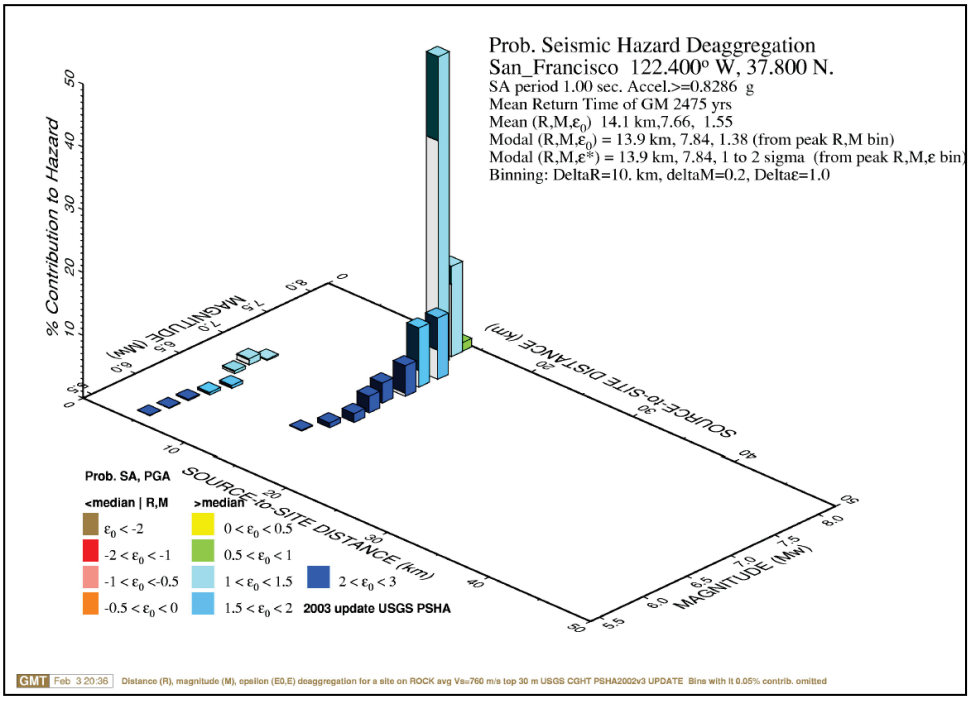
$$\varepsilon = \frac{\ln S_a - \ln \theta}{\beta} \qquad \text{(B-14)}$$

where all variables vary as a function of period; S_a is the computed spectral acceleration for a given probability of exceedance (e.g., 2%) in a specified time period (e.g., 50 years) equal to 0.829 g in this instance at a period of 1 second; θ is the median value of spectral acceleration computed by an appropriate attenuation relationship for the dominant [M, r] pair equal to [7.8, 14] in this instance); and β is the dispersion in the attenuation relationship. In this example, and using the modal [M, r, ε] triple, ε ranges between 1 and 2, meaning that less than 15% of moment magnitude 7.8

earthquakes at a distance of 14 km would produce geomean spectral demands in excess of 0.829 g.



(a) 0.2 second deaggregation



(b) 1.0 second deaggregation

Figure B-8 Sample deaggregation of a hazard curve (www.usgs.gov).

Baker and Cornell (2005 and 2006) observed that ε is an indicator of spectral shape, with positive (or negative) values of ε at a given period tending to indicate a relative peak (or valley) in the acceleration response spectrum at that period. Figure B-9 illustrates these trends using six bins of 20 ground motions defined by $\varepsilon \geq 2.25$, $-0.06 \leq \varepsilon \leq 0.06$ and $\varepsilon \leq -2.25$, respectively, at periods of 0.8 (Figure B-9a) and 0.3 second (Figure B-9b). The relative peak (or valley) in the spectra for the $+\varepsilon$ ($-\varepsilon$) bin of j motions at the two periods is clearly evident. No relative peak or valley at the reference periods is associated with the ε–neutral bin.

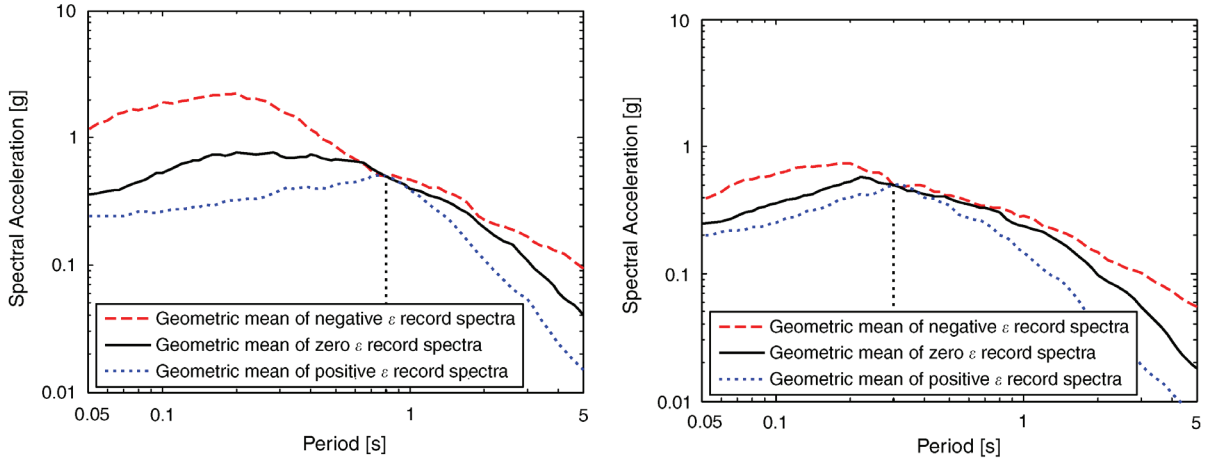


Figure B-9 Sample geometric-mean response spectra for negative-, zero- and positive-ε record sets, with each record scaled to: (a) S_a(0.8 s) = 0.5 g; and (b) S_a(0.3 s) = 0.5 g (Baker and Cornell 2006).

B.4.4 Conditional Mean Spectrum and Spectral Shape

Ordinates of uniform hazard spectra are each associated with the same annual frequency of exceedance. Building code and seismic design provisions for nonlinear response history analysis recommend scaling ground motions to match a target uniform hazard spectrum over a wide period range. Although this is convenient for design, and likely conservative, such scaling procedures have the following limitations:

- If the spectral ordinates of the uniform hazard spectrum are governed by multiple scenario events, the spectral shape will not be representative of any of the governing events, regardless of the return period (Baker and Cornell, 2006).
- For earthquake shaking with long return periods, the spectral ordinates of uniform hazard spectra are typically associated with high values of ε (greater than 1) across a wide range of periods (Harmsen, 2001). For the case in which the geomean spectral ordinate of a ground motion pair

matches the uniform hazard spectrum ordinate at a given period, the geomean spectral ordinates are likely to be less than the uniform hazard spectrum at other periods. The geomean spectra for the $+\varepsilon$ record sets in Figure B-9 support this observation.

Baker and Cornell (2005, 2006) introduced the Conditional Mean Spectrum (CMS) which considers the correlation of spectral demands (represented by values of ε) at different periods, to address these limitations. Conditional Mean Spectra estimate the median geomean spectral acceleration response of a pair of ground motions given an [*M*, *r*] pair and a target spectral ordinate, $\overline{S}_a(T_1)$, from which ε_T is back-calculated using an appropriate attenuation relationship. Baker and Cornell (2005) used the following equation to generate conditional mean spectra:

$$CMS_{\overline{S}_a(T_1)}(T_2) = \theta(M,r,T_2) \cdot \exp\left[\beta(M,r,T_2) \cdot \rho_{\varepsilon(T_1),\varepsilon(T_2)} \cdot \varepsilon_{T_1}\right] \qquad \text{(B-15)}$$

where $CMS_{\overline{S}_a(T_1)}(T_2)$ is the ordinate of the spectrum at period T_2 given that the spectral demand at T_1 is $\overline{S}_a(T_1)$; $\theta(M,r,T_2)$ and $\beta(M,r,T_2)$ are the median and logarithmic standard deviation of spectral acceleration at T_2 computed using a ground motion attenuation relationship for the [*M*, *r*] pair of interest; ε_T is the value of ε associated with $\overline{S}_a(T_1)$; and $\rho_{\varepsilon(T_1),\varepsilon(T_2)}$ is the correlation coefficient for ε between T_1 and T_2.

Baker and Jayaram (2008) developed a model for $\rho_{\varepsilon(T_1),\varepsilon(T_2)}$ using the NGA ground motion database (www.peer.berkeley.edu):

$$\begin{array}{ll} \text{if } T_{\max} < 0.109 & \rho_{\varepsilon(T_1),\varepsilon(T_2)} = C_2 \\ \text{else if } T_{\min} > 0.109 & \rho_{\varepsilon(T_1),\varepsilon(T_2)} = C_1 \\ \text{else if } T_{\max} < 0.109 & \rho_{\varepsilon(T_1),\varepsilon(T_2)} = \min(C_2, C_4) \\ \text{else} & \rho_{\varepsilon(T_1),\varepsilon(T_2)} = C_4 \end{array} \qquad \text{(B-16)}$$

where: $T_{\min} = \min(T_1, T_2)$, $T_{\max} = \max(T_1, T_2)$, and

$$C_1 = 1 - \cos\left(\frac{\pi}{2} - 0.366 \ln\left(\frac{T_{\max}}{\max(T_{\min}, 0.11)}\right)\right) \qquad \text{(B-17)}$$

$$C_2 = \begin{cases} 1 - 0.105\left(1 - \dfrac{1}{1+e^{100T_{\max}-5}}\right)\left(\dfrac{T_{\max}-T_{\min}}{T_{\max}-0.01}\right), & \text{if } T_{\max} < 0.2 \text{ sec} \\ 0, & \text{otherwise} \end{cases} \qquad \text{(B-18)}$$

$$C_3 = \begin{cases} C_2 \text{ if } T_{\max} < 0.11 \text{ sec} \\ C_1 \text{ if } T_{\max} \geq 0.11 \text{ sec} \end{cases} \qquad \text{(B-19)}$$

$$C_4 = C_1 + 0.5(\sqrt{C_3} - C_3)(1 + \cos\left(\frac{\pi T_{\min}}{0.11}\right) \quad \text{(B-20)}$$

Conditional Mean Spectra can be constructed using the following procedure:

1. Determine the value of $\overline{S}_a(T_1)$ from the probabilistic seismic hazard analysis at the desired mean annual frequency of exceedance.
2. Deaggregate the hazard at $\overline{S}_a(T_1)$ and identify the modal [M, r, ε] triple.
3. Select an appropriate ground motion attenuation relationship.
4. Generate the spectrum using Equations B-15 through B-20 and the selected attenuation relationship for the [M, r, ε] triple of Step 2.
5. Amplitude scale the spectrum to recover $\overline{S}_a(T_1)$.

As an illustration, consider the deaggregation results of Figure B-8b for a site in San Francisco. As presented in Figure B-8b, the value of $\overline{S}_a(T_1)$ is 0.83 g for a return period of 2,475 years, and the modal [M, r, ε] triple for the hazard is [7.8, 14 km, 1 to 2]. In this example, $\varepsilon = 1.5$ (taken as the midpoint of 1 and 2), and the Chiou and Youngs (2008) NGA relationship was selected. Figure B-10 presents the results of Steps 4 and 5 using dotted and solid lines, respectively (if $\varepsilon = 2$ is used in Step 4, the scale factor for Step 5 is 1). The figure also presents the uniform hazard spectrum for this site at a return period of 2475 years. Except at period T_1, the ordinates of the uniform hazard spectrum are greater than those of the scaled Conditional Mean Spectrum.

The Conditional Mean Spectrum can be refined to also consider uncertainty in each spectral acceleration value at periods other than $\overline{S}_a(T_1)$. This is done because the probabilities associated with the target spectrum are associated only with $\overline{S}_a(T_1)$, and real ground motions with the target $\overline{S}_a(T_1)$ also have variability. Baker and Cornell (2005) computed the conditional standard deviation of spectral accelerations as follows:

$$\beta_{\overline{S_a}(T_1)=x}(T_2) = \beta(M, r, T_2)\sqrt{1 - \rho^2_{\varepsilon(T_1),\varepsilon(T_2)}} \quad \text{(B-21)}$$

where $\beta_{\overline{S_a}(T_1)=x}(T_2)$ is the conditional dispersion in $S_a(T_2)$ given $\overline{S}_a(T_1)$ and the other variables are as defined above. The target spectrum computed using Equation B-15 and Equation B-21 has been termed a Conditional Spectrum (Abrahamson and Al Atik, 2010), because, unlike the Conditional Mean Spectrum, it is not just a mean value. Figure B-11 shows the Conditional Spectrum corresponding to the Conditional Mean Spectrum plotted in Figure B-10. Methods and software tools are available to find ground motions that match a target mean and standard deviation (Jayaram et al., 2011).

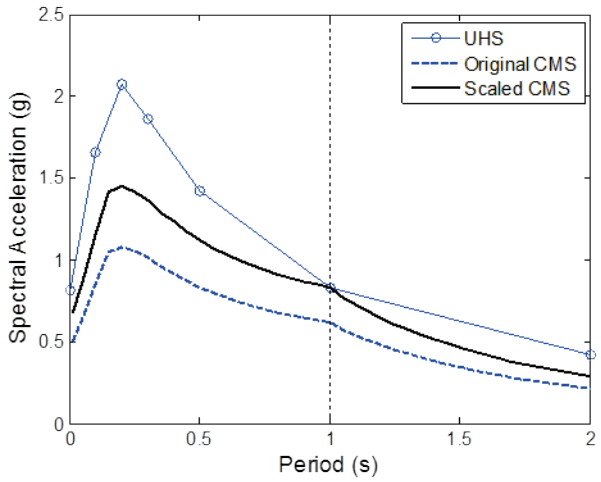

Figure B-10 Uniform Hazard Spectrum with 2% probability of exceedance in 50 years, Conditional Mean Spectrum, and scaled Conditional Mean Spectrum for a rock site in San Francisco.

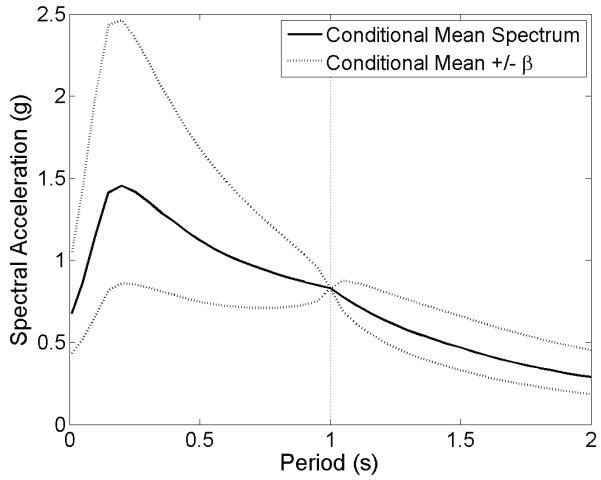

Figure B-11 Conditional Spectrum for S_a(1s) with 2% probability of exceedance in 50 years for a rock site in San Francisco.

B.5 Vertical Earthquake Shaking

Vertical response spectra can be generated using ground motion prediction equations for vertical ground shaking parameters and probabilistic seismic hazard analysis to determine ordinates of spectral response at the desired annual frequencies of exceedance. This technique is discussed in Gülerce and Abrahamson (2011).

This section presents simplified procedures that can be used to generate vertical response spectra from horizontal spectra for the same site using approximate relationships between typical vertical and horizontal spectra.

Extracted from FEMA P-750, *NEHRP Recommended Seismic Provisions for New Buildings and Other Structures* (FEMA, 2009a), these procedures can be used for most buildings where important periods of vertical response are less than or equal to 1.0 second. For buildings with important periods of vertical response in excess of 1.0 second, site-specific analysis should be conducted.

B.5.1 Procedure for Site Classes A, B, and C

For structural periods less than or equal to 1.0 second, the vertical response spectrum can be constructed by scaling the corresponding ordinates of the horizontal response spectrum, S_a, as follows:

- For periods less than or equal to 0.1 second, the vertical spectral acceleration, S_v, can be taken as

$$S_v = S_a \tag{B-22}$$

- For periods between 0.1 and 0.3 second, the vertical spectral acceleration, S_v, can be taken as

$$S_v = (1 - 1.048[\log(T) + 1])S_a \tag{B-23}$$

- For periods between 0.3 and 1.0 second, the vertical spectral acceleration, S_v, can be taken as

$$S_v = 0.5S_a \tag{B-24}$$

B.5.2 Procedure for Site Classes D and E

For structural periods less than or equal to 1.0 second, the vertical response spectrum can be constructed by scaling the corresponding ordinates of the horizontal response spectrum, S_a, as follows:

- For periods less than or equal to 0.1 second, the vertical spectral acceleration, S_v, can be taken as

$$S_v = \eta S_a \tag{B-25}$$

- For periods between 0.1 and 0.3 second, the vertical spectral acceleration, S_v, can be taken as

$$S_v = (\eta - 2.1(\eta - 0.5)[\log(T) + 1])S_a \tag{B-26}$$

- For periods between 0.3 and 1.0 second, the vertical spectral acceleration, S_v, can be taken as

$$S_v = 0.5S_a \tag{B-27}$$

In Equations B-25 through B-27, η can be taken as 1.0 for $S_s \le 0.5\,\text{g}$; 1.5 for $S_s \le 1.5\,\text{g}$; and $(1 + 0.5(S_s - 0.5))$ for $0.5\,\text{g} \le S_s \le 1.5\,\text{g}$.

B.6 Soil-Structure Interaction

Structural response to earthquake shaking is affected by the dynamic interactions of the soil-structure system. Soil-structure interaction involves foundation flexibility, kinematic interaction, and foundation damping. Soil-structure interaction analysis includes direct or indirect (simplified) simulation of the system to prescribed free-field input motions, which are typically imposed as bedrock motions.

Approaches to soil-structure interaction analysis are illustrated in Figure B-12. Typical structural analysis assumes a rigid base (Figure B-12a) and neglects the effects of soil-structure interaction. Input motions at the base of the foundation are derived using code-based procedures assuming the soil classification at the site.

Use of fixed-base models can overestimate demands on stiff seismic-force-resisting systems (e.g., reinforced concrete shear walls, steel braced frames) because the response of such systems is sensitive to small base rotations and translations that occur as a result of foundation flexibility. Relatively flexible systems (e.g., moment-resisting frames) are less sensitive to foundation movement, and are often not significantly affected by soil-structure interaction.

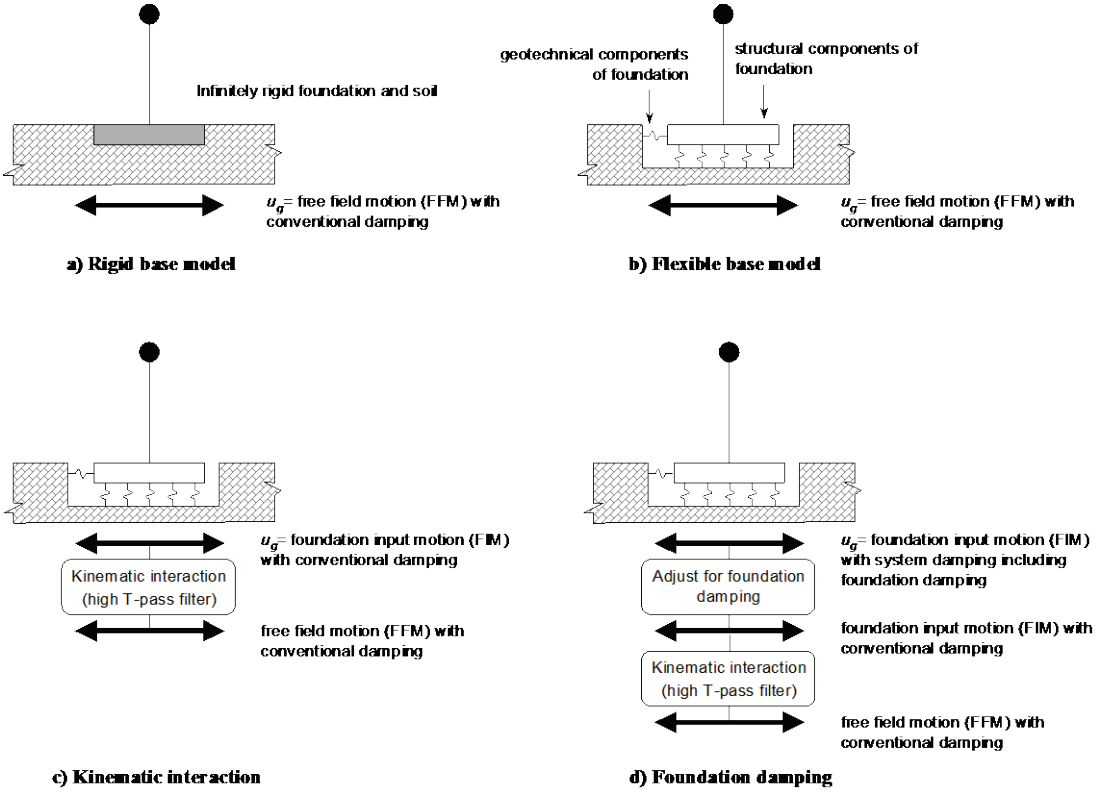

Figure B-12 Analysis for soil-structure interaction (FEMA, 2005).

B.6.1 Direct Analysis

Soil-structure interaction can be directly analyzed using finite-element models that represent the soil as discretized solid finite elements. Soil elements can either use equivalent linear properties, or full nonlinear representation. Direct analysis can explicitly address foundation flexibility, kinematic interaction, and foundation damping effects. Solution of the kinematic interaction problem is often difficult without customized finite element codes because typical codes cannot account for wave inclination and wave incoherence effects, both of which can be important.

Response history analysis requires the development of a three-dimensional numerical model of the soil-foundation-structure system. Stress-strain or constitutive models (linear, nonlinear or equivalent linear) for the soils in the model should be developed based on test data. Appropriate and consistent frequency-dependent stiffness and damping matrices should be developed for the boundaries of the soil in the numerical model.

B.6.2 Simplified Analysis

Simplified procedures for including the effects of soil-structure interaction in response analysis are based on FEMA 440, *Improvement of Nonlinear Static Seismic Analysis Procedures* (FEMA, 2005). More guidance on detailed procedures that can be used, together with example applications of these procedures, is provided in NIST GCR 12-917-21, *Soil-Structure Interaction for Building Structures* (NIST, 2012).

Foundation Flexibility

Figure B-12b illustrates the incorporation of foundation flexibility into the numerical model of a building. Current procedures, such as ASCE/SEI 41-06, *Seismic Rehabilitation of Existing Buildings* (ASCE, 2007) partially address foundation flexibility effects by providing guidance on the stiffness and strength of the soil components of the soil-foundation-structure system.

Numerical simulation including foundation flexibility provides global response predictions that include elastic and inelastic deformations in the soil-foundation system. These deformations are sometimes referred to as inertial effects. Inclusion of inertial effects can provide significantly different and more accurate response predictions than fixed base assumptions. Also, foundation response and failures (e.g., rocking, soil bearing failure, pier/pile slip) can be explicitly evaluated using such an approach. However, incorporation of foundation flexibility alone does not capture the reduction in shaking demand that occurs, relative to the free-field

motion, due to kinematic interaction or foundation damping effects, as described below.

Kinematic Interaction

Kinematic interaction, illustrated in Figure B-12c, is a result of relatively stiff foundation elements within soil stratum that causes foundation input motions to deviate from free-field motions. The effects on superstructure response are strongly period-dependent, being maximized at short periods. They can be visualized as a filter applied to the high-frequency components of the free-field ground motion. Kinematic effects include base slab averaging and embedment effects:

- **Base slab averaging.** Ground motion shaking is spatially variable. In the absence of a foundation, each point within a building footprint, would experience somewhat different shaking at the same instant in time. Placement of a structure and foundation across these spatially variable motions produces an averaging effect, and the overall motion experienced by the building is less than the localized maxima that would have occurred in the free-field, particularly at short periods. Base slab averaging occurs to some extent in virtually all buildings. The slab averaging effect occurs at the foundation level for mats or spread footings interconnected by either grade beams or reinforced concrete slabs. Even if a laterally stiff foundation system is not present, averaging can occur at the first elevated level of buildings with rigid diaphragms. Base slab averaging effects should be neglected in buildings with disconnected foundation elements and flexible floor and roof diaphragms.
- **Embedment effects.** Embedment effects are associated with the reduction of ground motion with depth into a soil stratum. Embedment effects should not be considered for buildings without basements, even if the footings are embedded. Embedment effects tend to be significant when the depth of embedment is greater than about 10 feet.

Simplified procedures are available (FEMA, 2005; NIST, 2012) to reduce the free field motion to a foundation input motion in response to kinematic interaction effects. A ratio-of-response-spectra factor can be used, which is the ratio of the response spectral ordinates imposed on the foundation (i.e., the foundation input motion) to the free-field spectral ordinates. The 5% damped free-field spectrum is multiplied by the product of the period-dependent reduction factors for base-slab averaging and embedment to derive the foundation input motion spectrum. Since the embedment computation is dependent on the peak horizontal ground acceleration, the computation must

be repeated for every level of hazard considered for the performance and loss assessment.

The resulting foundation input motion can be applied to a fixed-base model or combined with a flexible-base model. Kinematic effects tend to be important for buildings with relatively short fundamental periods (e.g., less than 0.5 second), large plan dimensions, and embedded basements.

Foundation Damping

Figure B-12d illustrates foundation damping effects that are another result of inertial interaction. Foundation damping results from the relative movements of the foundation and free-field soil. It is associated with radiation of energy away from the foundation and hysteretic damping within the soil. The result is an effective decrease in the spectral ordinates of ground motion experienced by the structure. Foundation damping effects tend to be greatest for stiff structural framing systems (e.g., reinforced concrete shear walls, steel braced frames) and relatively soft foundation soils (e.g., Site Classes D and E).

Simplified procedures are available (FEMA, 2005; NIST, 2012) to assess foundation damping. In these procedures, foundation radiation damping reduces the ordinates of the 5% damped acceleration response spectrum used as the basis for selecting and scaling ground motions. Hysteretic damping in the soil should be captured directly through the use of nonlinear soil springs.

B.7 Alternative Procedure for Hazard Characterization to Explicitly Consider Ground Motion Dispersion in Nonlinear Response History Analysis

Scenario-based assessments consider uncertainty in spectral demand. Ground motion intensity is assumed to be lognormally distributed with median value θ, and dispersion, β. In Chapter 5, ground motion dispersion is indirectly considered in the modeling uncertainty assumed in response calculation. This section presents an alternative procedure for ground motion selection in conjunction with nonlinear response history analysis that can be used to explicitly consider ground motion dispersion. If this procedure is selected, assumptions for modeling uncertainty used in response calculation must be adjusted accordingly.

Eleven values of spectral acceleration at each user-selected interval are used to characterize the distribution of seismic demand for scenario-based assessments as follows:

$$S_{ai} = \theta e^{\beta \eta_i} \quad \text{for } i = 1, 11 \tag{B-28}$$

where S_{ai} is the i^{th} target spectral acceleration at a given period, and values of η_i are listed in Table B-2.

Table B-2 Values of η_i for Generating a Distribution of $S_{ai}(T)$

i	η_i	*i*	η_i	*i*	η_i
1	-1.69	5	-0.23	9	0.75
2	-1.10	6	0	10	1.10
3	-0.75	7	0.23	11	1.69
4	-0.47	8	0.47		

Figure B-13 illustrates this process for a scenario earthquake having a median spectral acceleration of 0.3 g and dispersion of 0.4. The figure shows the cumulative probability distribution represented by this median and dispersion, along with 11 equally spaced intervals, each having a probability of occurrence of 9.09%.

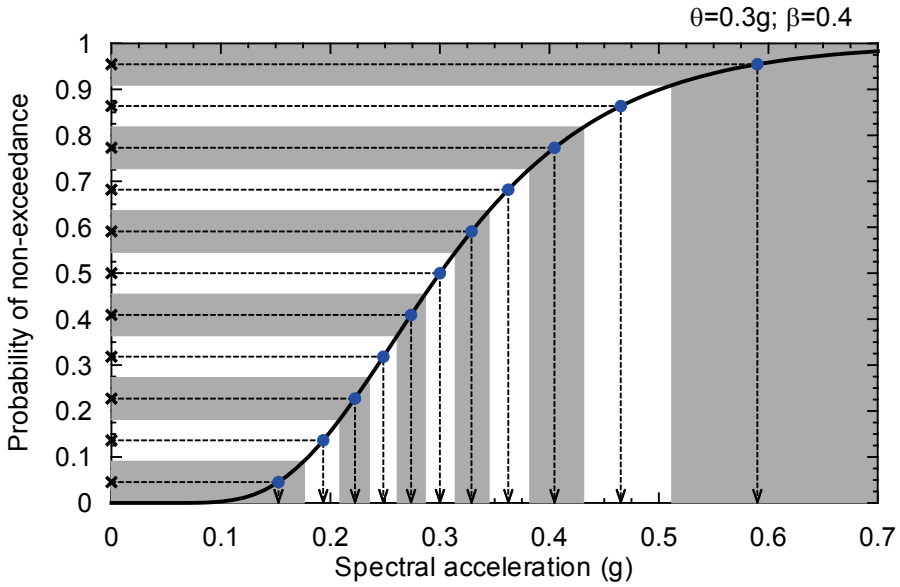

Figure B-13 Cumulative probability distribution for a scenario earthquake divided into 11 intervals with an equal probability of occurrence.

For each horizontal stripe, the central or midpoint value of the probability of non-exceedance is shown by the symbol "×" with values of 4.55%, 13.64%, 22.73%, 31.82%, 40.91%, 50%, 59.09%, 68.18%, 77.27%, 86.36%, and 95.45%. A dashed horizontal line extends across the plot from the vertical axis to the cumulative distribution function, and then vertically down to the horizontal axis, where spectral acceleration values of 0.153 g, 0.193 g,

0.222 g, 0.248 g, 0.274 g, 0.300 g, 0.329 g, 0.362 g, 0.405 g, 0.465 g and 0.590 g, respectively, can be read.

The values of spectral acceleration, S_{a1} to S_{a11}, characterize the distribution of spectral acceleration shown in the figure and can be obtained from the following equation:

$$S_{ai} = \theta \cdot e^{\beta \cdot \Phi^{-1}(P_i)} \tag{B-29}$$

where Φ^{-1} is the inverse standardized normal distribution, and P_i is the midpoint cumulative probability for region i. The values for η_i in Table B-2 are calculated from $\Phi^{-1}(P_i)$ for 11 target spectral accelerations. Alternatively, these values can be generated using an Excel worksheet and the function LOGINV (p, ln(θ), β), where p = (0.04545 ….. 0.9545), ln(0.3) = -1.204 is the mean, and β =0.4 is the dispersion.

Identical to the procedures involving a Uniform Hazard Spectrum, users must specify a period range (T_{max}, T_{min}) for scaling pairs of ground motions. The characterization of the earthquake hazard can involve the following steps:

1. Select the magnitude and site-to-source distance for the scenario event.
2. Select an appropriate attenuation relationship(s) for the region, site soil type, and source characteristics.
3. Establish the period range (T_{max}, T_{min}) for scaling pairs of ground motions.
4. Determine the median spectral acceleration demands, θ, and the corresponding dispersions, β, in the period range (T_{max}, T_{min}) using the attenuation relationship(s) of Step 2.
5. Establish 11 target spectra, $S_{ai}(\overline{T}), i = 1, 11$, using the medians and dispersions from Step 4 and Equation B-29 in the period range (T_{max}, T_{min}).
6. Select 11 pairs of ground motions.
7. Construct a geomean spectrum for each pair of ground motions.
8. For each target spectrum of Step 5, scale a pair of motions such that for each period in the range (T_{max}, T_{min}), the geomean spectrum matches the response spectrum $S_{ai}(T)$.
9. Repeat Step 8 for the remaining 10 spectra.

This procedure will result in 11 pairs of earthquake histories to represent the potential range of intensities associated with the scenario.

Step 8 in this procedure requires the selection of pairs of motions in Step 6 with geomean spectra in the period range (T_{max}, T_{min}) that are similar in shape to the target spectra of Step 5. If appropriate pairs of motions are unavailable, an alternative to Steps 7, 8 and 9 is to spectrally match pairs of motions to the target spectra of Step 5, with each component in a pair matched to the same target spectrum.

A refinement to the above procedure involves the use of Conditional Mean Spectra and the effective fundamental period, $\overline{T}$, as defined in Chapter 4. Steps 4 through 9 above are altered as follows:

4. Determine the median spectral acceleration demand, θ, and the corresponding dispersion, β, at effective fundamental period $\overline{T}$, using the attenuation relationship(s) of Step 2.
5. Compute 11 target values of spectral acceleration, $S_{ai}(\overline{T}), i = 1, 11$, using the medians and dispersions from Step 3.
6. Generate Conditional Mean Spectra, CMS_i, for the 11 target values of $S_{ai}(\overline{T})$ given magnitude and distance from Step 1 and η from Section B.7.
7. Select 11 pairs of ground motions, p_i, $i = 1,11$, such that the shape of the geomean spectrum for p_i is similar to that of the CMS_i of Step 5 over a user-specified period range, which must include T_1^X and T_1^Y.
8. Amplitude scale the geomean spectral acceleration of the two components of p_i to $S_{ai}(\overline{T})$.
9. Repeat Step 8 for the remaining 10 spectra.

Similarly, spectral matching of pairs of motions can be used in lieu of selecting pairs of ground motions with geomean spectral shapes that are similar to CMS_i.

Appendix C

Residual Drift

C.1 Introduction

Residual drift (i.e., permanent set) is an important consideration in judging the post-earthquake safety of a building and the economic feasibility of repair. Modest levels of residual drift can require costly and difficult adjustments to certain nonstructural components (e.g., re-alignment of elevator rails and building facades), and can also lead to concerns that a building is unsafe for post-earthquake inspection or repair. Larger residual drifts can result in attempts to straighten the structural frame, or implementation of other measures intended to improve the stability of the system. Residual drifts can become large enough to seriously jeopardize structural stability in aftershocks, and render the building uneconomical to repair (i.e., the cost of repair is comparable to the cost of replacing the building).

Research has shown that residual drifts predicted by nonlinear response-history analysis are highly variable and sensitive to modeling assumptions. Key factors include the post-yield hardening/softening slope and unloading response. Also, residual drift can be larger for near-fault records with forward directivity pulses or long-duration records that cause many cycles of significant inelastic response. Accurate statistical simulation of residual drift requires advanced nonlinear response-history analyses, with a large number of ground motions and careful attention to the cyclic hysteretic response of the models and numerical accuracy of the solution.

Since the requirements for direct simulation of residual drift are computationally complex and not practical for general implementation, equations were developed to estimate residual drift as a function of the peak transient response of the structure. This appendix provides background information on the basis for the recommended relationships.

C.2 Past Research on Prediction of Residual Drift

Analytical studies by Riddell and Newmark (1979) and Mahin and Bertero (1981) first identified some of the key behavioral aspects associated with

calculating residual drift. Recent studies, including MacRae and Kawashima (1997), MacRae (1994), Christopoulos et al. (2003), Christopoulos and Pampanin (2004), Pampanin et al. (2003), and Ruiz-Garcia and Miranda (2005, 2006), have confirmed that residual drifts are largely dependent on the following parameters: (1) magnitude of peak transient inelastic drifts; (2) lateral strength of the structure relative to earthquake demand; (3) inelastic post-yield stiffness; (4) cyclic unloading response; (5) pulses in the ground motions; and (6) duration of ground shaking. The effects of these parameters are interrelated, and some are implicitly accounted for in the assessment of story drift. It is desirable that analytical models for residual drift account for variations in post-yield stiffness and cyclic unloading response because these parameters are structural parameters that can be influenced in design. For example, assessment of residual drift should differentiate between conventional structures and systems that employ self-centering devices that are designed to minimize residual drift.

Figure C-1 presents a schematic plot of peak story drift ratio versus ground motion intensity, relating predicted peak transient drift and residual drift under increasing intensity. Point "a" in the figure corresponds to the onset of inelastic response, below which residual drift does not occur. Point "c" corresponds to collapse of the structure, where residual and transient responses converge. Point "b" corresponds to the region between these two limits, where the residual drift is shown as some fraction of the transient drift.

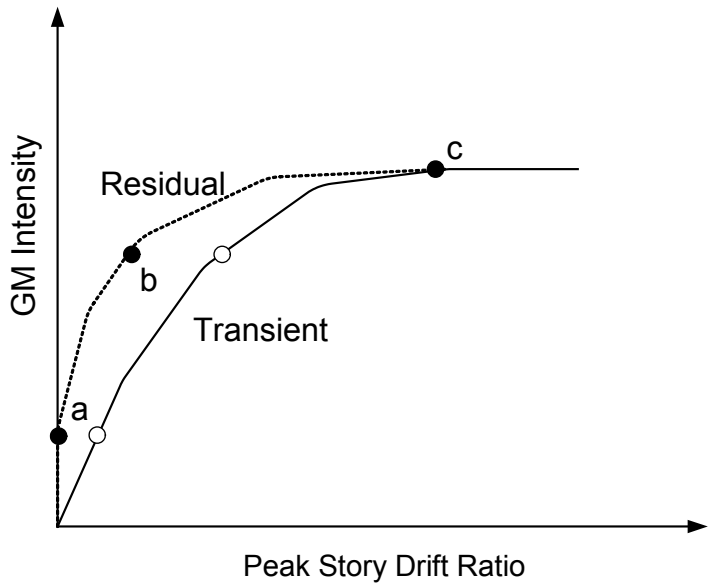

Figure C-1 Plot of peak story drift ratio versus ground motion intensity, relating predicted peak transient drift and residual drift ratios.

The figure indicates that the ratio between residual drift and transient drift is not constant, but it may be reasonable to treat this ratio as a constant. Much of the existing literature to date has evaluated residual drift at intermediate levels of response, sometimes distinguishing between the degree of inelasticity by varying the strength of the structure, either by adjusting the strength using a response modification factor or by adjusting the transient story ductility demand.

The characteristics of unloading behavior can have a significant impact on residual displacements. Figure C-2 presents load versus deflection plots representing the types of unloading behaviors that have been identified as important in prior research. These studies have consistently shown that residual displacements are largest in elastic-plastic (EP) systems, due to their tendency to preserve the inelastic displacements upon unloading. This is in contrast to general inelastic (GI) response, where pinching or other effects lead to smaller unloading stiffness. Most recently, researchers have been examining the benefits of so-called self-centering (SC) systems, which are specifically designed with unloading characteristics (e.g., restoring forces) intended to minimize (or potentially eliminate) residual displacements. There are also structural behavioral characteristics, such as foundation rocking, which have natural self-centering tendencies.

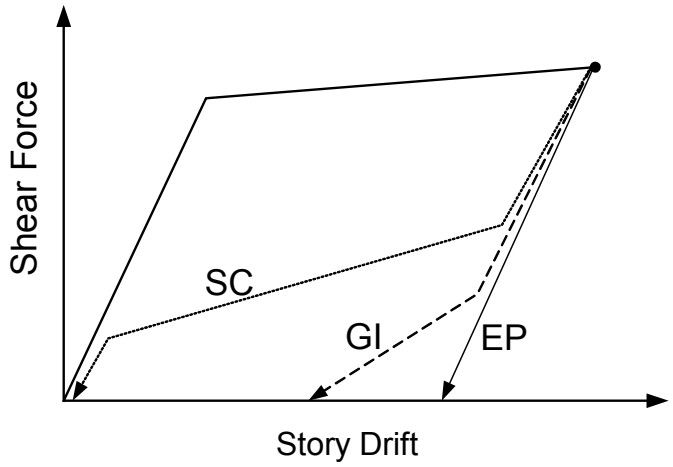

Figure C-2 Idealized unloading response characteristics for elastic-plastic (EP), general inelastic (GI), and self-centering (SC) systems.

Due to the variety of approaches and parameters addressed by various researchers, it is difficult to generalize the results of all prior research. However, important overall results and observations from key analytical studies can be summarized as follows:

- MacRae and Kawashima (1997) investigated residual displacements in single-degree-of-freedom bilinear oscillators with a focus on bridge

design, where the presence of residual displacements was cited as a major factor in bridge closures and replacement. They proposed a model to estimate residual displacements as a function of the peak inelastic displacement, unloading properties of the inelastic oscillator, and a statistical coefficient based on nonlinear response history analyses. In an illustrative example, they predicted residual displacements equal to about 0.16 times the maximum transient displacement. According to their proposed model, the residual displacement ratio could be deaggregated into the following product, 0.16 = 0.67 x 0.9 x 0.27, where 0.67 is the ratio of plastic to total drift (equal to the sum of the elastic and plastic drift), 0.9 represents the effect of reduced unloading stiffness, and 0.27 is a statistical parameter accounting for inelastic dynamic response. The specific value of 0.27 represents the mean plus one standard deviation from a range of analyses for systems with modest strain hardening and a ductility demand ratio of 4.

- Christopoulos et al. (2003) conducted analyses of single-degree-of-freedom models with a primary emphasis on characterizing the effects of post-yield hardening stiffness and hysteretic unloading behavior on response. The models were generally representative of modern ductile moment frame buildings, ranging in height from 4 to 20 stories, designed with base shear yield ratios, V_y/W, ranging from 0.26 to 0.11, respectively. They applied ground motions to represent both design and maximum earthquakes. Maximum drift ratios observed in their analyses were in the range of 2% to 3%. Analyses of elastic-plastic (EP) models with zero hardening had residual displacements ranging from 0.1 to 0.4 times the peak inelastic transient displacements. These ratios reduced to 0.1 to 0.2 for systems with 5% strain-hardening, and increased up to 0.7 for systems with 5% strain-softening (i.e., –5 % hardening). The largest residual displacements and peak transient ductilities (up to 5 times yield) were observed in a 4-story building with strain-softening (approximate period equal to1 second). Comparable analyses using a general inelastic model (i.e., Takeda model) had significantly smaller residual drifts, ranging between 0.07 to 0.12 times peak transient drifts for systems with zero or positive strain-hardening, and 0.10 to 0.15 times peak transient drifts for systems with strain-softening. In related studies of multi-degree-of-freedom models (Pampanin et al., 2003), residual drifts were on the order of 0.05 to 0.25 times the total transient drift, depending on post-yield hardening and hysteretic modeling assumptions.
- Ruiz-Garcia and Miranda (2005, 2006) conducted an extensive parametric study of single- and multi-degree-of-freedom systems with the goal to characterize probabilistic residual drift hazard curves. They

generally expressed their results in terms of a parameter, C_r, relating residual drift to elastic spectral displacement. For consistency with other prior research studies, this parameter would need to be modified to account for the difference between peak inelastic transient displacement and elastic spectral displacement. Presumably, this adjustment is close to unity when the equal displacement approximation is expected to be applicable (i.e., in long period systems dominated by single mode behavior under small to moderate displacements). For elastic-plastic models with periods greater than 1 second, and elastic demand to yield strength ratios of R = 1.5 to 6, they reported median values of C_r = 0.25 to 0.5. This ratio increased to C_r = 0.8 for oscillators with periods between 0.5 and 1 second, and became even larger for smaller periods. Since the ratio is conditioned on elastic spectral displacement, the large amplification at small periods is probably a reflection of the amplification between elastic and inelastic transient displacements that occurs in the short period range. For stiffness-degrading systems, the median value of C_r reduced to about 0.1 to 0.3. They also reported dispersion in C_r of about 0.8, which was fairly constant across various periods and building strengths.

C.3 Model to Calculate Residual Drift

Based on the results of prior analytical studies, the following set of equations were developed to relate residual story drift, Δ_r, to story drift, Δ:

$$\begin{aligned} \Delta_r &= 0 && \text{for } \Delta \le \Delta_y \\ \Delta_r &= 0.3\left(\Delta - \Delta_y\right) && \text{for } \Delta_y < \Delta < 4\Delta_y \\ \Delta_r &= \left(\Delta - 3\Delta_y\right) && \text{for } \Delta \ge 4\Delta_y \end{aligned} \qquad \text{(C-1)}$$

where Δ_y is the story drift at yield. These equations were calibrated such that at a ductility ratio of 4, the ratio of residual drift to peak transient drift is 0.23. At ductility ratios of 2 and 6, the ratios of residual drift to peak transient drift are 0.15 and 0.5, respectively. Ultimately, as the collapse point is reached, residual drift and peak story drift will converge. The relationship between these equations is illustrated in Figure C-3.

The equations apply to typical building systems. They are intentionally simplistic due to a lack of physical data for validation of modeling of residual displacements and the analytical complexity necessary to obtain significant improvement in residual drift estimates. The equations do not distinguish between many of the behavioral characteristics known to affect residual drift. For example, where previous studies of idealized models have shown a correlation between post-yield stiffness and residual drift, this is not directly

reflected in the equations. Characteristics like post-yield stiffness are, however, considered in the overall process to the extent that they impact story drift calculations upon which residual drift estimates are based.

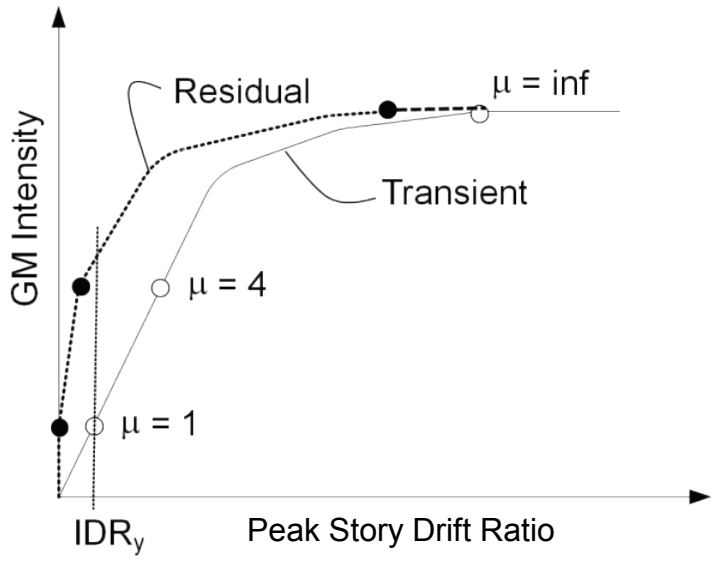

Figure C-3 Idealized model to estimate residual drift from transient story drift.

To illustrate how the equations work, consider a steel moment frame with a yield drift ratio of 1%. At 3% total drift, the predicted residual drift ratio would be 0.6%, or about 0.20 times the peak transient drift ratio. At 5% total drift, the predicted residual drift ratio would be about 1.9%, or about 0.38 times the peak transient drift ratio. At 7% total drift (approaching the collapse point), the residual drift ratio would be about 3.9%, or 0.56 times the peak transient drift ratio.

Per Ruiz-Garcia and Miranda (2005, 2006), the dispersion on residual drift estimates is about 0.8. Alternative ways to consider this dispersion in a performance assessment include: (1) calculate the median residual drift demand fragility using Equation C-1 based on the median transient and yield drift ratios, and then apply a dispersion of 0.8; or (2) calculate the residual drift probability based on integration of the conditional probability of residual drift and the transient drift. In the latter case, the dispersion on the conditional probability of residual drift should be reduced by the record-to-record variability in the transient drift.

C.4 Damage States for Residual Drift

Table C-1 identifies four damage states (DS_i) associated with residual drift. These damage states range from the onset of damage to nonstructural components to near-collapse of the structure. The proposed median story

drifts (residual drift as a percentage of story height) are approximate and based on a combination of judgment and limits previously suggested in Table C1-3 of FEMA 356, *Prestandard and Commentary for the Seismic Rehabilitation of Buildings* (FEMA, 2000b). For DS4, limits on residual drift expressed in terms of the design shear force are intended to cover cases in regions of low seismicity where the destabilizing effects of *P*-delta might dominate at smaller drift ratios than the values noted.

Table C-1 Damage States for Residual Story Drift Ratio

Damage State	Description	Residual Story Drift Ratio Δ / h[(1)]
DS1	No structural realignment is necessary for structural stability; however, the building may require adjustment and repairs to nonstructural and mechanical components that are sensitive to building alignment (e.g., elevator rails, curtain walls, and doors).	0.2% (equal to the maximum out-of-plumb tolerance typically permitted in new construction)
DS2	Realignment of structural frame and related structural repairs required to maintain permissible drift limits for nonstructural and mechanical components and to limit degradation in structural stability (i.e., collapse safety)	0.5%
DS3	Major structural realignment is required to restore margin of safety for lateral stability; however, the required realignment and repair of the structure may not be economically and practically feasible (i.e., the structure might be at total economic loss).	1%
DS4	Residual drift is sufficiently large that the structure is in danger of collapse from earthquake aftershocks (note: this performance point might be considered as equal to collapse, but with greater uncertainty).	High Ductility Systems $4\% < 0.5V_{design}/W$
		Moderate Ductility Systems $2\% < 0.5V_{design}/W$
		Limited Ductility Systems $1\% < 0.5V_{design}/W$

Notes: (1) h is the story height.

Further work is needed to establish appropriate parameters to describe the uncertainty in these limits and loss functions to define the direct economic loss and downtime losses associated with these damage states. For example, DS1 may require repairs to nonstructural components that may not otherwise be damaged, except for the need to realign components. Similarly, depending on the type of system, DS2 may require extensive structural repairs beyond those evident from the assessment of structural component damage.

The relationship between transient and residual drift demands, per Equation C-1, can be combined with the information in Table C-1 to relate these

damage states to story drifts. Through the yield drift, Δ_y, the relationship between the residual drift damage states and peak transient drift will depend on the stiffness of the system. Some example relationships are summarized in Table C-2, which are based on the assumed yield drift ratios noted.

Table C-2 Sample Transient Story Drift Ratios, Δ / h, associated with Damage State Definitions for Residual Drift

Sample Framing System	Δ_y / h	Δ / h			
		DS1[(1)]	DS2[(1)]	DS3[(1)]	DS4[(2)]
Steel ductile moment resisting frame	1%	1.5%	2.7%	4.1%	7.1%
Reinforced concrete shear wall	0.5%	1%	2.2%	2.6%	3.6%
Timber shear wall	1%	1.5%	2.7%	4.1%	5.1%

Notes: (1) Δ_r / h = 0.2%, 0.5% and 1.0% for DS1, DS2 and DS3, respectively.

(2) Δ_r / h = 4%, 2% and 2% for steel moment resisting frames, reinforced concrete shear walls, and timber shear walls, respectively.

Appendix D

Component Fragility Specifications

D.1 Summary of Provided Fragility Specifications

Fragility specifications are detailed descriptions of potential component damage states, fragility functions, and consequence functions. Table D-1 provides a summary listing of structural and nonstructural component fragility specifications provided as part of the methodology. The table is organized by general system type, and includes the fragility group classification number, a description of the type of components included in the fragility group, and the number of sub-categories available for each component type. The fragility classification numbers are based on NISTIR 6389, *UNIFORMAT II Elemental Classification for Building Specifications, Cost Estimating and Cost Analysis* (NIST, 1999). The sub-categories have been developed to differentiate between components with:

- different vulnerability to damage (e.g., code compliance, details of construction, braced versus unbraced systems, and anchored versus unanchored equipment); and
- different repair, life-safety, or occupancy consequences associated with damage (e.g., gypsum wallboard repairs consisting of patch and paint versus replacement of ceramic tile).

Differences in structural vulnerability are generally related to compliance with ductile detailing requirements in material design standards for special, intermediate, or ordinary systems. Differences in nonstructural system vulnerability are generally related to bracing and anchorage and the governing code at the time of installation.

Differences in consequence functions are generally related to repair costs, which are a function of the quantity of material damaged. For example, fragility specifications for low aspect ratio concrete shear walls include sub-categories for the following wall thicknesses:

- less than 8 inches thick
- 8 to 16 inches thick

- 16 to 24 inches thick

The relative difficulty in accessing or conducting repairs and the quality of finish materials also affect repair costs. For each of the above low aspect ratio wall thicknesses, for example, additional sub-categories have been developed to account for differences in repair costs related to panel height, considering panels that are:

- Less than 15 feet tall
- 16 to 24 feet tall
- 25 to 40 feet tall

Similar logic for other structural and nonstructural components and systems expands the list to more than 700 individual fragility specifications. Each fragility specification includes a description of the component, a description of the possible damage states, the logical interrelationship between the damage states, the demand parameter used to determine damage state occurrence, the consequence functions associated with each damage state, and a quality rating for the specification. The quality rating is an indication of the reliability of the data and procedures used in the development of the fragility.

All vulnerable structural components, nonstructural components, and contents are assigned a fragility specification and categorized into fragility groups and performance groups. Procedures for selecting appropriate fragility specifications for individual building components, along with procedures for creating user-defined, building-specific fragility specifications, are provided in *Volume 2 – Implementation Guide*. Details including the specific attributes of each fragility specification are provided in *Volume 3 – Supporting Electronic Materials*, accessible through the Fragility Manager in the *Performance Assessment Calculation Tool* (PACT), or viewed directly in the *Fragility Database* (Excel workbook), or the *Fragility Specification* (PDF file).

Table D-1 List of Provided Fragility Specifications

General System Description	Fragility Classification Number	Component Description	Number of Sub-Categories
Miscellaneous Structural Steel Components/ Connections	B1031.001	Bolted shear tab gravity connections	1
	B1031.011	Steel column base plates	3
	B1031.021	Welded column splices	3
Structural Steel Special Concentrically Braced Frames	B1033.001	Special Concentrically Braced Frame with wide flange (WF) braces, balanced design criteria, chevron brace	3
	B1033.002	Special Concentrically Braced Frame with WF braces, balanced design criteria, single diagonal	3
	B1033.003	Special Concentrically Braced Frame with WF braces, balanced design criteria, X Brace	3
	B1033.011	Special Concentrically Braced Frame with hollow structural section (HSS) braces, balanced design criteria, chevron brace	3
	B1033.012	Special Concentrically Braced Frame with HSS braces, balanced design criteria, single diagonal	3
	B1033.013	Special Concentrically Braced Frame with HSS braces, balanced design criteria, X Brace	3
	B1033.021	Special Concentrically Braced Frame with HSS braces, tapered gusset plates, design to AISC minimum standard, chevron brace	3
	B1033.022	Special Concentrically Braced Frame with HSS braces, tapered gusset plates, design to AISC minimum standard, single diagonal	3
	B1033.023	Special Concentrically Braced Frame with HSS braces, tapered gusset plates, design to AISC minimum standard, X Brace	3
	B1033.031	Special Concentrically Braced Frame, design to AISC minimum standards, chevron brace	3
	B1033.032	Special Concentrically Braced Frame, design to AISC minimum standards, single diagonal	3
	B1033.033	Special Concentrically Braced Frame, design to AISC minimum standards, X Brace	3

	F1012.001	Steel storage racks	1

Appendix E

Population Models

E.1 Population Models

Population models are used to determine the distribution of people within a building envelope, and the variability of this distribution over time of day and day of the year. Population models include a definition of the peak population, which is the number of people likely to be present at times of peak occupancy, and the fraction of this peak population likely to be present at other times. In this appendix, population models are provided for the following occupancies:

- Commercial Office
- Education (K-12) – typical elementary, middle school, and high school classrooms
- Healthcare – general in-patient hospitals
- Hospitality – hotels and motels
- Multi-Unit Residential – also applicable to single-family detached housing, with some modification
- Research Laboratories
- Retail – shopping malls and department stores
- Warehouse

Peak population values for each occupancy are defined Chapter 3. Table E-1 presents a series of daily population models for different occupancies in terms of the fraction of the peak population present in a building at different times of day for weekdays and weekends. Figures E-1 through E-5 plot the variation in population versus time of day, as depicted in Table E-1.

Table E-2 presents the monthly variation in population, relative to the daily population model for weekdays and weekends for each occupancy. Monthly variations are used to characterize the effects of holidays by prorating weekday populations considering the number of holidays per month and the total number of weekdays, on average, for that month.

Table E-1 Default Variation in Population by Time of Day and Day of Week, Relative to Expected Peak Population for Different Occupancies

Appendix F
Normative Quantities

F.1 Normative Quantities

Normative quantities are an estimate of the components and contents likely to be present in a building of a specific occupancy on a gross square foot (gsf) basis. They can be used to provide an approximate inventory of the type and quantity of typical components found in typical buildings. Normative quantity values for 10^{th}, 50^{th}, and 90^{th} percentile quantities were developed based on data from surveys of 3,000 typical buildings across various occupancies. Normative quantity units of measurement are consistent with the basic units of measure used to determine repair cost and repair time consequences in the fragility specifications.

Table F-1 through Table F-8 summarize normative quantity information provided for the following occupancies:

- Commercial Office
- Education (K-12) – typical elementary, middle school, and high school classrooms
- Healthcare – general in-patient hospitals, medical equipment excluded
- Hospitality – hotels and motels
- Multi-Unit Residential – also applicable to single-family detached housing, with some modification
- Research – special purpose laboratory equipment excluded
- Retail – shopping malls and department stores
- Warehouse – inventory excluded

Information in these tables is utilized in a companion *Normative Quantity Estimation Tool*, which is an Excel workbook designed to assist in estimating quantities of components and contents for building performance modeling provided as part of *Volume 3 – Supporting Electronic Materials and Background Documentation*.

Table F-1 Normative Quantities for Commercial Office Occupancies

Component Type	Unit of Measurement	10th Percentile Quantity	50th Percentile Quantity	90th Percentile Quantity
Gross area	SF	10,000	85,000	1,103,000
Volume	CF per 1 gsf	10.300	13.600	18.000
Cladding				
Gross wall area	SF per 1 gsf	0.380	0.645	1.200
Windows or glazing area	100 SF per 1 gsf	8.0E-04	3.0E-03	6.0E-03
Roof area - total	SF per 1 gsf	0.025	0.270	1.300
Interior partition length	100 LF per 1 gsf	7.0E-04	1.0E-03	1.2E-03
Ceramic tile floors	SF per 1 gsf	0.020	0.042	0.104
Ceramic tile walls	100 LF per 1 gsf	3.6E-05	7.6E-05	1.9E-04
Ceilings				
Ceiling - lay in tile percentage	%		90%	
Ceiling - gypsum board percentage	%		5%	
Ceiling - exposed percentage	%		3%	
Ceiling - other (high end) percentage	%		2%	
Stairs	FL per 1 gsf	8.0E-05	1.0E-04	1.2E-04
Elevators	EA per 1 gsf	1.5E-05	2.8E-05	7.9E-05
Plumbing				
Plumbing fixtures	EA per 1 gsf	5.0E-04	1.1E-03	2.6E-03
Piping				
Cold domestic water piping - 2 ½ inch diameter or smaller	1,000 LF per 1 gsf	2.0E-05	4.2E-05	1.0E-04
Cold domestic water piping – greater than 2 ½ diameter	1,000 LF per 1 gsf	1.0E-05	1.5E-05	2.0E-05
Hot domestic water piping - 2 ½ inch diameter or smaller	1,000 LF per 1 gsf	4.0E-05	8.4E-05	2.1E-04
Hot domestic waster piping – greater than 2 ½ diameter	1,000 LF per 1 gsf	2.0E-05	3.0E-05	4.0E-05
Gas supply piping	1,000 LF per 1 gsf	1.0E-05	1.5E-05	2.0E-05
Sanitary waste piping	1,000 LF per 1 gsf	3.0E-05	5.7E-05	1.2E-04
HVAC				
Chiller capacity	TN per 1 gsf	2.5E-03	2.9E-03	3.3E-03
Cooling tower capacity	TN per 1 gsf	2.5E-03	2.9E-03	3.3E-03
Boiler capacity	BTU per 1 gsf	30.000	45.000	60.000

Table F-1 Normative Quantities for Commercial Office Occupancies (continued)

Component Type	Unit of Measurement	10th Percentile Quantity	50th Percentile Quantity	90th Percentile Quantity
Air handling units	CFM per 1 gsf	0.500	0.700	0.900
Fans	CFM per 1 gsf	0.000	0.000	0.000
HVAC ducts – 6 sq. ft. or larger	1,000 LF per 1 gsf	1.5E-05	2.0E-05	2.5E-05
HVAC ducts – less than 6 sq. ft.	1,000 LF per 1 gsf	5.0E-05	7.5E-05	9.0E-05
HVAC in-line drops and diffusers	EA per 1 gsf	6.0E-03	9.0E-03	2.0E-02
HVAC in-line coils	EA per 1 gsf	3.0E-03	5.0E-03	6.0E-03
VAV boxes	EA per 1 gsf	1.0E-03	2.0E-03	4.0E-03
Piping				
Steam and chilled water piping - 2 ½ inch diameter or smaller	1,000 LF per 1 gsf	0.0E+00	0.0E+00	5.0E-06
Steam and chilled water piping – greater than 2 ½ diameter	1,000 LF per 1 gsf	0.0E+00	0.0E+00	5.0E-06
Heating water piping - 2 ½ inch diameter or smaller	1,000 LF per 1 gsf	0.0E+00	5.0E-06	1.0E-05
Heating water piping – greater than 2 ½ diameter	1,000 LF per 1 gsf	0.0E+00	5.0E-06	1.0E-05
Electrical				
Electrical load	W per 1 gsf	6.000	16.200	27.000
Electrical distribution conduits	LF per 1 gsf	7.0E-02	2.0E-01	4.0E-01
Electrical distribution – cable trays	LF per 1 gsf	0.0E+00	2.0E-02	5.0E-02
Wall mounted switchgear	EA per 1 gsf	1.0E-04	1.5E-04	2.0E-04
Lighting fixtures – lay in fluorescent	EA per 1 gsf	1.0E-02	1.5E-02	2.0E-02
Lighting fixtures – stem hung fluorescent	EA per 1 gsf	1.0E-02	1.5E-02	2.0E-02
Standby generators	KVA per 1 gsf	0.0E+00	0.0E+00	0.0E+00
Fire protection				
Sprinkler piping	20 LF per 1 gsf	8.5E-03	1.0E-02	1.1E-02
Sprinkler drops	EA per 1 gsf	7.0E-03	9.0E-03	1.2E-02

Appendix G

Generation of Simulated Demands

G.1 Introduction

The methodology uses a Monte Carlo procedure to calculate the distribution of probable losses for each ground motion intensity or earthquake scenario. In this process, a large number of earthquake realizations (hundreds to thousands) are developed. Each realization represents one possible building performance outcome in response to earthquake shaking, and each realization requires a unique set of demands (e.g., peak floor accelerations, story drift ratios, story velocities) to determine damage states and resulting consequences.

Rather than requiring a large number of structural analyses to develop these demands, the results from a limited suite of analyses are mathematically transformed into a large series of simulated demand sets. This appendix describes the algorithms used to transform the demands developed from a limited number of structural analyses into the larger number of simulated demand sets used to calculate performance.

G.2 Nonlinear Response History Analysis

When nonlinear response history analysis is used, results from structural analyses are assembled into a matrix with each row representing the responses obtained from a particular analysis, and each column containing the peak value of a particular demand parameter at a specified location in the building (e.g., peak floor acceleration at the third floor in the east-west direction) obtained from that analysis. This demand matrix is considered to be representative of a jointly lognormal distribution. Mathematical manipulation is performed to determine a median value for each parameter based on the analysis results, and also a covariance matrix that indicates the relationship of each parameter to the others in the set. Then a large number of simulated demand vectors are mathematically generated using a random number selection process, the median values, and the covariance matrix. The required minimum number of nonlinear analyses depends on many factors, including the required accuracy of the loss calculation; the dynamic properties of the building and number of stories; and, the characteristics of

the ground motion. In this appendix, 11 analyses are used for the purposes of illustration.

G.2.1 Algorithm

Yang (Yang et al., 2006; Yang et al., 2009) developed the original algorithm used to generate simulated demands. The algorithm was extended to address the effects of modeling uncertainty, β_m and ground motion uncertainty, β_{gm}, on demand distribution.

Let m represent the number of response analyses performed at an intensity level, or scenario. For each analysis, the peak absolute value of each demand parameter is assembled into a row vector with n entries, where n is the number of demand parameters. The m row vectors are catenated to form an $m \times n$ matrix (m rows $\times$ n columns, which is m analyses $\times$ n demand parameters), with each column representing m values of one demand parameter.

Denote the matrix of demand parameters, $\mathbf{X}$. The entries in $\mathbf{X}$ are assumed to be jointly lognormal. The natural logarithm of each entry in $\mathbf{X}$ is computed to form an $m \times n$ matrix $\mathbf{Y}$. The entries in $\mathbf{Y}$ are assumed to be jointly normal and can be characterized by a $1 \times n$ mean vector, $\mathbf{M_Y}$, containing the means of the natural logarithms of each demand and an $n \times n$ covariance matrix, $\Sigma_{\mathbf{YY}}$.

A vector of natural logarithm of demand parameters, $\mathbf{Z}$, can be generated with the same statistical distribution as $\mathbf{Y}$ using a vector of uncorrelated standard normal random variables, $\mathbf{U}$, with a mean of $\mathbf{0}$, which is vector of zeroes, and a covariance of $\mathbf{I}$ as shown in Equation G-1, where $\mathbf{A}$ and $\mathbf{B}$ are matrices of constant coefficients that linearly transforms $\mathbf{U}$ to $\mathbf{Z}$.

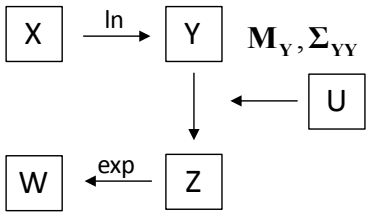
$$\mathbf{Z} = \mathbf{AU} + \mathbf{B} = \mathbf{L}_{np}\mathbf{D}_{pp}\mathbf{U} + \mathbf{M_Y} \tag{G-1}$$

In Equation G-1, p is the rank of the covariance matrix $\Sigma_{\mathbf{YY}}$, obtained by counting the number nonzero eigenvalues of $\Sigma_{\mathbf{YY}}$. If $\Sigma_{\mathbf{YY}}$ is full-rank, then $p = n$. The rank of $\Sigma_{\mathbf{YY}}$ may not be full (i.e., $p \leq n$) for two reasons: (1) the number of analyses m is less than or equal to the number of demand variables n, a common situation; or (2) one or more vectors of peak demands obtained from analyses are a linear combination of other analysis vectors. In either case, a non-full-rank covariance matrix can be interpreted as a condition of insufficient data for generating the covariance matrix. For example, using 11 analyses (m = 11) to assess to develop simulated demands for an 8-story planar frame building would result in 11 demand vectors, each having 8 entries representing peak story drift ratios, and 9 entries representing peak

accelerations at the floor levels of the building (i.e., 1st floor, 2nd floor, …8th floor, roof) resulting in a 17×17 ($n = 8 + 9 = 17$) covariance matrix that is not-full-rank with $p = 10$.

PACT utilizes Equation G-1 to generate the demand parameter vector, $\mathbf{Z}$. This equation can handle both full-rank and non-full-rank $\Sigma_{\mathbf{YY}}$. In Equation G-1, $\mathbf{D}_{pp}$ is a $p \times p$ matrix obtained by partitioning the square-root of eigenvalues of covariance matrix $\Sigma_{\mathbf{YY}}$, denoted as $\mathbf{D}_{\mathrm{Y}}$, which is an $n \times n$ matrix. As mentioned earlier, p is the rank of $\Sigma_{\mathbf{YY}}$, therefore, if $\Sigma_{\mathbf{YY}}$ is full rank, $p = n$; and if $\Sigma_{\mathbf{YY}}$ is not-full-rank, then $p < n$. Similarly, matrix $\mathbf{L}_{np}$ is an $n \times p$ matrix obtained by partitioning the $n \times n$ eigenvector matrix of $\Sigma_{\mathbf{YY}}$, denoted as $\mathbf{L}_{\mathrm{Y}}$.

The effect of modeling uncertainty, β_m and ground motion uncertainty, β_{gm}, in estimation of losses is implemented in the process for estimation of $\mathbf{Z}$. Once the covariance matrix of observations, $\Sigma_{\mathbf{YY}}$, is generated, it is decomposed into two matrices: (1) a variance matrix; and (2) a correlation coefficient matrix. The variance matrix consists of variance of each demand parameter, and is inflated with β_m and β_{gm} using a square-root-sum-of-squares technique. A new covariance matrix is assembled using the original correlation coefficient matrix and the inflated variance matrix. The process of estimation of $\mathbf{Z}$ using Equation G-1 then continues, as illustrated in Figure G-1.



Where:
X – is the matrix of analytically determined demands (observations)
Y – is the natural logarithm of X
$\mathbf{M}_{\mathbf{Y}}$ – is the mean demand vector
$\mathbf{\Sigma}_{\mathbf{YY}}$ – is the covariance matrix of demand vector
Z – is the natural logarithm of realizations
W – is the matrix of statistically determined demands

Figure G-1 Generation of simulated vectors of correlated demand parameters (adapted from Yang et al., 2006).

One simulated demand is generated by: (1) computing $\mathbf{M}_{\mathbf{Y}}$, and $\Sigma_{\mathbf{YY}}$ from the matrix of the logarithms of the analysis results $\mathbf{Y}$; (2) updating $\Sigma_{\mathbf{YY}}$ for modeling uncertainty; (3) populating $\mathbf{U}$ by random sampling each demand parameter on a distribution with a mean of $\mathbf{0}$ and a covariance matrix of $\mathbf{I}$; (4) computing $\mathbf{Z}$ per equation G-1; and (5) taking the exponential of every entry in $\mathbf{Z}$ to recover the vector of simulated demand parameters $\mathbf{W}$. N vectors of $\mathbf{U}$ are required for the N simulations using one vector per

simulation. The process is computationally efficient because $\mathbf{M}_Y$ and Σ_{YY} are computed just once for each intensity of shaking.

G.2.2 Sample Application of the Algorithm

This section illustrates the process described above for a sample 3-story, planar building. In this example, 7 demand parameters (n = 7), 3 story drift ratios (δ_1, δ_2, δ_3) and 4 floor accelerations (a_1, a_2, a_3, a_4), are used to assess performance. N is selected as 10000. Eleven analyses (m = 11) are performed. Although not considered in this example, residual drift ratios and floor velocities are included in the actual implementation of the methodology. Table G-1 presents the demand parameter matrix $\mathbf{X}$ of 11 rows (one per analysis) × 7 columns (one per demand parameter) for this example. Modeling uncertainty, record-to-record variability, and ground motion variability are set aside to simplify the presentation. Because $m > n$, the covariance matrix of observations is full-rank, therefore $p = n = 7$.

G.2.2.1 Generation of Realizations Using Full-Rank Covariance Matrices

To visually illustrate the process of drawing realizations using observed data, consider the matrix $\mathbf{X} = [\mathbf{X}_1, \mathbf{X}_2 ..... \mathbf{X}_7]$ in Table G-1, with 7 columns (vectors) of demand, with 11 entries (rows) per vector. Joint probability distributions can be developed for pairs of vectors. For example: (1) between $\mathbf{X}_1$ (first story drift ratio) and $\mathbf{X}_3$ (third story drift ratio); and (2) between $\mathbf{X}_4$ (ground floor acceleration) and $\mathbf{X}_7$ (roof acceleration). In Figure G-2, the black solid circles show the relationship between $\mathbf{X}_1$ and $\mathbf{X}_3$, and $\mathbf{X}_4$ and $\mathbf{X}_7$, constructed using the data of Table G-1. $\mathbf{X}_1$ and $\mathbf{X}_3$ are weakly correlated, while $\mathbf{X}_4$ and $\mathbf{X}_7$ are strongly correlated.

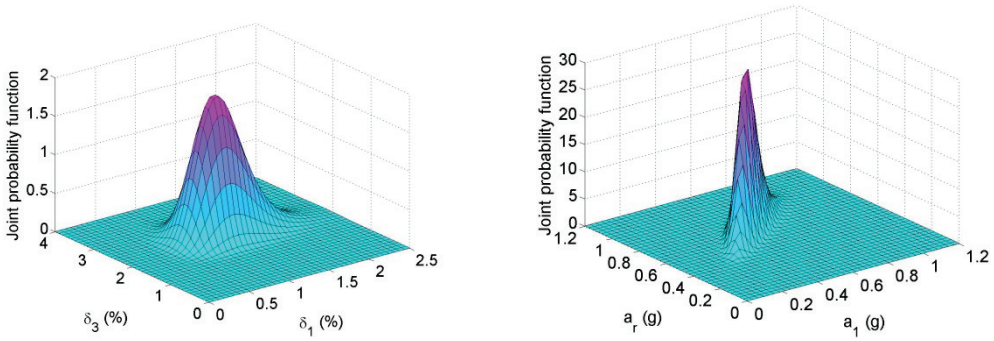
(a) $\mathbf{X}_1$ and $\mathbf{X}_3$ (b) $\mathbf{X}_4$ and $\mathbf{X}_7$

Figure G-2 Plots illustrating the correlation relationship between demand parameters.

A joint probability density function of the type shown in Figure G-3 can be constructed for any pair of vectors given two means, two variances, a covariance, and type of distribution (e.g., normal or log-normal). This figure presents the joint probability density functions for $\mathbf{X}_1$ and $\mathbf{X}_3$, and $\mathbf{X}_4$ and $\mathbf{X}_7$ constructed using the data of Table G-2, hereafter termed the original data.



(a) $\mathbf{X}_1$ and $\mathbf{X}_3$ (b) $\mathbf{X}_4$ and $\mathbf{X}_7$

Figure G-3 Joint probability density functions.

The entries in matrix $\mathbf{X}$ are assumed to be jointly lognormal. The log of each entry in $\mathbf{X}$ is used to construct the entries in matrix $\mathbf{Y}$, which are now assumed to be jointly normal. Table G-2 presents the entries in $\mathbf{Y}$; the last row in the table contains the mean of each column vector in $\mathbf{Y}$ representing the mean vector $\mathbf{M}_\mathbf{Y}$ of Equation G-1. Table G-3 presents the covariance matrix $\Sigma_{\mathbf{YY}}$ of $\mathbf{Y}$. Table G-4 presents the diagonal matrix of the square root of eigenvalues of $\Sigma_{\mathbf{YY}}$, denoted as $\mathbf{D}_\mathbf{Y}$. All diagonal terms in $\mathbf{D}_\mathbf{Y}$ are positive, showing that $\Sigma_{\mathbf{YY}}$ is full-rank.

All of the matrices required to generate the correlated vectors have been constructed. The next step in the process is to compute the 7×1 vector $\mathbf{U}$ of uncorrelated standard normal random variables, with a mean of **0** and a covariance matrix of **I**. In this example, the **randn** function in Matlab is used, but any random generation algorithm can be used. This process is repeated 9999 times to construct the 10000 simulations. The next step involves taking the exponential of each value in the 7×10000 matrix to recover the demand parameters. Table G-6 presents the first 10 simulations of the 10000.

Table G-6 Matrix of Simulated Demand Parameters (first 10 vectors of 10000)

	δ_1 (%)	δ_2 (%)	δ_3 (%)	a_1 (g)	a_2 (g)	a_3 (g)	a_r (g)

As a last step, the statistics of the simulated demands should be compared with those of the demands calculated by response history analysis. A rigorous comparison of the analytical and simulated demands is achieved by computing the ratios of the mean vectors and the covariance matrices. Table G-7 presents ratios of elements of mean simulated response vector to elements of mean response history response vector. All values are close to 1.0. Table G-8 presents similar ratios of element covariance matrices

obtained from realizations and observations covariance matrices. Again, all values are close to 1.0. The data in Table G-7 and Table G-8 indicate that the simulated vectors of demand have the same underlying statistics as those of the original demand vectors.

G.2.2.2 Generation of Realizations Using Non-Full-Rank Covariance Matrices

This section illustrates the process and approximations involved in a case where the covariance matrix of demand parameters is non-full-rank, using the same example considered in the previous section. In this illustration, it is assumed that only five analyses ($m = 5$) are performed. In this case $m < n$, therefore the covariance matrix of observations is non-full-rank. Table G-9 shows the natural logarithm of these five analyses, which are the first five out of eleven used in the previous example (Table G-2). This matrix of demand parameters is denoted as $\mathbf{Y}'$. The last row in Table G-9 tabulates the mean of each column vector in $\mathbf{Y}'$ representing the mean vector $\mathbf{M}_{\mathbf{Y}'}$ of Equation G-1. Table G-10 presents the covariance matrix $\Sigma_{\mathbf{Y}'\mathbf{Y}'}$ of $\mathbf{Y}'$. Table G-11 presents the diagonal matrix $\mathbf{D}_{\mathbf{Y}'}$ of square root of eigenvalues of $\Sigma_{\mathbf{Y}'\mathbf{Y}'}$. Only the last four diagonal terms in $\mathbf{D}_{\mathbf{Y}}$ are positive, indicating that $\Sigma_{\mathbf{Y}'\mathbf{Y}'}$ is non-full-rank, and $p = 4$.

The matrix $\mathbf{D}_{pp}$ in Equation G-1, is a 4×4 matrix. It is shaded in gray in Table G-11, and separately illustrated in Table G-12. In the same fashion, the matrix of eigenvectors of $\Sigma_{\mathbf{Y}'\mathbf{Y}'}$, denoted as $\mathbf{L}_{\mathbf{Y}'}$, is shown in Table G-13, where the shaded area corresponds to matrix $\mathbf{L}_{np}$ in (G-1) and is separately shown in Table G-14. The matrix $\mathbf{L}_{np}$ in this example is a 7×4 matrix.

Given matrices $\mathbf{D}_{pp}$, $\mathbf{L}_{np}$, and $\mathbf{M}_{Y'}$, Equation G-1 is used to generate realizations based on the five analyses. In this process $\mathbf{U}$ is a 4×1 vector of uncorrelated standard normal random variables, with a mean of $\mathbf{0}$ and a covariance matrix of $\mathbf{I}$. The fact that only a vector of 4 random numbers are used to draw a vector of seven demand parameters for one realization shows how insufficient data can affect drawing realizations. By repeating this exercise 9999 times, 10000 realizations are generated per Equation G-1 to create the 7×10000 matrix $\mathbf{Z}$. Finally, the exponential of $\mathbf{Z}$ is obtained as $\mathbf{W}$. Table G-15 presents the first 10 simulations of $\mathbf{W}$.

Table G-16 and Table G-17 presents ratios of mean simulated response to mean response history analysis results, and ratios of the simulated to response history covariance matrix elements. The data in Table G-16 and Table G-17 indicate that the simulated vectors of demand have similar underlying statistics to those of the original demand vectors, but with less precision than when a larger number of analyses were performed, as was the case with a full-rank matrix, where m = 11.

G.2.3 Matlab Code

The Matlab macro below can be used to generate correlated simulated vectors of demand parameters. The vectors of demand parameters established by response history analysis, EDP.txt file, should have the same construction as Table G-1; that is, one demand parameter per column, one analysis per row. The file beta.txt includes a $2\times n$ matrix where the values in the two rows are for β_m and β_{gm}, respectively, and those in each column are for each demand parameter.

For intensity-based and time-based assessments, the user should input dispersions for analysis and modeling for each demand parameter, and set the dispersion for ground motion equal to zero. For scenario-based assessments using the procedures of Chapter 5, the user should input for dispersions for analysis, modeling, and ground motion for each demand parameter.

Example Matlab Code:

```
% Develop underlying statistics of the response history analysis
clear;
num_realization = 10000;

% loading information: EDP, epistemic variability,
EDPs =load('EDP.txt');
B=load('beta.txt');%matrix for dispersions βm and βgm ,

% taking natural logarithm of the EDPs.  Calling it lnEDPs
lnEDPs=log(EDPs); % Table G-2, or Table G-9
[num_rec num_var]=size(lnEDPs);

% finding the mean matrix of lnEDPs.  Calling it lnEDPs_mean
 lnEDPs_mean=mean(lnEDPs); % last row in Table G-2, or Table G-9
 lnEDPs_mean=lnEDPs_mean';

% finding the covariance matrix of lnEDPs.  Calling it lnEDPs_cov
 lnEDPs_cov=cov(lnEDPs); % Table G-3, or Table G-10

% finding the rank of covariance matrix of lnEDPs.  Calling it
% lnEDPs_cov_rank
 lnEDPs_cov_rank=rank(lnEDPs_cov);

 % inflating the variances with epistemic variability
sigma = sqrt(diag(lnEDPs_cov)); % sqrt first to avoid under/overflow
sigmap2 = sigma.*sigma;

 R = lnEDPs_cov ./ (sigma*sigma');
B=B';
sigmap2=sigmap2+(B(:,1).* B(:,1)); % Inflating variance for βm
sigmap2=sigmap2+(B(:,2).* B(:,2)); % Inflating variance for βgm
sigma=sqrt(sigmap2);
sigma2=sigma*sigma';
 lnEDPs_cov_inflated=R.*sigma2;

 % finding the eigenvalues eigenvectors of the covariance matrix.
Calling
 % them D2_total and L_total
 [L_total D2_total]=eig(lnEDPs_cov_inflated);  % Table G-5, Table G-
13
  D2_total=eig(lnEDPs_cov_inflated);
```

```
% Partition L_total to L_use.  L_use is the part of eigenvector matrix
% L_total that corresponds to positive eigenvalues
 if lnEDPs_cov_rank >= num_var
    L_use =L_total; % Table G-5
else
    L_use =(L_total(:,num_var- lnEDPs_cov_rank+1:num_var));
%Table G-13
end
% Partition the D2_total to D2_use.  D2_use is the part of eigenvalue
%vector D2_total that corresponds to positive eigenvalues
if lnEDPs_cov_rank >= num_var
   D2_use =D2_total;
else
   D2_use =D2_total(num_var- lnEDPs_cov_rank+1:num_var);
end

% Find the square root of D2_use and call is D_use.
 D_use =diag((D2_use).^0.5); %Table G-4, or Table G-12

% Generate Standard random numbers
if lnEDPs_cov_rank >= num_var
    U = randn(num_realization,num_var) ;
else
    U = randn(num_realization, lnEDPs_cov_rank) ;
end
U = U' ;

% Create Lambda = D_use .  L_use
Lambda = L_use * D_use ;

% Create realizations matrix
Z = Lambda * U + lnEDPs_mean * ones(1,num_realization) ;

lnEDPs_sim_mean=mean(Z');
lnEDPs_sim_cov=cov(Z');

A=lnEDPs_sim_mean./lnEDPs_mean'; %Table G-7, or Table G-16
B=lnEDPs_sim_cov./lnEDPs_cov; %Table G-8, or Table G-17

W=exp(Z);

%end
```

G.3 Simplified Analysis

When the simplified analysis procedure is used, only a single analysis is performed for each intensity level or scenario. The results of this analysis are transformed into estimated median demands, which are then associated

with a judgmentally determined dispersion for use in simulated demand generation.

For performance assessment using the simplified analysis procedure, PACT internally generates a set of N statistically consistent demand vectors, given the single column vector of demand parameters, $\{\theta\}$ and a value of the dispersion, β, using the following two-step procedure:

1. N values of z are randomly generated, where z is normally distributed with a mean value of 0 and a standard deviation of 1.0.
2. $\{\theta\}\exp(z\beta)$ is computed for each value of z.

Each vector computed using Step 2 is used to generate one value of loss.

Appendix H
Fragility Development

H.1 Introduction

This appendix provides quantitative procedures for developing the median, θ, and dispersion, β, for fragility functions based on various levels of available data. The procedures can be used for structural and nonstructural components, elements, and systems.

H.1.1 Fragility Function Definition

Fragility functions are statistical distributions used to indicate the probability that a component, element, or system will be damaged as a function of a single predictive demand parameter, such as story drift or floor acceleration. Fragility functions take the form of lognormal cumulative distribution functions, having a median value, θ, and logarithmic standard deviation, or dispersion, β. The mathematical form for such a fragility function is:

$$F_i(D) = \Phi\left(\frac{\ln\left(D/\theta_i\right)}{\beta_i}\right) \qquad \text{(H-1)}$$

where $F_i(D)$ is the conditional probability that the component will be damaged to damage state "i" (or more severe damage state) as a function of a demand parameter, D; Φ denotes the standard normal (Gaussian) cumulative distribution function; θ_i denotes the median value of the probability distribution; and β_i denotes the logarithmic standard deviation. Both θ and β are established for each component type and damage state using one of the methods presented in Section H.2.

For sequential damage states, the conditional probability that a component will be damaged to damage state "i," given that it experiences demand, D, is:

$$P\left[i\middle|D\right] = F_{i+1}\left(D\right) - F_i\left(D\right) \qquad \text{(H-2)}$$

where $F_{i+1}(D)$ is the conditional probability that the component will be damaged to damage state "i+1" or a more severe state, and $F_i(D)$ is as previously defined. Note that, when β_{i+1} is greater than β_i, the fragilities functions are crossing, and Equation H-2 can produce a negative probability at some levels of D, which is meaningless. This condition is addressed in Section H.3.4.

Figure H-1 shows the form of a typical lognormal fragility function when plotted in the form of a cumulative distribution function, and illustrates the calculation of the probability that a component will be in damage state "*i*" at a particular level of demand, *d*.

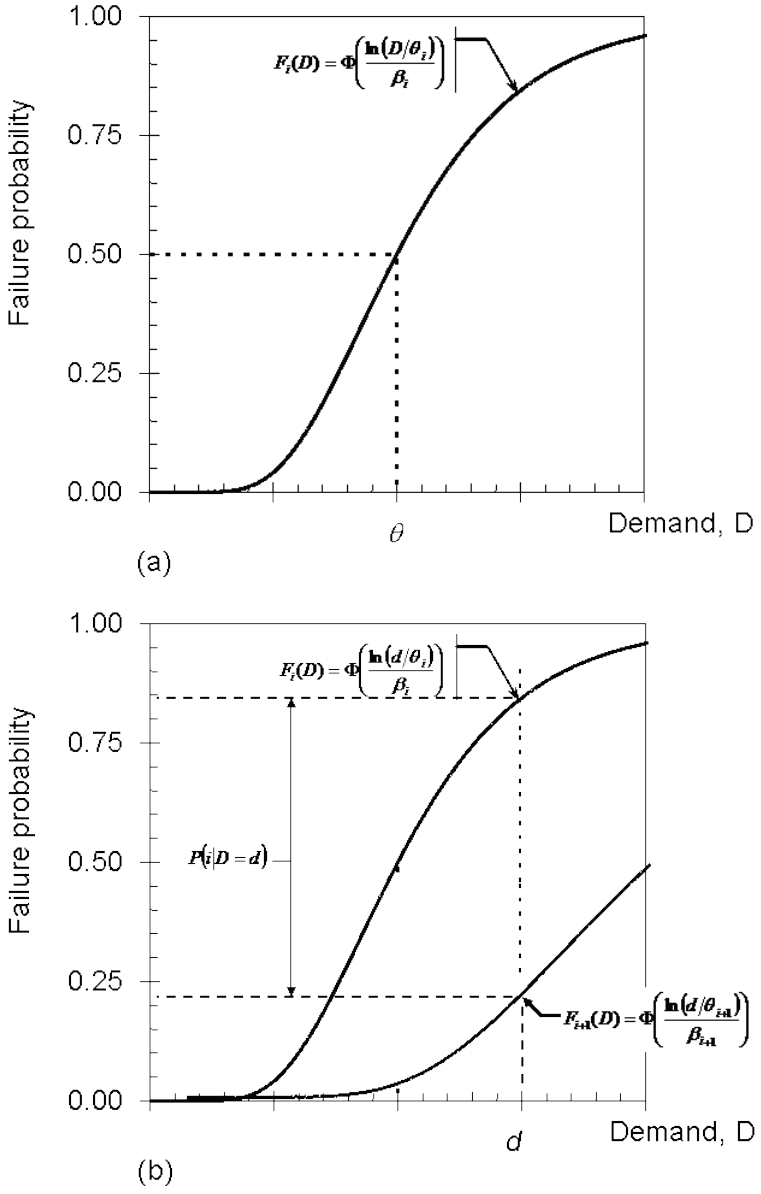

Figure H-1 Illustration of: (a) typical lognormal fragility function; and (b) evaluation of individual damage-state probabilities.

The dispersion, β, represents uncertainty in the actual value of demand, D, at which a damage state is likely to initiate. This uncertainty is the result of variability in the quality of construction and installation of components in a building, as well as variability in the loading history that a component might experience before it fails. When fragility parameters are determined on the

basis of a limited set of test data, two contributors to uncertainty should be considered. The first of these, termed β_r, represents the random variability that is observed in the test data from which the fragility parameters are determined. The second, termed β_u, represents uncertainty that the tests represent actual conditions of installation and loading, or uncertainty that the available data are an adequate sample size to accurately represent the true random variability. The total dispersion, β, is computed as:

$$\beta = \sqrt{\beta_r^2 + \beta_u^2} \tag{H-3}$$

The following minimum values of uncertainty, β_u, are recommended:

- A minimum value of $\beta_u = 0.25$ should be used if any of the following apply:
    - Test data are available for five (5) or fewer specimens.
    - In an actual building, a component can be installed in a number of different configurations, but all specimens were tested with the same configuration.
    - All specimens were subjected to the same loading protocol.
    - Actual behavior of the component is expected to be dependent on two or more demand parameters (e.g., simultaneous drift in two orthogonal directions), but specimens were loaded using only one demand parameter.
- Otherwise, a value of $\beta_u = 0.10$ may be used.

H.1.2 Methods of Derivation

Fragility functions are best derived from a large quantity of test data that investigate the behavior of the component of interest at varying levels of demand. FEMA 461, *Interim Testing Protocols for Determining the Seismic Performance Characteristics of Structural and Nonstructural Components* (FEMA, 2007), provides recommended procedures for laboratory testing intended to develop fragility data.

Because testing is expensive and time consuming, there are limited data presently available for use as a basis to develop fragility functions for most building components. The procedures in this appendix provide guidance for deriving values of the median, θ, and dispersion, β, for fragility functions given the following varying levels of available data:

- **Actual Demand Data.** Data are available from m individual specimen tests, and each tested specimen experienced the damage state of interest at a known value of demand, D.

- **Bounding Demand Data.** Test data or earthquake experience data are available from m individual specimen tests, but the damage state of interest only occurred in some specimens. For the other specimens, testing was terminated before the damage state of interest occurred, or the earthquake did not result in damage to the specimens. The maximum demand, D_i, that each specimen was subjected to is known, but this maximum demand may not be the demand at which the damage state initiated.

- **Capable Demand Data.** Test data or earthquake experience data are available from m individual specimen tests, but the damage state of interest did not occur in any of the specimens. The maximum demand, D_i, that each specimen was subjected to is known.

- **Derivation.** No data are available, but it is possible to model the behavior and analytically estimate the level of demand at which the damage state of interest will occur.

- **Expert Opinion.** No data are available and analysis of the behavior is not feasible, but one or more knowledgeable individuals can offer an opinion as to the level of demand at which damage is likely to occur, based on experience or engineering judgment.

Additionally, Section H.2.6 provides guidance for updating existing fragility functions as more data become available (e.g., from additional testing).

H.1.3 Documentation

Each fragility function should be accompanied by documentation of data sources and procedures used so that others can evaluate the quality of the resulting fragility parameters. As a minimum, documentation should include:

- **Applicability.** Description of the type of component addressed, including any limitations on the type of installation to which the fragility applies.

- **Specimen types.** Description of the specimens used to establish the fragility, including the number of specimens examined, their locations, and the specific details of the specimen fabrication, construction, mounting, and installation.

- **Demand parameters and application of loads.** Description of the loading protocol or characteristics of earthquake motion applied to each specimen; identification of the demand parameters examined that might be most closely related to failure probability, and how demand is calculated or inferred from the loading protocol or excitation; indication of whether or not the reported demand quantities are the value at which damage occurred, or the maxima to which each specimen was subjected.
- **Damage states.** Description of each damage state, including the physical damage observed and any force-deformation quantities recorded, quantitative definition of damage states in terms of the repairs required, and possible casualty or unsafe placard consequences.
- **Observation summary, analysis method, and results.** Tabular or graphical listing of specimens, demand parameters, and damage states identifying the method(s) used to derive fragility parameters; summary of the resulting fragility function parameters, θ and β; and results of tests to establish fragility function quality, including sample calculations.

H.2 Derivation of Fragility Parameters

H.2.1 Actual Demand Data

When data are available from a suitable series of tests, and the damage state of interest was initiated at a known value of the demand, d_i, for each tested specimen, the median value of the demand at which the damage state is likely to initiate, θ, is given by the equation:

$$\theta = e^{\left(\frac{1}{M}\sum_{i=1}^{M}\ln d_i\right)} \tag{H-4}$$

where:

M = total number of specimens tested

d_i = demand in test "i" at which the damage state was first observed to occur.

The value of the random dispersion, β_r, is given by:

$$\beta_r = \sqrt{\left(\frac{1}{M-1}\sum_{i=1}^{M}\left(\ln\left(d_i/\theta\right)\right)^2\right)^2} \tag{H-5}$$

where M, d_i, and θ are as defined above.

If one or more of the values of d_i appear to be significantly above or below the bulk of the data, the procedure for outliers specified in Section H.3.2 should be applied. The resulting fragility parameters should be tested using

the goodness-of-fit test specified in Section H.3.3. If the test passes at the 5% significance level, the fragility parameters are deemed acceptable.

Example: Determine the parameters θ and β from a series of 10 tests, all of which produced the damage state of interest. The damage state initiated at story drift ratios of: 0.9, 0.9, 1.0, 1.1, 1.1, 1.2, 1.3, 1.4, 1.7, and 2 percent.

Test #	Demand di	ln(di)	ln(di/θi)	ln(di/θi)^2
1	0.9	-0.10536	-0.30384	0.092321
2	0.9	-0.10536	-0.30384	0.092321
3	1	0	-0.19848	0.039396
4	1.1	0.09531	-0.10317	0.010645
5	1.1	0.09531	-0.10317	0.010645
6	1.2	0.182322	-0.01616	0.000261
7	1.3	0.262364	0.063881	0.004081
8	1.4	0.336472	0.137989	0.019041
9	1.7	0.530628	0.332145	0.11032
10	2	0.693147	0.494664	0.244692
Σ		1.984833		0.623723

$$\theta = e^{\left(\frac{1}{M}\sum_{i=1}^{M}\ln d_i\right)} = e^{\left(\frac{1}{10}(1.9848)\right)} = 1.22$$

$$\beta_r = \sqrt{\frac{1}{M-1}\sum_{i=1}^{M}\left(\ln\left(d_i/\theta\right)\right)^2} = \sqrt{\frac{1}{(10-1)}(0.6237)} = 0.26$$

H.2.2 Bounding Demand Data

When data are available from a suitable series of tests, but the damage state of interest was initiated in only some of the specimens, bounding demand data can be used to derive fragility parameters. For each specimen "*i*," it is necessary to know the maximum value of the demand, d_i, to which the specimen was subjected, and whether or not the damage state of interest occurred in the specimen.

The data should be divided into a series of *N* bins. It is suggested, but not essential, that *N* be taken as the largest integer that is less than or equal to the square root of *M*, where *M* is the total number of specimens available (this will usually result in an appropriate number of approximately equally sized sets). To divide the specimens into bins, data should be sorted in order of ascending maximum demand value, d_i, for each test, then divided into *N* groups of approximately equal size. Each group "*j*" will have M_j specimens, where:

$$\sum_{i=1}^{N} M_j = M \qquad \text{(H-6)}$$

The average value of the maximum demand for each bin of specimens is:

$$\bar{d}_j = \frac{1}{M_j}\sum_{k=1}^{M_j} d_k \tag{H-7}$$

The natural logarithm of d_j (i.e., $\ln(d_j)$) is taken as the value of x_j. Determine the number of specimens within each bin in which the damage state of interest was achieved, m_j, and the inverse standard normal distribution, y_j, of the failed fraction of specimens in the bin as:

$$y_j = \Phi^{-1}\left(\frac{m_j + 1}{M_j + 1}\right) \tag{H-8}$$

This is also the number of standard deviations above the mean that the stated fraction lies, assuming a mean value, $\mu = 0$ and a standard deviation, $\sigma = 1$, and can be determined using the "normsinv" function in an Excel worksheet, or by referring to standard Gaussian tables for normal distributions.

A straight line is fit to the data points, x_j and y_j, using a least-squares approach. The straight line will have the form:

$$y = bx + c \tag{H-9}$$

where, b is the slope of the line and c is the y-intercept. The slope b is given by:

$$b = \frac{\sum_{i=1}^{M}\left(x_j - \bar{x}\right)\left(y_j - \bar{y}\right)}{\sum_{i=1}^{M}\left(x_j - \bar{x}\right)^2} \tag{H-10}$$

$$\bar{x} = \frac{1}{M}\sum_{j=1}^{M} x_j \tag{H-11}$$

$$\bar{y} = \frac{1}{M}\sum_{j=1}^{M} y_j \tag{H-12}$$

Determine the value of the random dispersion, β_r as:

$$\beta_r = \frac{1}{b} = \frac{\sum_{i=1}^{M}\left(x_j - \bar{x}\right)}{\sum_{i=1}^{M}\left(x_j - \bar{x}\right)\left(y_j - \bar{y}\right)} \tag{H-13}$$

and the value of the median, θ, as:

$$\theta = e^{-c\beta_r} = e^{\left(\bar{x} - \bar{y}\beta_r\right)} \tag{H-14}$$

Example: Consider the damage statistics shown in the figure below depicting the hypothetical performance of motor control centers (MCCs) observed after various earthquakes in 45 facilities. Each stack of boxes represents data from one facility. Each box represents one specimen and several damage states are recorded. Crosshatched boxes represent MCCs that experienced a noticeable earthquake effect, such as shifting on their supports, but remained operable. Black boxes represent MCCs that were found to be inoperable following an earthquake. Calculate the fragility function using *PGA* as the demand parameter, binning at halfway points between the *PGA* values shown in the figure.

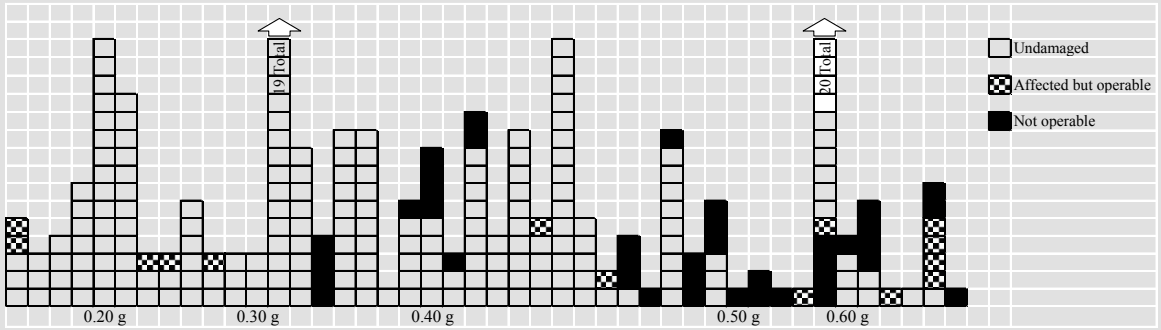

Figure H-2 Hypothetical observed earthquake damage data for motor control centers.

The number of bins, N, and lower bound demands, a_j, are dictated by the available data. N is taken as 5 with lower bounds of a_j = 0.15g, 0.25g, 0.35g, 0.45g, and 0.55g respectively. The damage state of interest is loss of post-earthquake functionality (black boxes in the figure). Values of M_j and m_j are determined by counting all boxes (M_j) and black boxes (m_j) in each bin, and are shown in the table below. The value of M is the summation: $\Sigma M_j = 260$. Values x_j and y_j are calculated as $x_j = \ln(\bar{d}_j)$, and $y_j = \Phi^{-1}((m_j+1)/(M_j+1))$. Average values are calculated as: $\bar{x} = -0.99$, $\bar{y} = -1.05$. For each bin, the values of $x_j - \bar{x}$ and $y_j - \bar{y}$ are shown in the table.

Table H-1 Example Solution Data

j	a_j(g)	$\bar{r}_j(g)$	M_j	m_j	x_j	y_j	$x_j - \bar{x}$	$y_j - \bar{y}$	$(x_j - \bar{x})^2$	$(x_j - \bar{x})(y_j - \bar{y})$
1	0.15	0.2	52	0	-1.61	-2.08	-0.623	-1.031	0.388	0.642
2	0.25	0.3	48	4	-1.20	-1.27	-0.217	-0.223	0.047	0.049
3	0.35	0.4	84	8	-0.92	-1.25	0.070	-0.202	0.005	-0.014
4	0.45	0.5	35	15	-0.69	-0.14	0.294	0.907	0.086	0.266
5	0.55	0.6	41	12	-0.51	-0.50	0.476	0.549	0.226	0.261
$\sum$=			**260**		**-4.93**	**-5.23**			**0.753**	**1.204**
		Average=			-0.99	-1.05				

Then, β and θ are calculated as:

$$\beta_r = \frac{\sum_{j=1}^{N}\left(x_j - \bar{x}\right)^2}{\left(x_j - \bar{x}\right)\left(y_j - \bar{y}\right)} = \frac{0.753}{1.204} = 0.63$$

$$\theta = e^{(\bar{x} - \bar{y}\beta_r)} = e^{(-0.99+1.05(0.63))} = e^{(-0.329)} = 0.72g$$

H.2.3 Capable Demand Data

When data are available from a suitable series of tests, but the damage state of interest was not initiated in any of the specimens, capable demand data can be used to estimate fragility functions. For each specimen "*i*," it is necessary to know the maximum value of the demand, d_i, to which the specimen was subjected, and whether or not the specimen experienced any damage or distress.

From the *M* specimen tests, the maximum demand experienced by each specimen, d_{max}, and the minimum demand experienced by any of the specimens that exhibited damage, d_{min}, must be determined. The value, d_a, is taken as the smaller of d_{min} or $0.7d_{max}$. If none of the specimens in any of the tests exhibited any sign of damage or distress, the value of d_m can be taken as d_{max}. If one or more of the specimens exhibited some type of damage or distress, d_m is taken as:

$$d_m = \frac{d_{\max} + d_a}{2} \tag{H-15}$$

Determine the subjective failure probability, *S*, at d_m as:

$$S = \frac{0.5M_C + 0.1M_B}{M_A + M_B + M_C} \tag{H-16}$$

where M_A is the number of specimens that did not exhibit damage or distress, but that were loaded with demands, $d_i \geq d_a$; M_B is the number of specimens that exhibited damage or distress, but did not appear to be initiating or on the verge of initiating the damage state of interest; and M_C is the number of specimens that appeared to be on the verge of initiating the damage state of interest. Determine the median, θ, as:

$$\theta = d_m e^{-0.4z} \tag{H-17}$$

where *z* is determined from Table H-1 based on the value of M_A and *S*. The logarithmic standard deviation is taken as $\beta = 0.4$.

Table H-2 Values of Parameter, *z*, Given M_A and *S*

Conditions	*z*
$M_A \geq 3$ and $S = 0$	-2.326
$M_A < 3$ and $S \leq 0.075$	-1.645
$0.075 < S \leq 0.15$	-1.282
$0.15 < S \leq 0.3$	-0.842
$S > 0.3$	-0.253

Example: Determine the parameters θ and β from 10 specimen tests. Five of the specimens had maximum imposed drift ratio demands of 1% with no observable signs of distress. Three of the specimens had maximum imposed drift ratio demands of 1.5% and exhibited minor distress, but did not appear to be at or near initiation of the damage state of interest. Two of the specimens had maximum imposed drift ratio demands of 2%, and did not exhibit the damage state of interest during the test, but appeared to be about to initiate such damage. From the data provided, $d_{max} = 2\%$; $d_{min} = 1.5\%$; d_a is the smaller of $0.7d_{max}$ or d_{min} , which is 0.7(2%) = 1.4%; $M_A = 0$; $M_B = 3$; and $M_C = 2$.

$$d_m = \frac{d_{\max} + d_a}{2} = \frac{2\% + 1.4\%}{2} = 1.7\%$$

$$S = \frac{0.5M_C + 0.1M_B}{M_A + M_B + M_C} = \frac{0.5(2) + 0.1(3)}{0 + 3 + 2} = 0.26$$

From Table H-1, z is -0.842. Therefore,

$$\theta = d_m e^{-0.4z} = 1.7\% e^{-0.4(-0.842)} = 2.4\%$$

and β is taken as 0.4.

H.2.4 Derivation

Where no test data are available, there are two methods available for analytical derivation of fragility parameters. The first uses a single calculation of the probable capacity and a default value of the logarithmic standard deviation. The second uses Monte Carlo analysis to explore the effect of variation in material strength, construction quality, and other random variables on the resulting capacity calculation.

- **Single calculation.** The capacity of the component, Q, is calculated in terms of a demand parameter, d, using average material properties, dimensions, and estimates of workmanship. Resistance factors are taken as unity, and any conservative bias that exists in code equations, if such equations are used, should be removed. The logarithmic standard deviation is taken as $\beta = 0.4$. The median capacity, θ, is taken as:

$$\theta = 0.92Q \qquad \text{(H-18)}$$

- **Monte Carlo simulation.** All factors that are important to predicting capacity and are also uncertain (e.g., material strength, cross section dimensions, member straightness, and workmanship) are identified. A median value and dispersion for each of these random variables is estimated. Sufficient analyses are conducted by randomly selecting the values of each of these variables in accordance with their estimated

distribution properties, and the capacity is calculated each time. The median value of the capacity is determined as the capacity that is exceeded in 50% of the calculations. The random logarithmic standard deviation, β_r, is taken as the standard deviation of the natural logarithm of the calculated capacity values. Equation H-3 is used to determine the total logarithmic standard deviation, β, assuming a value of $\beta_u = 0.25$.

H.2.5 Expert Opinion

Where no test data exist, and calculation of probable capacity is not feasible, expert opinion can be used to determine approximate fragility parameters. One or more experts with professional experience in the design or post-earthquake damage observation of the component of interest are selected. Advice is solicited using a format similar to the example shown.

Note the suggested inclusion of representative images, which should be recorded with the responses. If an expert refuses to provide estimates or limits them to certain conditions, either narrow the component definition accordingly and iterate, or ignore that expert's response and analyze the remaining ones.

Calculate the median value, θ, as:

$$\theta = \frac{\sum_{i=1}^{N} w_i^{1.5} \theta_i}{\sum_{i=1}^{N} w_i^{1.5}} \tag{H-19}$$

where, N is the number of experts providing an opinion; θ_i is expert "i's" opinion as to the median value, and w_i is expert "i's" level of expertise, on a 1-5 scale.

Calculate the lower bound value for the capacity as:

$$d_l = \frac{\sum_{i=1}^{N} w_i^{1.5} d_{li}}{\sum_{i=1}^{N} w_i^{1.5}} \tag{H-20}$$

where, d_{li} is expert "i's" opinion as to the lower bound value and other terms are as previously defined. The value of the logarithmic standard deviation, β, is taken as:

$$\beta = \frac{\ln\left(\theta / d_l\right)}{1.28} \tag{H-21}$$

If this calculation produces an estimate of β that is less than 0.4, either justify the β, or take β as having a value of 0.4 and recalculate θ as:

$$\theta = 1.67 d_l \quad \text{(H-22)}$$

Example: Solicitation of Expert Opinion

Objective. This form solicits judgment about the values of a demand parameter, *D,* at which a particular structural or nonstructural component experiences a particular damage state. Judgment is needed because relevant empirical and/or analytical data are currently unavailable or are impractical to acquire at this time.

Definitions. Please provide judgment regarding the damageability of the component of interest, including relevant damage states and a corresponding demand parameter that best correlates with the anticipated damage. Images of a representative sample of the component and damage state may be attached.
Component name:_____
Component definition:_____
Damage state name:_____
Damage state definition:_____
Relevant Demand Parameter:_____
Definition of Demand Parameter:_____

Uncertainty/Personal Bias. Uncertainty is to be expected. Because of variability in design, construction, installation, inspection, age, maintenance, and interaction with nearby components, there is likely no precise threshold level of demand that causes damage. Judgment should be based on the overall class of components in general, not any one particular instance, and not on cases in which the expert was personally involved in designing, constructing, checking, or reviewing.

Estimated Capacities. To account for expected uncertainties, please provide median and lower bound values of demand at which damage would be expected to occur:

Estimated median capacity:_____
Damage would occur at this level of demand in 5 cases out of 10; alternatively, in a single instance, there is an equal chance that the median estimate provided is too low or too high.

Estimated lower-bound capacity:_____
Damage would occur at this level of demand in 1 case out of 10; alternatively, in a single instance, there is a 10% chance that the estimate is too high. The lower bound should be judged carefully. Research shows that without careful thought, expert judgment of the lower bound tends to be too close to the median estimate. After an initial estimate is made, consider all conditions that might make the actual threshold for damage lower (e.g., errors in design, construction, installation, deterioration, interaction with nearby components), and revise accordingly.

Expertise. On a scale of 1 to 5, where 1 means "no experience or expertise," and 5 means "very familiar and highly experienced," rate your experience and expertise with this component and its damageability.
Level of expertise:_____
Name:_____ Date:_____

H.2.6 Updating Fragility Functions with New Data

Fragility parameters for a component can be updated as additional data become available. Pre-existing and updated fragility parameters are termed θ, β, θ', and β', respectively. The additional data are assumed to be a set of M specimens with known maximum demands and known damage. It is not necessary that any of the specimens experienced the damage state of interest.

The revised median, θ', and logarithmic standard deviation, β', are calculated as:

$$\theta' = e^{\sum_{j=1}^{5} w'_j \ln(d_j)} \tag{H-23}$$

$$\beta' = \sum_{j=1}^{5} w'_j \beta_j \tag{H-24}$$

where:

$$w'_j = \frac{w_j \prod_{i=1}^{M} L(i,j)}{\sum_{j=1}^{5} w_j \prod_{i=1}^{M} L(i,j)} \tag{H-25}$$

and $\prod$ denotes the product of the terms that follow. If specimen "*i*" did not experience the damage state of interest, then:

$$L(i,j) = 1 - \Phi\left(\frac{\ln\left(d_i / x_j\right)}{0.707 s \beta_j}\right) \tag{H-26}$$

If specimen "*i*" did experience the damage state of interest (or a more severe damage state), then:

$$L(i,j) = \Phi\left(\frac{\ln\left(d_i / x_j\right)}{0.707 s \beta_j}\right) \tag{H-27}$$

where:

$$x_1 = x_4 = x_5 = \theta$$
$$x_2 = \theta e^{-1.22\beta}$$
$$x_3 = \theta e^{1.22\beta}$$
$$\beta_1 = \beta_2 = \beta_3 = \beta$$
$$\beta_4 = 0.64\beta$$
$$\beta_5 = 1.36\beta$$
$$w_1 = 1/3$$
$$w_2 = w_3 = w_4 = w_5 = 1/6$$

H.3 Assessing Fragility Function Quality

The quality of fragility function parameters can be assessed using the procedures of this section.

H.3.1 Competing Demand Parameters

The behavior of some components may depend on several types of demands, for example in-plane and out-of-plane drift, or both drift and acceleration. It is not always clear which demand parameter is the best single predictor of component damage. If sufficient data are available, fragility functions for each relevant demand parameter should be developed. The fragility relationship with the lowest dispersion, β, should be selected.

H.3.2 Elimination of Outliers

When fragilities are determined on the basis of actual demand data, it is possible that one or more tests reported spurious values of demand, d_i, that reflect experimental errors rather than true demands at which the specimens failed. In cases where one or more values of d_i in the data set are obvious outliers from the bulk of the data, the data should be investigated for relevance to the component damage process, especially where $d_i << \theta$ for the outliers. If there is no indication that these data reflect a real recurring issue in the damage process, Peirce's criterion (Ross, 2003) should be applied to test and eliminate doubtful observations of d_i, as follows:

1. Calculate $\ln(\theta)$ and β of the complete data set.
2. Let D denote the number of doubtful observations, and let R denote the maximum distance of an observation from the body of the data, defined as:

$$R = \frac{\left|\ln(d) - \ln\theta\right|}{\beta} \tag{H-28}$$

   where θ, β, and M are as previously defined, d is a measured demand. Values of R are as shown in Table H-3. Begin with the assumption that $D = 1$, even if there appears to be more than one doubtful observation.
3. Calculate the maximum allowable deviation: $\left|\ln(d) - \ln(\theta)\right|_{\max}$. Note that this can include values for $d >> \theta$ and $d << \theta$.
4. For any suspicious measurement d_i, obtain $\left|\ln(d_i) - \ln(\theta)\right|$.
5. Eliminate the suspicious measurements if: $\left|\ln(d_i) - \ln(\theta)\right| > \left|\ln(d) - \ln(\theta)\right|_{\max}$
6. If this results in the rejection of one measurement, assume $D = 2$, keeping the original values of θ and β, and go on to Step 8.
7. If more than one measurement is rejected in the above test, assume the next highest value of doubtful observations. For example, if two

measurements are rejected in Step 5, assume $D = 3$, keeping the original values of θ and β as the process is continued.

8. Repeat Steps 2 through 5, sequentially increasing D until no additional data measurements are eliminated.

9. Obtain θ and β for the reduced data set as was done for the original data set.

Table H-3 Values of *R* for Applying Peirce's Criterion

M	*D*=1	*D*=2	*D*=3	*D*=4	*D*=5	*D*=6	*D*=7	*D*=8	*D*=9
3	1.1960

H.3.3 Goodness-of-Fit Testing

Fragility parameters that are developed on the basis of actual demand data should be tested for goodness-of-fit (Lilliefors, 1967) in accordance with this section. Calculate:

$$D = \max_x \left| F_i(d) - S_M(d) \right| \qquad \text{(H-29)}$$

where $S_M(d)$ denotes the sample cumulative distribution function

$$S_M(d) = \frac{1}{M}\sum_{i=1}^{M} H(d_i - d) \tag{H-30}$$

and H is taken as:

- 1.0 if $d_i - d$ is positive
- ½ if $d_i - d$ is zero
- 0 if $d_i - d$ is negative

If $D > D_{\text{critical}}$ from Table H-3, the fragility function fails the goodness-of-fit test. Use values at a significance level of $\alpha = 0.05$ in assigning a quality rating for a fragility function.

Table H-4 Critical Values for the Lilliefors Goodness-of-Fit Test

Significance Level	$D_{critical}$
$\alpha = 0.15$	$0.775 / (M^{0.5} - 0.01 + 0.85M^{-0.5})$
$\alpha = 0.10$	$0.819 / (M^{0.5} - 0.01 + 0.85M^{-0.5})$
$\alpha = 0.05$	$0.895 / (M^{0.5} - 0.01 + 0.85M^{-0.5})$
$\alpha = 0.025$	$0.995 / (M^{0.5} - 0.01 + 0.85M^{-0.5})$

H.3.4 Adjusting Fragility Functions that Cross

Some components will have two or more possible damage states, with a defined fragility function for each. For any two (cumulative lognormal) fragility functions i and j with medians $\theta_j > \theta_i$ and logarithmic standard deviations $\beta_i \neq \beta_j$, the fragility functions will cross at extreme values. When fragility functions cross, it is possible to get negative values of probability for being in damage state "i," which is meaningless. In such cases, the fragility functions can be adjusted using either of the following two methods:

- **Method 1.** Adjust the fragility functions such that:

$$F_i(D) = \max_j \left\{ \Phi\left(\frac{\ln(D/\theta_i)}{\beta_i} \right) \right\} \quad \text{for all } j \geq i \tag{H-31}$$

  This method assures that the probability of failure for the damage state with the higher median value, $F_i(D_j)$, is never taken as less than the probability of failure for a damage state with a lower median value $F_i(D_i)$.

- **Method 2.** Establish values of θ and β for the various damage states independently. Calculate the average of the dispersion values for each of the damage states with crossing fragility curves as:

$$\beta_i' = \frac{1}{N}\sum_{i=1}^{N}\beta_i \qquad \text{(H-32)}$$

The average logarithmic standard deviation, β', is used as a replacement for the independently calculated values of dispersion. Using the average dispersion, an adjusted median value must be calculated for each of the crossing fragilities as:

$$\theta_i' = e^{\left(1.28\left(\beta' - \beta_i\right) + \ln\theta_i\right)} \qquad \text{(H-33)}$$

H.3.5 Fragility Function Quality Levels

Fragility functions should be assigned a quality level of high, medium, or low, in accordance with the criteria in Table H-4.

Table H-5 Criteria for Fragility Function Quality Levels

Quality	Method	Peer Reviewed[1]	Number of specimens	Notes
High	Actual	Yes	≥ 5	Passes Lilliefors test at 5% significance level. Examine and justify: (a) differences greater than 20% in θ or β, compared with past estimates; and (b) any case of $\beta < 0.2$ or $\beta > 0.6$.
	Bounding	Yes	≥ 20	Examine and justify: (a) differences greater than 20% in θ or β, compared with past estimates; and (b) any case of $\beta < 0.2$ or $\beta > 0.6$.
	Update	Yes	≥ 6	Prior was at least moderate quality
Moderate	Actual		≥ 3	Examine and justify any case of $\beta < 0.2$ or $\beta > 0.6$.
	Bounding		≥ 16	Examine and justify any case of $\beta < 0.2$ or $\beta > 0.6$.
	Capable	Yes	≥ 6	
	Dreviation	Yes		
	Expert	Yes		At least 3 experts with experience rating ≥ 3
	Update		≥ 6	Prior was at least moderate quality
Low				All other cases

Notes: (1) Data and derivation published in a peer-reviewed journal.

Appendix I
Rugged Components

I.1 Rugged Components

Rugged components are components that are not susceptible to earthquake shaking-induced damage, or have very high thresholds for damage. High thresholds for damage include shaking intensities that are not likely to be encountered in typical building structures. Since rugged components are not directly damaged by earthquake shaking, they are not expected to contribute to earthquake impacts, and are not explicitly included in the building performance model. Estimates of building replacement cost and replacement time, however, must consider the presence of rugged components in the building.

Table I-1 provides a list of structural and nonstructural components that have been identified as rugged. This list was developed based on post-earthquake observations and laboratory testing. The table is organized by the general system description and classification numbering system used for fragility specifications, NISTIR 6389, *UNIFORMAT II Elemental Classification for Building Specifications, Cost Estimating and Cost Analysis* (NIST, 1999).

Because items identified in Table I-1 are considered rugged, fragility and consequence data have not been developed for these components. If such a component is determined to be vulnerable to damage (i.e., not rugged) in a particular building or assessment, user-defined fragilities and consequences must be developed to assess their impact on performance. Similarly, if a fragility specification associated with a vulnerable component is omitted from a building performance model, it has the same effect as considering that component to be rugged for the purposes of that assessment.

Table I-1 List of Rugged Components

General System Description	NISTIR Classification Number	Component Description
Foundations	A10	Spread footings, mat foundations, grade beams
Basement Construction	A20	Basement walls and slabs
Floor Construction	B101	Gravity-frame components of floor systems that do not participate in lateral resistance. This includes most floor framing and sheathing other than concrete slab-column frames
Roof Construction	B102	Gravity-frame components of roof systems that do not participate in lateral resistance. This includes most roof framing other than concrete slab-column frames. This also includes most diaphragm sheathing.
Structural Steel	B103	Simple beam framing
Reinforced Concrete	B104	Floor and roof framing other than slab-column frames and beam-column frames
Cold-Formed Steel	B106	Horizontal floor and roof framing.
Light-framed Wood	B107	Horizontal floor and roof framing.
Roof Coverings	B301	Composite and built-up roofing systems (including flashing and insulation) except tile roofing on sloped surfaces.
Roof Openings	B302	Roof hatches and skylights
Floor Finishes	C302	Floor finishes, including carpeting, except when water leaks occur
Plumbing Fixtures	D201	Toilets, sinks, tubs, urinals
Rain Water Drainage	D204	Rain water leaders and gutters
Electrical Distribution Systems	D304	Conduits and raceways
Standpipes	D402	Wet and dry standpipes
Other Fire Protection Systems	D409	Smoke detectors, heat detectors, and alarm control systems
Lighting and Branch Wiring	D502	Lighting panels and wiring
Communications and Security	D503	Communications and security equipment
Commercial Equipment	E101	Commercial equipment (note: occupancy-specific equipment deemed fragile or important require user-defined fragility and consequence data for performance assessment)

Appendix J
Collapse Fragility Development Using Incremental Dynamic Analysis

J.1 Introduction

This appendix describes the use of incremental dynamic analysis (IDA) for development of collapse fragilities. Additional information on assessing structural collapse using incremental dynamic analysis techniques is provided in FEMA P-695, *Quantification of Building Seismic Performance Factors* (FEMA, 2009b).

J.2 Procedure

Incremental dynamic analysis (IDA) involves a large number of nonlinear response history analyses that are performed using ground motions that are systematically scaled to increasing earthquake intensities until collapse occurs. Incremental dynamic analysis yields a distribution of results at varying intensities that can be used to generate a collapse fragility.

In general, each ground motion pair is scaled to an initial intensity level, characterized by a common value of the geomean spectral response acceleration at the first mode period, $S_a(\overline{T})$. The structure is subjected to nonlinear response history analysis, using each of these ground motion pairs, and the number of analyses that produce collapse predictions is determined. Then, ground motion amplitudes are systematically incremented, and the process repeated, until 50% or more of the analyses at the intensity level result in collapse. The intensity at which 50% of the analyses predict collapse is taken as the median collapse intensity. A dispersion is fit to the collapse data and modified to account for other uncertainties. The basic steps in the procedure are as follows:

1. Construct a mathematical model representing the structure.
2. Select an appropriate suite of ground motion pairs that represent scenario events likely to result in collapse of the structure, considering the site seismic hazard.

3. Scale the ground motion suite such that the geomean spectral acceleration at the first mode period of the structure, $S_a(\overline{T})$, for each pair is at a value low enough for inelastic response to be negligible.
4. Analyze the mathematical model for each scaled ground motion pair and determine the maximum value of story drift.
5. Increment the intensity of the effective first mode spectral response acceleration, $S_a(\overline{T})$, to which each ground motion pair is scaled.
6. Analyze the structure for each incrementally scaled ground motion pair and record the maximum value of story drift.
7. Repeat Steps 5 and 6 above for each ground motion pair until the analysis:
    a. produces a very large increase in drift for a small increment in the value of intensity, indicating the onset of dynamic instability;
    b. results in numerical instability suggesting collapse;
    c. results in predicted demands on gravity-load carrying components that exceed their reliable capacities; or
    d. predicts drift levels that exceed the range of model validity.
8. Determine the value of spectral acceleration, $S_a(\overline{T})$ at which 50% of the ground motion pairs produce predictions of collapse. This value of $S_a(\overline{T})$ is taken as the median collapse capacity, $\hat{S}_a(\overline{T})$.
9. Determine a dispersion for the collapse fragility.

J.3 Mathematical Models

Three dimensional mathematical models should be used unless structural response is independent in each of two orthogonal directions. Additional guidance on modeling provided in Chapters 5 and 6 is also applicable.

J.4 Ground Motion Selection and Scaling

Ground motion selection and scaling can utilize uniform hazard spectra (UHS) or conditional mean spectra (CMS), described in Appendix B. In both cases, a sufficient number of ground motions should be used to provide stable estimates of median collapse capacity. In limited study, use of 11 pairs of motions, each rotated 90 degrees to produce a total of 22 motion sets, were found to be sufficient. For some structures, stable prediction of median collapse capacity may be possible with fewer motions.

Ground motions generated for response-history analysis as described in Chapter 4, which are at an intensity level that is approximately equal to the median collapse capacity, $\hat{S}_a(\overline{T})$, can also be used.

J.4.1 Uniform Hazard Spectrum

Ground motion pairs for incremental dynamic analysis based on a uniform hazard spectrum should be selected as follows:

1. Estimate the median collapse capacity, $\hat{S}_a(\overline{T})$, and the mean annual frequency of exceedance corresponding to $\hat{S}_a(\overline{T})$. For buildings that conform to the seismic design and detailing criteria contained in ASCE/SEI 7-10, $\hat{S}_a(\overline{T})$ can be estimated as approximately 3 times the value of the design level spectral ordinate at period, $\overline{T}$.
2. Develop a target uniform hazard spectrum consistent with the mean annual frequency of exceedance for $\hat{S}_a(\overline{T})$ estimated in Step 1.
3. Select an appropriate suite of ground motion pairs with geometric mean spectra that have a shape similar to the target uniform hazard spectrum.

If the estimate of median collapse capacity, $\hat{S}_a(\overline{T})$, in Step 1 is significantly different (i.e., larger or smaller) than the value computed from incremental dynamic analysis, a new uniform hazard spectrum should be determined for the mean annual frequency of exceedance corresponding to $\hat{S}_a(\overline{T})$ determined by analysis. If the shape of the new spectrum is significantly different from the target spectrum initially developed in Step 2, a new suite of motions should be selected to match the new spectrum, and the analyses repeated.

J.4.2 Conditional Mean Spectrum

Ground motion pairs for incremental dynamic analysis based on a conditional mean spectrum should be selected as follows:

1. Estimate the median collapse capacity, $\hat{S}_a(\overline{T})$, and the mean annual frequency of exceedance corresponding to $\hat{S}_a(\overline{T})$. For buildings that conform to the seismic design and detailing criteria contained in ASCE/SEI 7-10, $\hat{S}_a(\overline{T})$ can be estimated as approximately 3 times the value of the design level spectral ordinate at period, $\overline{T}$.
2. Deaggregate the seismic hazard at the mean annual frequency of exceedance (see Appendix B) to determine the magnitude and distance of characteristic events that dominate the hazard at this level of shaking.
3. Generate a conditional mean spectrum at period $\overline{T}$ for the $[M, r, \varepsilon]$ triple corresponding to the events selected in Step 2, using an appropriate

attenuation function (see Appendix B). Normalize the conditional mean spectrum so that the peak ordinate is equal to 1.0.

4. Select an appropriate suite of ground motions with geometric mean spectra that have a shape and period at peak spectral response that are similar to the target conditional mean spectrum.

If the estimate of median collapse capacity, $\hat{S}_a(\overline{T})$, in Step 1 is significantly different (i.e., larger or smaller) than the value computed from incremental dynamic analysis, a new conditional mean spectrum should be generated for the mean annual frequency of exceedance corresponding to $\hat{S}_a(\overline{T})$ determined by analysis. If the shape of the new spectrum is significantly different from the target spectrum initially developed in Step 3, a new suite of motions should be selected to match the new spectrum, and the analyses repeated.

J.5 Collapse Fragility Development

The amplitude of each ground motion pair should be incremented, and nonlinear response history analysis performed, until a measure of collapse is achieved. The median collapse capacity is taken as the value of $S_a(\overline{T})$ at which 50% of the ground motion pairs produce collapse, as measured by: numerical instability, simulated collapse, non-simulated collapse criteria, or excessive lateral drift for a small increase in $S_a(\overline{T})$.

Figure J-1 presents a collapse fragility plot constructed using the median and dispersion values obtained from incremental dynamic analysis results and the assumption of a lognormal distribution.

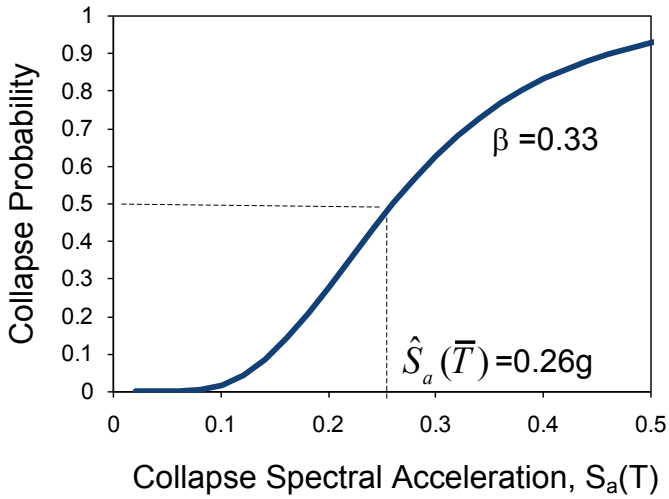

Figure J-1 Lognormal collapse fragility curve plotted using median and dispersion values from incremental dynamic analysis.

Note that the dispersion in Figure J-1, which is based on analysis of a mathematical model constructed using best estimate mechanical properties, does not include all sources of uncertainty. The following additional sources of uncertainty must also be considered in calculating the total dispersion to define the final collapse fragility curve:

- Variation in calculated story drift resulting from different ground motion records, $\beta_{a\Delta}$, (also termed analysis record-to-record uncertainty). Default values of $\beta_{a\Delta}$ are provided in Chapter 5, Table 5-6. Alternatively, a value of 0.45 can be used.
- Uncertainty due to ambiguity in building definition and construction quality, β_c. Values of β_c based on the level of building definition and construction quality assurance are provided in Chapter 5.
- Uncertainty associated with the quality and completeness of the nonlinear analysis model, β_q. Values of β_q based on the quality of the analytical model are provided in Chapter 5. Given that few component force-deformation models have been validated by large-scale experimental testing, β_q should typically have a value between 0.3 and 0.5.

Total dispersion can be estimated using Equation J-1 and the information above. Alternatively, a default total dispersion of 0.6 can be used to define the lognormal collapse fragility curve.

$$\beta = \sqrt{\beta_{a\Delta}^2 + (\beta_c^2 + \beta_q^2)} = \sqrt{\beta_{a\Delta}^2 + \beta_m^2} \qquad \text{(J-1)}$$

Appendix K

Sliding and Overturning

K.1 Introduction

This appendix provides the derivation and assumptions underlying procedures for calculation of fragility functions related to overturning and sliding of unanchored components. These procedures are based on Section 7.1, Section A.2, and Appendix B of ASCE/SEI 43-05, *Seismic Design Criteria for Structures, Systems, and Components in Nuclear Facilities* (ASCE, 2005).

The procedures cover only the development of fragility parameters for sliding and overturning damage states. In each case, users must determine the extent of damage that will result from the controlling behavior, and the consequences of that damage.

K.2 Overturning

Fragility functions for overturning are based on peak total floor velocity, V_{PT}, as the demand parameter. Fragility parameters include the median peak total floor velocity, $\hat{V}_{PT}$, at which overturning initiates, and a dispersion reflecting the uncertainty in this behavior mode.

Unanchored components are assumed to exhibit an oscillatory rocking behavior until a critical displacement is reached and the object becomes unstable. The critical displacement is represented in the form of a tipping angle, α, at which the center of mass of the component is located directly over the leading edge (or toe), as shown in Figure K-1.

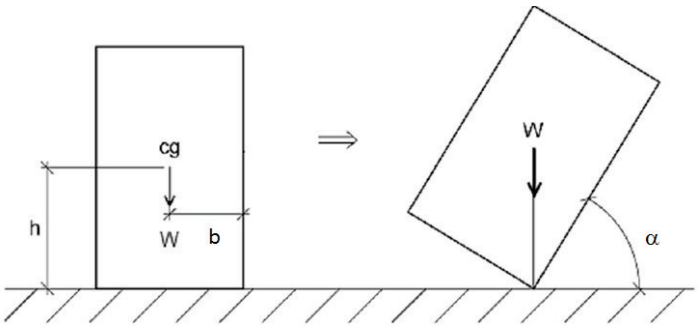

Figure K-1 Overturning of unanchored components.

Housner (1963) developed an expression for overturning failure of unanchored objects as a function of peak ground velocity:

$$PGV = 2gR\sqrt{(1-\cos\alpha)} \tag{K-1}$$

where PGV is the peak ground velocity at which overturning initiates, $R = \sqrt{b^2 + h^2}$, and the quantities α, b and h are as defined in Figure K-1.

The procedure, as adapted from ASCE 43-05, uses estimates of the component effective rocking frequency, f_r, and damping ratio, β_r, to express the probability of overturning occurrence as a function peak total floor velocity, V_{PT}, defined as the peak value of the sum of the ground velocity and the relative velocity between the ground and the floor level. It reflects a more detailed understanding of the dynamics associated with overturning instability, and provides general corroboration with Housner's equation for aspect ratios of typical concern. Key assumptions include the following:

- The relationship between peak ground velocity, PGV, and the component rocking frequencies and damping remain valid for use on elevated floor levels (i.e., above grade), with V_{PT} substituted for peak ground velocity.
- Overturning occurs about a single axis as a result of horizontal shaking in one direction. Simultaneous rocking about two axes is neglected, as are the effects of vertical acceleration.
- The component has a rectangular shape with height, 2h, and width, 2b.
- Component weight, W, is uniformly distributed.

From geometry, the critical tipping angle at which a component will become unstable is given by:

$$\alpha = \arctan\left(\frac{b}{h}\right) \tag{K-2}$$

The horizontal spectral acceleration that will tip the component to the critical angle, α, is determined by:

$$S_{aO} = \frac{2B}{\alpha} \tag{K-3}$$

where B is given by the equation:

$$B = \cos(\alpha) + \frac{b}{h}\sin(\alpha) - 1 \tag{K-4}$$

The value of S_{aO} is used in the calculation of median peak total floor velocity, $\hat{V}_{PT}$. It is also used to determine whether sliding or overturning will be the controlling behavior mode. If the spectral acceleration that will tip the

component to the critical angle, S_{aO}, is greater than the coefficient of static friction, μ_S, then the component will be expected to slide rather than overturn. Conversely, if S_{aO} is less than μ_S, the component will be expected to overturn rather than slide.

The effective rocking frequency, f_r, and damping ratio, β_r, are determined by:

$$f_r = \frac{1}{2\pi}\sqrt{\frac{2gB}{C_3\alpha^2 h}} \tag{K-5}$$

$$\beta_r = \frac{\gamma}{\sqrt{4\pi^2 + \gamma^2}} \tag{K-6}$$

where:

$$C_3 = \frac{4}{3}\left(1 + \left(\frac{b}{h}\right)^2\right) \tag{K-7}$$

$$\gamma = -2 * \ln\left(C_R\right) \tag{K-8}$$

$$C_R = 1 - \frac{2\left(\frac{b}{h}\right)^2}{C_3} \tag{K-9}$$

Spectral floor velocity, S_v, as a function of damping, β, is represented by the equation:

$$S_v\left(\beta\right) = V_{PT} D_{amp} \tag{K-10}$$

The spectral amplification factor is derived from Table 2 of Newmark and Hall (1982) assuming that the effective rocking frequency, f_r, falls within the constant velocity domain of the spectrum. This yields:

$$D_{amp} = 2.31 - 0.41 * \ln\left(100\beta_r\right) \tag{K-11}$$

Spectral velocity can be related to pseudo spectral acceleration using the relationship:

$$S_v\left(\beta\right) = \frac{S_a\left(f_r, \beta\right)}{2\pi f_r} \tag{K-12}$$

Substituting S_{aO} for $S_a\left(f_r, \beta\right)$ in Equation K-12, and setting Equation K-10 equal to Equation K-12, yields the median peak total floor velocity for overturning:

$$\hat{V}_{PT} = \frac{S_{aO} g}{2\pi f_r D_{amp}} \quad \text{(K-13)}$$

Due to considerable uncertainty associated with this behavior mode and the assumptions underlying this derivation, a dispersion of 0.5 is recommended for this fragility.

K.3 Sliding

Unanchored components resting on surfaces with a static coefficient of friction, μ_S, that is less than the horizontal spectral acceleration that will tip the component to the critical angle, S_{aO}, are likely to slide rather than overturn. This procedure provides an estimate of the median peak total floor velocity at which the sliding displacement of an unanchored object will equal or exceed a limiting displacement. For sliding behaviors, users must determine a sliding displacement, δ, at which the component is likely to become damaged either by falling off a bearing surface or impacting an adjacent object.

Sliding displacement is a function of the square of peak total floor velocity, V_{PT}, and the dynamic coefficient of friction, μ_D, at the base. The procedure for estimating median V_{PT} is based on the reserve energy approach described in Section 7.1, Section A.1, and Appendix B of ASCE 43-05. It relies on the observation that peak sliding displacements tend to be related to the frequency associated with 10%-damped spectral velocity ordinates that are equal to or greater than twice the dynamic coefficient of friction, μ_D. The procedure additionally assumes the following:

- Spectral characteristics of motion, as characterized by response spectra, at elevated floor levels (i.e., above grade) are similar to shaking at the ground level, and the assumed relationships between critical sliding frequencies, 10% damped spectral velocity ordinates, and V_{PT} remain valid.
- The component aspect ratio and coefficient of friction are such that sliding, rather than overturning, is likely to occur.
- The effects of vertical shaking are neglected.
- For any floor response spectrum, the frequency at which the 10%-damped spectral acceleration equals or exceeds $2\mu_D$ is within the constant velocity domain of the spectrum.
- Damping associated with sliding can be approximated as 10% of critical, and the corresponding spectral velocity amplification factor, D_{amp} for 10%-damped behavior has a value of 1.37.

The sliding frequency f_s in the constant velocity domain of the response spectrum is related to spectral acceleration by the equation:

$$S_a = 2\pi f_s S_v \tag{K-14}$$

Substituting $2\mu_D$ for the critical value of spectral acceleration at which sliding occurs, and using the relationship of Equation K-10:

$$2\mu_D = 2\pi f_s S_v = 2\pi f_s \left(1.37 V_{PT}\right) \tag{K-15}$$

and:

$$2\pi f_s = \frac{2\mu_D g}{V_{PT}} \tag{K-16}$$

From ASCE 43-05, sliding displacement can be approximated by:

$$\delta = \frac{2\mu g}{\left(2\pi f_s\right)^2} \tag{K-17}$$

Substituting the expression from Equation K-16 for $2\pi f_s$ yields:

$$\delta = 2\mu_D g \left(\frac{1.37 V_{PT}}{2\mu_D g}\right)^2 \tag{K-18}$$

Solving for V_{PT} yields the median peak total floor velocity for sliding:

$$\hat{V}_{PT} = \frac{\sqrt{2\mu_D g \delta}}{1.37} \tag{K-19}$$

As with overturning, due to considerable uncertainty associated with this behavior mode and the assumptions underlying this derivation, a dispersion of 0.5 is recommended for this fragility.

Progress Report on the Technical Development of the 2014 NEHRP Recommended Seismic Provisions

David R. Bonneville
Degenkolb Engineers

SUMMARY
The 2014 *NEHRP Recommended Seismic Provisions for New Buildings and Other Structures* (NEHRP Provisions) will represent the ninth edition of the national consensus publication that serves as the state-of-the-art resource document for US seismic codes and standards. The NEHRP Provisions are developed by the Building Seismic Safety Council (BSSC) through a five-year project sponsored by the Federal Emergency Management Agency (FEMA). The Provisions are developed for the BSSC by its Provisions Update Committee (PUC). In this update cycle, the PUC is supported by eleven Issue Teams, which develop technical concepts in the form of either seismic provisions with commentary or resource papers. The author serves as Chair of the PUC and presents this work as part of BSSC's commitment to ongoing outreach to the engineering community. This paper summarizes the framework for the 2014 NEHRP Provisions and the concepts currently under development by the Issue Teams.

1. INTRODUCTION

The National Earthquake Hazards Reduction Program (NEHRP) was created in 1979 to provide a framework to reduce the risk of earthquakes. The *NEHRP Recommended Provisions for New Buildings and Other Structures* (NEHRP Provisions) serve as a national resource for design professionals and the US standards and code-development community. In general, the NEHRP Provisions are viewed as a vehicle for the introduction of seismic concepts that will later be developed into code language by standards development organizations, most notably by the American Society of Civil Engineers Structural Engineering Institute (ASCE/SEI). The 2014 edition of the NEHRP Provisions is being developed by the Building Seismic Safety Council (BSSC) through a five-year contract sponsored by the Federal Emergency Management Agency (FEMA). The NEHRP Provisions are developed for the BSSC by its Provisions Update Committee (PUC) and most of the technical development work of the PUC is done through Issue Teams, which bring forth technical proposals covering a range of seismic topics.

During the development of the 2009 NEHRP Provisions (BSSC, 2009) a collaborative effort was established between the PUC and the seismic subcommittee of ASCE/SEI 7, which developed the seismic provisions for the national consensus design loads standard, ASCE/SEI 7-05, *Minimum Design Loads for Buildings and Other Structures* (ASCE, 2005). This resulted in the adoption of ASCE/SEI 7-05 by reference in the 2009 NEHRP Provisions. This collaboration continues in the current cycle and the 2014 NEHRP Provisions will adopt by reference the seismic requirements of ASCE/SEI 7-10 (ASCE, 2010).

As initiated in the 2009 edition, the NEHRP Provisions are presented in three parts. Part 1 will include consensus-approved modifications to ASCE/SEI 7-10. Part 2 will provide commentary, also consistent with ASCE/SEI 7-10 and Part 3 will provide resource papers covering material intended to stimulate discussion from the engineering community on new seismic design concepts. BSSC policies and procedures require that material developed for the Provisions, whether by Issue Teams or by the

PUC itself, go through balloting by the PUC, then following approval by the BSSC Board of Direction, though balloting by the 62 BSSC member organizations.

In the following sections the major efforts underway by the Issue Teams are described briefly. At the time of the writing of this paper all of the work of the Issue Teams is in the developmental stage, prior to PUC balloting, so this is intended to serve as information related to the general direction of the 2014 Provisions and to solicit comments.

2. INCORPORATION OF FEMA P695 AND P795

FEMA P695 – *Quantification of Building Seismic Performance Factors* (ATC, 2009) is a methodology to quantify the seismic performance factors for code-defined structural systems and to verify the adequacy of proposed new systems. FEMA P795 – *Component Equivalency Method* (ATC, 2011) is a component-based methodology for verifying equivalency of components, connections and sub-assemblies proposed for substitution into an established structural system. Since their publication, P695 and P795 have been generally accepted as the most appropriate approach to assigning seismic design coefficients to new systems and for qualifying new components. However, the NEHRP Provisions have not incorporated these methodologies or other analytical approaches for justifying seismic design coefficients for alternative systems or for establishment of equivalency of new components. Code language providing specific targets for collapse probabilities conditioned on the occurrence of MCE_R (risk targeted maximum considered earthquake) ground shaking is being considered, along with analysis and testing requirements. Similarly specific performance and analysis/testing language related to component substitution is being considered. This issue team is chaired by Ronald Hamburger.

3. EVALUATION AND QUANTIFICATION OF SEISMIC PERFORMANCE OBJECTIVES

This issue team is examining the seismic performance that is inherent in our current provisions and considering modifications to design procedures to improve our ability to achieve desired performance across all risk categories. Among the issues being considered are: how does seismic risk in general compare with other natural hazards; how do collapse risk and other performance levels vary among structural systems, risk categories and seismic design categories; and how does seismic risk vary with seismic hazard. Of interest for Risk Category IV (critical) buildings is the intensity at which building function is lost. Changes being considered include establishment of seismic design coefficients for collapse, functional design and economic design; and ground motion maps for very rare, rare and frequent events. This team is chaired by James Harris.

The work described above is being carried out in close coordination with a team chaired by John Hooper that is studying system exclusions, height limits and Seismic Design Categories. This team is evaluating the rationale behind the current SDC boundaries and the possibility of reducing the number of categories from the current four to either two or three. It is also reviewing the current system exclusions and system height limits given in the Seismic Design Coefficients (R-factor) table.

The efforts of these two teams are being supported by two ongoing Applied Technology Council (ATC) projects. First, input is provided from work on the National Institute of Standards and Technology (NIST) funded project, *ACT-84 – Tentative Framework for Development of Advanced Seismic Design Criteria for New Buildings – 100 % Draft* (ATC, 2012), Charles Kircher, Project Director. In addition, the Applied Technology Council (ATC) was recently awarded a FEMA contract to benchmark building code (structural and nonstructural) performance on various building types using established FEMA methodologies, including *FEMA P-695 – Quantification of Building Seismic Performance Factors* (ATC, 2009), Charles Kircher - Project Technical Director, for collapse prevention and *FEMA P-58 – Seismic Performance Assessment of Buildings – 100% Draft* (ATC, 2012), Ronald Hamburger - Project Technical Director, for all other performance levels. This project,

tentatively titled *ATC 63-2 - Development of Seismic Performance and Methodology Calibration*, Ronald Hamburger - Project Technical Director, is being carried out on a schedule that will allow it to provide valuable input into this issue team.

4. SEISMIC ANCHORAGE TO CONCRETE

This issue team is studying seismic anchorage to concrete and issues related to the application of *ACI 318-11 Building Code Requirements for Structural Concrete* (ACI, 2011) Appendix D. The issue team supports the technical basis for the Appendix D provisions, but is interested in a better understanding of its seismic application, potential opportunities for simplification and potential exceptions where it can be assured that strength and ductility demands are satisfied through yielding elsewhere within the seismic load path. Considerations include anchorage detailing to assure sufficient anchor stretch length and development of hinging elsewhere in the connection. The establishment of nominal anchor strength based on 5 percent fractile test strength is being considered in view of system over-strengths and redundancies that in some seismic applications cases may suggest consideration of less conservatism. This issue team is chaired by Kevin Moore.

5. RESPONSE HISTORY ANALYSIS

The issue team, chaired by Curt Haselton, is undertaking a complete review and revision of the Seismic Response History Analysis requirements given in Chapter 16 of ASCE/SEI 7-10. The PUC judged that the current requirements lack specificity in many areas, leading to inconsistencies in interpretation. The team contains the following task groups:

General Requirements: How performance goals will be either implicitly demonstrated through predictable stable response under MCER ground motion or explicitly through fulfillment of performance goals related to collapse probability and possibly other performance levels, as a function of Risk Category.

Ground Motion Selection and Scaling: Definition of the target spectrum (or spectra) using either the ASCE/SEI 7-10 Chapter 11 mapped or site specific ground motion values or through one or more site specific scenario spectra covering MCER ground motion at appropriate (significant) periods of vibration of the building. Consideration is given to specifying earthquake events that capture frequency content at appropriate magnitude and distance, including where appropriate, requirements to address multiple earthquakes having distinct characteristics. Use of a maximum direction spectrum is considered along with the period range for scaling. Consideration is given to use of simulated records (similar to current provisions) where appropriate records are not available. Provisions for use of spectral matching are being considered, along with guidance and limitations. Orientation (fault-normal and fault-parallel) of ground motions for sites within 5 km of controlling faults is addressed, as is the lack of specificity of orientation at other sites. Consideration is given for input ground motion at subterranean levels and for soil-foundation-structure interaction.

Modeling, Analysis and Acceptance Criteria: System modeling considerations include the use of two-dimensional and three-dimensional modeling (including where to allow 2-D models), when to require application of vertical ground motions, how to address non-participating elements and gravity loads, as well as diaphragm modeling, requirements for force controlled elements and guidance on soil-structure interaction. Analysis and acceptance criteria considerations include use of average vs. maximum criteria, treatment of outlier ground motions resulting analytically in collapse, treatment of gravity element collapse and consideration of residual drift.

6. SELF CENTERING ROCKING SYSTEMS

Current code provisions do not address the response of lateral force resisting systems to rocking behavior, although this type of behavior does occur in certain buildings that are subject to seismic forces in excess of design lateral forces. Such behavior, if controlled in such a way as to protect structural and nonstructural elements form damaging displacements, may result in favorable non-linear performance. Furthermore it is possible to incorporate self-centering/rocking behavior into a structural system through configuration and detailing of the lateral force resisting system resulting in controlled yielding of specially designed elements. If such systems are to become more commonly utilized in seismic design it is necessary to develop appropriate analysis and design requirements, as these are not currently addressed in building codes.

The goal of this team is to propose seismic design requirements for rocking behavior in buildings, including implementation of innovative systems that achieve self-centering response through rocking. Design limit states may include onset of rocking (initiation of structural damage), safety (onset of significant deterioration) at MCE, and preservation of self-centering. Design requirements may include elastic analysis and design and nonlinear analysis and design. Systems including self-centering braced frames and concrete shear walls are considered candidates for this type of controlled behavior. This issue team is chaired by Greg Deierlein.

7. DIAPHRAGM ISSUES

The issue team is evaluating the behavior and performance of cast-in-place concrete, precast concrete (with or without topping), metal and wood diaphragms. Considerations include material-specific issues, redistribution of vertical and horizontal forces (through diaphragms) within the structural system and behavior of buildings in which the diaphragm controls or significantly contributes to modal response. It is felt that common analysis and design practices may not always recognize these issues and that code provisions, particularly the equivalent lateral force procedure, do not offer sufficient direction.

Our code provisions have traditionally defined system ductility in terms of the vertical lateral force resisting system, with more than 80 systems defined in the table of seismic design coefficients. Many large footprint low-rise buildings have significant mass participation in the diaphragm, but design forces are prescribed only on the basis of the vertical lateral force resisting system. This may result in an underestimate of demands in some elements and overestimation in others. A consideration is whether diaphragms should be designed to perform elastically, as is currently implied by the provisions, or whether it would be appropriate and beneficial in some cases to recognize nonlinear diaphragm response. Additionally in taller buildings higher mode effects may result in increased diaphragm demands, not recognized in common rigid diaphragm modeling assumptions. This issue team is chaired by S.K. Ghosh.

8. LIQUEFACTION AND OTHER SITE CONSIDERATIONS

The Provisions require that buildings be assessed for potential consequences of liquefaction and soil strength loss, including but not limited to, estimation of total and differential settlement, lateral soil movement, lateral loads on foundations, reduction of foundation soil bearing capacity, reduction of axial and lateral soil reaction on piles and floatation of buried structures. These effects are to be analyzed on the basis of peak ground accelerations, earthquake magnitudes and source characteristics associated with MCE_G peak ground accelerations, where MCE_G represents the Maximum Considered Earthquake geometric mean ground motion. Evaluating liquefaction for MCE ground motions is intended to minimize risk of collapse for the rare MCE ground motion, rather than at the building design level, which assumes a certain level of reserve building structural capacity. This Issue Team will consider more closely the geotechnical effects of the expected ground failure and its implications related to building damage and performance.

The Provisions utilize site amplification coefficients F_a and F_v that scale the mapped spectral values S_S and S_1 to obtain acceleration response parameters for sites with classification other than Site Class B. These coefficients were originally developed in the 1990's based primarily on the 1989 Loma Prieta Earthquake and are being re-evaluated by this Issue team based on recorded data from more recent earthquakes and nonlinearity of site response. This work is based on studies underway at the Pacific Earthquake Engineering Research Center. This Issue Team is chaired by C.B. Crouse.

9. FOUNDATION SOIL-STRUCTURE INTERFACE

Traditional geotechnical engineering practice provides foundation requirements based on allowable stresses. Commonly, allowable soil stresses for dead loads are arbitrarily increased by one-third for load combinations that include seismic forces. This practice is overly conservative and not consistent with the design basis of the NEHRP Provisions or ASCE/SEI 7 since it is not based on expected soil strength or the dynamic properties of site soils. This Issue Team is developing proposed modifications to foundation design requirements that address horizontal load effects (considering inelastic demands based on response modifications factors), nominal strengths, resistance factors and acceptance criteria. Additional work by this team may involve the further development of concepts contained in a 2009 NEHRP Provisions Part 3 Resource Paper, which considered controlling behavior and load-deformation modeling of the system consisting of the structure, its anchorage to the foundation, the foundation itself and the soil. This Issue Team is chaired by Martin Johnson.

10. LEARNING FROM RECENT EARTHQUAKES

Recent major earthquakes in developed countries, particularly those in Chile (2010), New Zealand (2011) and Japan (2011), provide an opportunity to judge the adequacy of the NEHRP Provisions from the standpoint of actual building performance. This Issue Team, chaired by William Holmes, will collect research from organizations that have published relevant reports and from engineers who have direct reconnaissance experience following these events. This will be presented in a NEHRP Provisions Part 3 report.

11. DESIGN MAPPING TASK FORCE

The 2009 NEHRP Provisions introduced new seismic design maps based on seismic hazard maps issued in 2008 by the U.S. Geological Survey (USGS) along with significant design-related adjustments, including use of risk-targeted ground motions, use of maximum direction ground motions, and use of near-source 84^{th} percentile ground motions. In this update cycle changes of this magnitude are not being proposed. It is expected that mapping changes will involve the following:

-Prepare supplemental design values from USGS hazard values and compare with design maps
-Prepare serviceability level design maps analogous to MCE_R maps
-Consider improvements to T_L (long period) maps
-Update the design maps for American Samoa and Guam
-Reshape the MCR_R design spectrum with additional (up to 7) spectral periods
-Address S_S values greater than 3g
-Support other Issues Teams, particularly the team related to Evaluation and Quantification of Seismic Performance Objectives

The Design Mapping Task Force is chaired by Nico Luco.

12. CONCLUDING REMARKS

The 2014 NEHRP Provisions is intended to serve as a nationally applicable resource document including Part 1 charging language based on and modifying ASCE/SEI 7-10, Part 2 detailed commentary also consistent with ASCE/SEI 7-10, and Part 3 introducing of new technologies. This paper provides an overview of the work that is underway related to the Provisions update project and is intended to contribute to the FEMA goal of outreach to the engineering community.

ACKNOWLEDGEMENT

The author wishes to acknowledge those who are volunteering their time on the 2014 Provisions update effort, particularly the Provision Update Committee and the Issue Team chairs and members. In addition it is recognized that the Provisions update effort would not be possible without funding and technical support from FEMA and the staff of BSSC.

Additionally, neither ATC, DHS, FEMA, nor any of their employees, makes any warranty, expressed or implied, nor assumes any legal liability or responsibility for the accuracy, completeness, or usefulness of any information, product, or process included in this publication. Users of information from this publication assume all liability arising from such use.

Foreword

The Federal Emergency Management Agency (FEMA) has the goal of reducing the ever-increasing cost that disasters inflict on our country. Preventing losses before they happen by designing and building to withstand anticipated forces from these hazards is one of the key components of mitigation, and is the only truly effective way of reducing the cost of these disasters.

As part of its responsibilities under the National Earthquake Hazards Reduction Program (NEHRP), and in accordance with the National Earthquake Hazards Reduction Act of 1977 (PL 94-125) as amended, FEMA is charged with supporting mitigation activities necessary to improve technical quality in the field of earthquake engineering. The primary method of addressing this charge has been supporting the investigation of seismic and related multi-hazard technical issues as they are identified by FEMA, the development and publication of technical design and construction guidance products, the dissemination of these products, and support of training and related outreach efforts. These voluntary resource guidance products present criteria for the design, construction, upgrade, and function of buildings subject to earthquake ground motions in order to minimize the hazard to life for all buildings and increase the expected performance of critical and higher occupancy structures.

The linear design procedure contained in modern building codes is based on the concept of converting the complicated nonlinear dynamic behavior of a building structure under seismic loading to an equivalent linear problem. The design process starts with the selection of a basic seismic force resisting system for the structure. The code specifies a series of prescriptive requirements for structures based on each such system. These prescriptive requirements regulate configuration, size, materials of construction, detailing, and minimum required strength and stiffness. These seismic design performance requirements are controlled through the assignment of a series of system response coefficients (R, C_d, Ω_0), which represent the material properties and design detailing of the selected system. Based on the linear dynamic response characteristics of the structure and these response coefficients, design lateral forces are distributed to the building's various structural elements using linear analysis techniques and the resulting member

forces and structural deflections are calculated. Members are then proportioned to have adequate capacity to resist the calculated forces in combination with other prescribed loads to ensure that calculated displacements do not exceed maximum specified values.

As the codes have improved over the last several decades in how they address seismic design, one of the results was an expansion of code-approved seismic force resisting systems, with many individual systems classified by the type of detailing used. For each increment in detailing, response coefficients were assigned in the code, based largely on judgment and qualitative comparison with the known response capabilities of other systems. The result is that today's code includes more than 80 individual structural systems, each with individual system response coefficients somewhat arbitrarily assigned. Many of these recently defined structural systems have never been subjected to significant level of earthquake ground shaking and the potential response characteristics and ability to meet the design performance objectives is untested and unknown.

What was needed was a standard procedural methodology where the inelastic response characteristics and performance of typical structures designed to a set of structural system provisions could be quantified and the adequacy of the structural system provisions to meet the design performance objectives verified. Such a methodology would need to directly account for the potential variations in structure configuration of structures designed to a set of provisions, the variation in ground motion to which these structures may be subjected and available laboratory data on the behavioral characteristics of structural elements.

The objective of this publication was to develop a procedure to establish consistent and rational building system performance and response parameters (R, C_d, Ω_0) for the linear design methods traditionally used in current building codes. The primary application of the procedure is for the evaluation of structural systems for new construction with equivalent earthquake performance. The primary design performance objective was taken to minimize the risk of structural collapse under the seismic load of maximum considered earthquake as specified in the current *NEHRP Recommended Provisions for New Buildings and Other Structures* (FEMA 450). Although the R factor is the factor of most concern, displacements and material detailing to achieve the implied design ductilities were also included.

It is anticipated that this methodology will ultimately be used by the nation's model building codes and standards to set minimum acceptable design

criteria for standard code-approved systems, and to provide guidance in the selection of appropriate design criteria for other systems when linear design methods are applied. This publication will also provide a basis for future evaluation of the current tabulation of and limitations on code-approved structural systems for adequacy to achieve the inherent seismic performance objectives. This material could then potentially be used to modify or eliminate those systems or requirements that can not reliably meet these objectives.

FEMA wishes to express its sincere gratitude to Charlie Kircher, Project Technical Director, and to the members of the Project Team for their efforts in the development of this recommended methodology. The Project Management Committee consisted of Michael Constantinou, Greg Deierlein, Jim Harris, John Hooper, and Allan Porush. They in turn guided the Project Working Groups, which included Andre Filiatrault, Helmut Krawinkler, Kelly Cobeen, Curt Haselton, Abbie Liel, Jiannis Christovasilis, Jason Chou, Stephen Cranford, Brian Dean, Kevin Haas, Jiro Takagi, Assawin Wanitkorkul, and Farzin Zareian. The Project Review Panel consisted of Maryann Phipps (Chair), Amr Elnashai, S.K. Ghosh, Ramon Gilsanz, Ron Hamburger, Jack Hayes, Rich Klingner, Phil Line, Bonnie Manley, Andrei Reinhorn, and Rafael Sabelli, and they provided technical advice and consultation over the duration of the work. The names and affiliations of all who contributed to this report are provided in the list of Project Participants.

Without their dedication and hard work, this project would not have been possible. The American public who live, work and play in buildings in seismic areas are all in their debt.

Federal Emergency Management Agency

Preface

In September 2004 the Applied Technology Council (ATC) was awarded a "Seismic and Multi-Hazard Technical Guidance Development and Support" contract (HSFEHQ-04-D-0641) by the Federal Emergency Management Agency (FEMA) to conduct a variety of tasks, including one entitled "Quantification of Building System Performance and Response Parameters" (ATC-63 Project). The purpose of this project was to establish and document a recommended methodology for reliably quantifying building system performance and response parameters for use in seismic design. These factors include the response modification coefficient (*R* factor), the system overstrength factor (Ω_0), and the deflection amplification factor (C_d), collectively referred to as "seismic performance factors."

Seismic performance factors are used to estimate strength and deformation demands on systems that are designed using linear methods of analysis, but are responding in the nonlinear range. Their values are fundamentally critical in the specification of seismic loading. *R* factors were initially introduced in the ATC-3-06 report, *Tentative Provisions for the Development of Seismic Regulations for Buildings*, published in 1978, and subsequently replaced by the *NEHRP Recommended Provisions for Seismic Regulations for New Buildings and Other Structures*, published by FEMA. Original *R* factors were based on judgment or on qualitative comparisons with the known response capabilities of seismic-force-resisting systems in use at the time. Since then, the number of systems addressed in current seismic codes and standards has increased substantially, and their ability to meet intended seismic performance objectives is largely unknown.

The recommended methodology described in this report is based on a review of relevant research on nonlinear response and collapse simulation, benchmarking studies of selected structural systems, and evaluations of additional structural systems to verify the technical soundness and applicability of the approach. Technical review and comment at critical developmental stages was provided by a panel of experts, which included representatives from the steel, concrete, masonry and wood material industry groups. A workshop of invited experts and other interested stakeholders was convened to receive feedback on the recommended methodology, and input from this group was instrumental in shaping the final product.

ATC is indebted to the leadership of Charlie Kircher, Project Technical Director, and to the members of the ATC-63 Project Team for their efforts in the development of this recommended methodology. The Project Management Committee, consisting of Michael Constantinou, Greg Deierlein, Jim Harris, John Hooper, and Allan Porush monitored and guided the technical efforts of the Project Working Groups, which included Andre Filiatrault, Helmut Krawinkler, Kelly Cobeen, Curt Haselton, Abbie Liel, Jiannis Christovasilis, Jason Chou, Stephen Cranford, Brian Dean, Kevin Haas, Jiro Takagi, Assawin Wanitkorkul, and Farzin Zareian. The Project Review Panel, consisting of Maryann Phipps (Chair), Amr Elnashai, S.K. Ghosh, Ramon Gilsanz, Ron Hamburger, Jack Hayes, Rich Klingner, Phil Line, Bonnie Manley, Andrei Reinhorn, and Rafael Sabelli provided technical advice and consultation over the duration of the work. The names and affiliations of all who contributed to this report are provided in the list of Project Participants.

ATC also gratefully acknowledges Michael Mahoney (FEMA Project Officer), Robert Hanson (FEMA Technical Monitor), and William Holmes (ATC Project Technical Monitor) for their input and guidance in the preparation of this report, Peter N. Mork and Ayse Hortacsu for ATC report production services, and Ramon Gilsanz as ATC Board Contact.

ATC Executive Director

Executive Summary

This report describes a recommended methodology for reliably quantifying building system performance and response parameters for use in seismic design. The recommended methodology (referred to herein as the Methodology) provides a rational basis for establishing global seismic performance factors (SPFs), including the response modification coefficient (*R* factor), the system overstrength factor (Ω_0), and deflection amplification factor (C_d), of new seismic-force-resisting systems proposed for inclusion in model building codes.

The purpose of this Methodology is to provide a rational basis for determining building seismic performance factors that, when properly implemented in the seismic design process, will result in *equivalent safety against collapse in an earthquake, comparable to the inherent safety against collapse intended by current seismic codes, for buildings with different seismic-force-resisting systems*.

As developed, the following key principles outline the scope and basis of the Methodology:

- It is applicable to new building structural systems.
- It is compatible with the *NEHRP Recommended Provisions for Seismic Regulations for New Buildings and Other Structures* (FEMA, 2004a) and ASCE/SEI 7, *Minimum Design Loads for Buildings and Other Structures*, (ASCE, 2006a).
- It is consistent with a basic life safety performance objective inherent in current seismic codes and standards.
- Earthquake hazard is based on Maximum Considered Earthquake ground motions.
- Concepts are consistent with seismic performance factor definitions in current seismic codes and standards.
- Safety is expressed in terms of a collapse margin ratio.
- Performance is quantified through nonlinear collapse simulation on a set of archetype models.

- Uncertainty is explicitly considered in the collapse performance evaluation.

The Methodology is intended to apply broadly to all buildings, recognizing that this objective may not be fully achieved for certain seismic environments and building configurations. Likewise, the Methodology has incorporated certain simplifying assumptions deemed appropriate for reliable evaluation of seismic performance. Key assumptions and potential limitations of the Methodology are presented and summarized.

In the development of the Methodology, selected seismic-force-resisting systems were evaluated to illustrate the application of the Methodology and verify its methods. Results of these studies provide insight into the collapse performance of buildings and appropriate values of seismic performance factors. Observations and conclusions in terms of generic findings applicable to all systems, and specific findings for certain types of seismic-force-resisting systems are presented. These findings should be considered generally representative, but not necessarily indicative of all possible trends, given limitations in the number and types of systems evaluated.

The Methodology is recommended for use with model building codes and resource documents to set minimum acceptable design criteria for standard code-approved seismic-force-resisting systems, and to provide guidance in the selection of appropriate design criteria for other systems when linear design methods are applied. It also provides a basis for evaluation of current code-approved systems for their ability to achieve intended seismic performance objectives. It is possible that results of future work based on this Methodology could be used to modify or eliminate those systems or requirements that cannot reliably meet these objectives.

10. Supporting Studies 10-1
10.1 General 10-1
10.2 Assessment of Non-Simulated Failure Modes in a Steel Special Moment Frame System 10-1
10.2.1 Overview and Approach 10-1
10.2.2 Structural System Information 10-3
10.2.3 Nonlinear Analysis Model 10-4
10.2.4 Procedure for Collapse Performance Assessment, Incorporating Non-Simulated Failure Modes 10-6
10.3 Collapse Evaluation of Seismically Isolated Structures 10-12
10.3.1 Introduction 10-12
10.3.2 Isolator and Structural System Information 10-14
10.3.3 Modeling Isolated Structure Archetypes 10-16
10.3.4 Design Properties of Isolated Structure Archetypes 10-21
10.3.5 Nonlinear Static Analysis for Period-Based Ductility, SSFs, Record-to-Record Variability and Overstrength 10-27
10.3.6 Collapse Evaluation Results 10-30
10.3.7 Summary and Conclusion 10-39

11 Conclusions and Recommendations 11-1
11.1 Assumptions and Limitations 11-1
11.1.1 Far-Field Record Set Ground Motions 11-1
11.1.2 Influence of Secondary Systems on Collapse Performance 11-3
11.1.3 Buildings with Significant Irregularities 11-4
11.1.4 Redundancy of the Seismic-Force-Resisting System 11-5
11.2 Observations and Conclusions 11-5
11.2.1 Generic Findings 11-5
11.2.2 Specific Findings 11-8
11.3 Collapse Evaluation of Individual Buildings 11-9
11.3.1 Feasibility 11-10
11.3.2 Approach 11-10
11.4 Recommendations for Further Study 11-10
11.4.1 Studies Related to Improving and Refining the Methodology 11-11
11.4.2 Studies Related to Advancing Seismic Design Practice and Building Code Requirements (ASCE/SEI 7-05) 11-12

Appendix A: Ground Motion Record Sets A-1
A.1 Introduction A-1

A.2 Objectives A-2
A.3 Approach A-3
A.4 Spectral Shape Consideration A-4
A.5 Maximum Considered Earthquake and Design Earthquake Demand (*ASCE/SEI 7-05*) A-4
A.6 PEER NGA Database A-7
A.7 Record Selection Criteria A-8
A.8 Scaling Method A-9
A.9 Far-Field Record Set A-13
A.10 Near-Field Record Set A-20
A.11 Comparison of Far-Field and Near-Field Record Sets A-27
A.12 Robustness of Far-Field Record Set A-33
A.12.1 Approach to Evaluating Robustness A-33
A.12.2 Effects of PGA Selection Criteria Alone A-34
A.12.3 Effects of PGV Selection Criteria Alone A-36
A.12.4 Effects of both PGA and PGV Selection Criteria Simultaneously, as well as Selection of Two Records from Each Event A-37
A.12.5 Summary of the Robustness of the Far-Field Set A-38
A.13 Assessment of Record-to-Record Variability in Collapse Fragility A-39
A.14 Summary and Conclusion A-43

Appendix B: Adjustment of Collapse Capacity Considering Effects of Spectral Shape B-1
B.1 Introduction B-1
B.2 Previous Research on Simplified Methods to Account for Spectral Shape (Epsilon) B-4
B.3 Development of a Simplified Method to Adjust Collapse Capacity for Effects of Spectral Shape (Epsilon) B-6
B.3.1 Epsilon Values for the Ground Motions in the Far-Field Set B-7
B.3.2 Target Epsilon Values B-7
B.3.3 Impact of Spectral Shape (ε) on Median Collapse Capacity B-11
B.4 Final Simplified Factors to Adjust Median Collapse Capacity for the Effects of Spectral Shape B-21
B.5 Application to Site Specific Performance Assessment B-24

Appendix C: Development of Index Archetype Configurations C-1
C.1. Development of Index Archetype Configurations for a Reinforced Concrete Moment Frame System C-1
C.1.1 Establishing the Archetype Design Space C-1
C.1.2 Identifying Index Archetype Configurations and Populating Performance Groups C-4
C.1.3 Preparing Index Archetype Designs and Index Archetype Models C-7
C.2 Development of Index Archetype Configurations for a Wood Light-Frame Shear Wall System C-9
C.2.1 Establishing the Archetype Design Space C-9
C.2.2 Identifying Index Archetype Configurations and Populating Performance Groups C-10

C.2.3 Preparing Index Archetype Designs and Index Archetype Models C-10
C.2.4 Other Considerations for Wood Light-Frame Shear Wall Systems C-13

Appendix D: Consideration of Behavioral Effects D-1
D.1 Identification of Structural failure Modes D-1
D.2 System Definition D-2
D.3 Element Deterioration Modes D-3
D.3.1 Flexural Hinging of Beams and Columns D-5
D.3.2 Compressive Failure of Columns D-5
D.3.3 Shear Failure of Beam and Columns D-5
D.3.4 Joint Panel Shear Behavior D-6
D.3.5 Bond-Slip of Reinforcing Bars D-7
D.3.6 Punching Shear in Slab-Column Connections D-7
D.4 Local and Global Collapse Scenarios D-7
D.5 Likelihood of Collapse Scenarios D-8
D.6 Collapse Simulation D-9

Appendix E: Nonlinear Modeling of Reinforced Concrete Moment Frame Systems E-1
E.1 Purpose E-1
E.2 Structural Modeling Overview E-1
E.3 Beam-Column Element Model E-2
E.3.1 Element and Hysteretic Model E-3
E.3.2 Calibration of Parameters for the Reinforced Concrete Beam-Column Element Model E-5
E.4 Joint Modeling E-15
E.4.1 Shear Panel Spring E-16
E.4.2 Bond-Slip Spring Model E-16

Appendix F: Collapse Evaluation of Individual Buildings F-1
F.1 Introduction F-1
F.2 Feasibility F-1
F.3 Approach F-1
F.4 Collapse Evaluation of Individual Building Systems F-2
F.4.1 Step One: Develop Nonlinear Model(s) F-2
F.4.2 Step Two: Define Limit States and Acceptance Criteria F-3
F.4.3 Step Three: Determine Total System Uncertainty and Acceptable Collapse Margin Ratio F-3
F.4.4 Step Four: Perform Nonlinear Static Analysis (NSA) F-4
F.4.5 Step Five: Select Record Set and Scale Records F-4
F.4.6 Step Six: Perform Nonlinear Dynamic Analysis (NDA) and Evaluate Performance F-5

Figure 9-12 Structural modeling documentation for a 4-story reinforced concrete ordinary moment frame archetype (Archetype ID 9203)..... 9-33

Figure 9-13 Monotonic static pushover for reinforced concrete ordinary moment frame archetype (Archetype ID 9203)..... 9-34

Figure 9-14 Incremental dynamic analysis to collapse showing the Maximum Considered Earthquake ground motion (S_{MT}), median collapse capacity intensity ($\hat{S}_{CT}$), and sidesway collapse margin ratio (CMR_{SS}) for Archetype ID 9203.... 9-35

Figure 9-15 Building configurations considered for the definitions of wood light-frame archetype buildings..... 9-45

Figure 9-16 Hysteretic model of shear spring element included in SAWS program (after Folz and Filiatrault, 2004a, b).....9-49

Figure 9-17 Comparison of monotonic backbone curves of 8' x 8' shear wall specimens generated using the hysteretic parameters for 8d common nail on 7/16" OSB sheathing shown in Table 9-21 with average cyclic envelope test data provided by the wood industry (Line et al., 2008).....9-50

Figure 9-18 Monotonic static pushover curve and computation of Ω for two-story wood light-frame archetype (Archetype ID 5).....9-51

Figure 9-19 Results of incremental dynamic analysis to collapse for the two-story wood light-frame archetype (Archetype ID 5).....9-52

Figure 9-20 Collapse fragility curve for the two-story wood light-frame archetype (Archetype ID 5).....9-53

Figure 9-21 Monotonic static pushover curve and computation of $\delta_u/\delta_{y,eff}$ for the two-story wood light-frame Archetype ID 5.....9-55

Figure 10-1 Index archetype model of 4-story steel special moment frame seismic-force-resisting system.....10-3

Figure 10-2 Monotonic backbone showing calibrated concentrated plasticity model for a typical column (W24x162).....10-4

Figure 10-3 Illustration of fracture behavior (Engelhardt et al., 1998).....10-7

Figure 10-4 Component fragility function, describing probability of ductile fracture occurring as a function of the plastic rotation, θ_p.....10-7

Figure 10-5 Results of nonlinear static (pushover) analysis of a steel special moment frame, illustrating computation of period-based ductility from non-simulated collapse modes.....10-9

Figure 10-6 Selected simulation results for the steel special moment frame illustrating the identification of non-simulated collapse modes. The governing collapse point for each ground motion record is identified with an asterisk (*).....10-10

Figure 10-7 Comparison of steel special moment frame collapse fragilities for sidesway-only and combined simulated and non-simulated (sidesway and fracture-induced) collapse (not adjusted for spectral shape). 10-11

Figure 10-8 Index archetype model for isolated systems. 10-17

Figure 10-9 Example nominal, upper-bound and lower-bound bilinear springs and hysteretic properties used to model the isolation system..... 10-18

Figure 10-10 Five individual springs and effective composite spring used to model moat wall resistance for an example 30-inch moat wall gap..... 10-20

Figure 10-11 Pushover curves of a non-code-conforming isolated structure (NC1) and the same superstructure on a fixed base. 10-28

Figure 10-12 Normalized design shear (V_s/W) and maximum strength (V_{max}/W) of superstructures. 10-28

Figure 10-13 Illustration of calculation of period-based ductility, μ_T, for isolated system NC-1, where $\mu_T = \delta_u / \delta_{y,eff}$..... 10-29

Figure 10-14 Ratios of computed *ACMR* to acceptable $ACMR_{10\%}$ for reinforced concrete special moment frame Code-Conforming isolated archetypes with various moat wall gap sizes, evaluated for SDC D_{max} seismic criteria. 10-34

Figure 10-15 Ratios of computed *ACMR* to acceptable $ACMR_{10\%}$ for reinforced concrete special moment frame isolated archetypes with various superstructure strengths and moat wall gap sizes, evaluated for SDC D_{max} seismic criteria 10-36

Figure 10-16 Ratios of computed *ACMR* to acceptable $ACMR_{10\%}$ for reinforced concrete special moment frame and reinforced concrete ordinary moment frame isolated archetypes with different superstructure strengths, evaluated for SDC D_{max} seismic criteria 10-37

Figure 10-17 Ratios of computed *ACMR* to acceptable $ACMR_{10\%}$ for reinforced concrete ordinary moment frame isolated archetypes with various moat wall gap sizes, evaluated for SDC D_{max} 10-38

Figure 10-18 Ratios of computed *ACMR* to acceptable $ACMR_{10\%}$ for reinforced concrete ordinary moment frame isolated archetypes with various moat wall gap sizes, evaluated for SDC D_{max}, illustrating the effect of column shear failure on assessed collapse performance 10-39

Figure A-1 Plots of MCE response spectral accelerations used for collapse evaluation of Seismic Design Categories D, C and B structure archetypes A-6

Figure A-2 Example anchoring of median spectrum of the Far-Field record set to MCE spectral acceleration at 1 second for maximum and minimum seismic criteria of Seismic Design Categories B, C and D A-13

Figure A-3 Response spectra of the forty-four individual components of the normalized Far-Field record set and median, one and two standard deviation response spectra of the total record set A-18

Figure A-4 Median and one standard deviation response spectra of the normalized Far-Field record set, and plot of the standard deviation (natural log) of response spectral acceleration A-19

Figure A-5 Plot of median value of epsilon for the Far-Field record set A-20

Figure A-6 Response spectra of the fifty-six individual components of the normalized Near-Field record set, and median, one and two standard deviation response spectra of the total record A-26

Figure A-7 Median and one standard deviation response spectra of the normalized Near-Field record set, and plot of the standard deviation (natural log) of response spectral acceleration A-26

Figure A-8 Median value of epsilon for the Near-Field record set (and plot of median value of epsilon for the Far-Field record set for comparison) A-27

Figure A-9 Median response spectra of normalized Near-Field and Far-Field record sets, and the ratio of these spectra A-28

Figure A-10 Median response spectra of the normalized Near-Field record set, the Far-Field record set, and fault normal records of the Near-Field Pulse subset A-29

Figure A-11 Mean ε values, $\bar{\varepsilon}(T)_{,\text{records}}$, for the Far-Field ground motion set (duplicated from Figure B-3 of App. B) A-35

Figure A-12 Comparison of median spectra under the FEMA P695 normalization/scaling method and the S_a-component scaling method (scaled to four different periods: 0.25 s, 0.50 s, 1.0 s, and 1.2 s). The five curves on this plot are virtually indistinguishable..... A-40

Figure A-13 Comparison of logarithmic standard deviation of spectral ordinates, $\sigma_{LN,Sa}$, for FEMA P695 scaling method and S_a-component scaling method at different periods..... A-41

Figure A-14 Relationship between period-based ductility ($\mu_T = (\delta_u/\delta_{y,eff})$ and record-to-record variability (β_{RTR}) from collapse data for reinforced concrete frames. The FEMA P695 simplified relationship for predicting β_{RTR} is superimposed..... A-42

Figure B-1 Comparison of an observed spectrum with spectra predicted by Boore, Joyner, and Fumal (1997); after Haselton and Baker (2006) B-2

Figure B-2 Relationship between collapse spectral acceleration, S_{CT1} and $\varepsilon(T_1)$ for a single 5-story wood light-frame building (No. 15; R = 6 design, wood-only model). This includes linear regression analysis results which relate LN[$S_{CT1}(T_1)$] to $\varepsilon(T_1)$, along with confidence intervals (CIs) for the best-fit line. For this example, $\beta_0 = 0.524$ and $\beta_1 = 0.315$ B-5

Figure B-3 Mean ε values for the basic Far-Field ground motion set $\bar{\varepsilon}(T)_{,records}$ B-7

Figure B-4 Predicted $\bar{\varepsilon}_0$ values from dissagregation of ground motion hazard for Western United States. The values are for a 1.0 second period and the 2% exceedance in 50 year motion (Harmsen et al., 2003) B-8

Figure B-5 Mean predicted $\bar{\varepsilon}_0$ values from dissagregation of ground motion hazard for Eastern United States. The values are for (a) 1.0 second and (b) 0.2 second periods and the 2% exceedance in 50 year motion (Harmsen et al., 2003) B-9

Figure B-6 Idealized nonlinear static pushover curve (from Section 6.3).....B-12

Figure B-7 Relationship between β_1 and period-based ductility, μ_T, for three sets of reinforced concrete special moment frame buildings of constant height within each set B-20

Figure B-8 Comparison of predicted and observed values of β_1, for all 118 buildings used to create the predictive equation. Figure (a) shows all the data, and Figure (b) shows the average values for the individual subsets of building types B-22

Figure B-9 Mean ε values for the Near-Field ground motion set $\overline{\varepsilon}(T)_{,records,NF}$. B-25

Figure C-1 Different index archetype configurations for varying ratios of tributary areas for gravity A_{grav} and lateral loads A_{lat} C-4

Figure C-2 Index archetype model for reinforced concrete moment frame systems. C-5

Figure C-3 Index archetype configurations for a reinforced concrete moment frame system C-6

Figure D-1 Consideration of behavioral effects in developing index archetype configurations D-2

Figure D-2 Reinforced concrete frame plan and elevation views, showing location of possible deterioration modes D-4

Figure D-3 Illustration and classification of possible deterioration modes for reinforced concrete moment frame components D-4

Figure E-1 Schematic diagram illustrating key elements of nonlinear frame model for reinforced concrete frame systems E-2

Figure E-2 Monotonic and cyclic behavior of component model used to model reinforced concrete beam-column elements E-4

Figure E-3 Example of calibration procedure; calibration of reinforced concrete beam-column element to experimental test by Saatcioglu and Grira, specimen BG-6 ..... E-6

Figure E-4 Schematic diagram of joint model E-15

Chapter 1
Introduction

This report describes a recommended methodology for reliably quantifying building system performance and response parameters for use in seismic design. The recommended methodology (referred to herein as the Methodology) provides a rational basis for establishing global seismic performance factors (SPFs), including the response modification coefficient (*R* factor), the system overstrength factor (Ω_0), and deflection amplification factor (C_d), of new seismic-force-resisting systems proposed for inclusion in model building codes.

1.1 Background and Purpose

The Applied Technology Council (ATC) was commissioned by the Federal Emergency Management Agency (FEMA) under the ATC-63 Project to develop a methodology for quantitatively determining global seismic performance factors for use in seismic design.

Seismic performance factors are used in current building codes and standards to estimate strength and deformation demands on seismic-force-resisting systems that are designed using linear methods of analysis, but are responding in the nonlinear range. *R* factors were initially introduced in the ATC-3-06 report, *Tentative Provisions for the Development of Seismic Regulations for Buildings* (ATC, 1978), and their values have become fundamentally critical in the specification of design seismic loading.

Since then, the number of structural systems addressed in seismic codes has increased dramatically. The 2003 edition of the National Earthquake Hazards Reduction Program (NEHRP) *Recommended Provisions for Seismic Regulations for New Buildings and Other Structures* (*NEHRP Recommended Provisions*), (FEMA, 2004a), includes more than 75 individual systems, each having a somewhat arbitrarily assigned *R* factor.

Original *R* factors were based largely on judgment and qualitative comparisons with the known response capabilities of relatively few seismic-force-resisting systems in widespread use at the time. Many recently defined seismic-force-resisting systems have never been subjected to any significant level of earthquake ground shaking. As a result, the seismic response characteristics of many systems, and their ability to meet seismic design performance objectives, are both untested and unknown.

As new systems continue to be introduced during each code update cycle, uncertainty in the seismic performance capability of the new building stock continues to grow, and the need to quantify the seismic performance delivered by current seismic design regulations becomes more urgent. Advances in performance-based seismic design tools and technologies has resulted in the ability to use nonlinear collapse simulation techniques to link seismic performance factors to system performance capabilities on a probabilistic basis.

The purpose of this Methodology is to provide a rational basis for determining building system performance and response parameters that, when properly implemented in the seismic design process, will result in *equivalent safety against collapse in an earthquake, comparable to the inherent safety against collapse intended by current seismic codes, for buildings with different seismic-force-resisting systems.*

The Methodology is recommended for use with model building codes and resource documents to set minimum acceptable design criteria for standard code-approved seismic-force-resisting systems, and to provide guidance in the selection of appropriate design criteria for other systems when linear design methods are applied. It also provides a basis for evaluation of current code-approved systems for their ability to achieve intended seismic performance objectives. It is possible that results of future work based on this Methodology could be used to modify or eliminate those systems or requirements that cannot reliably meet these objectives.

1.2 Scope and Basis of the Methodology

The following key principles outline the scope and basis of the Methodology.

1.2.1 Applicable to New Building Structural Systems

The Methodology applies to the determination of seismic performance factors appropriate for the design of seismic-force-resisting systems in new building structures. While the Methodology is conceptually applicable (with some limitations) to design of non-building structures, and to retrofit of seismic-force-resisting systems in existing buildings, such systems were not explicitly considered. The Methodology is not intended to apply to the design of nonstructural systems.

1.2.2 Compatible with the NEHRP Recommended Provisions and ASCE/SEI 7

The Methodology is based on, and intended for use with, applicable design criteria and requirements of the most current editions of the *NEHRP*

Recommended Provisions for Seismic Regulations for New Buildings and Other Structures (NEHRP Recommended Provisions), (FEMA, 2004a), and the seismic provisions of ASCE/SEI 7-05, *Minimum Design Loads for Buildings and Other Structures*, (ASCE, 2006a). The Building Seismic Safety Council has adopted ASCE/SEI 7-05 as the "starting point" for the development of its 2009 and future editions of the *NEHRP Recommended Provisions*. At this time, ASCE/SEI 7-05 is the most current, published source of seismic regulations for model building codes in the United States.[1]

ASCE/SEI 7-05 provides the basis for ground motion criteria and "generic" structural design requirements applicable to currently accepted and future (proposed) seismic-force-resisting systems. ASCE/SEI 7-05 provisions include detailing requirements for currently approved systems that may also apply to new systems. By reference, other standards, such as ACI 318, *Building Code Requirements for Structural Concrete* (ACI, 2005), AISC/ANSI 341, *Seismic Provisions for Structural Steel Buildings* (AISC, 2005), ACI 530/ASCE 5/TMS 402, *Building Code Requirements for Masonry Structures* (ACI, 2002b), and ANSI/AF&PA, *National Design Specification for Wood Construction* (ANSI/AF&PA, 2005) apply to currently approved systems, and may also apply to new systems.

The Methodology requires the seismic-force-resisting system of interest to comply with all applicable design requirements in ASCE/SEI 7-05, including limits on system irregularity, drift, and height, except when such requirements are specifically excluded and explicitly evaluated in the application of the Methodology. For new (proposed) systems, the Methodology requires identification and use of applicable structural design and detailing requirements in ASCE/SEI 7-05, and development and use of new requirements as necessary to adequately describe system limitations and ensure predictable seismic behavior of components. The latest edition of the *NEHRP Recommended Provisions*, containing modifications and commentary to ASCE/SEI 7-05, may be a possible source for additional design requirements.

1.2.3 Consistent with the Life Safety Performance Objective

The Methodology is consistent with the primary "life safety" performance objective of seismic regulations in model building codes. As stated in the *Part 2: Commentary* to the *NEHRP Recommended Provisions for Seismic*

[1] This chapter and other sections of this document refer to ASCE/SEI 7-05 for design criteria and requirements to illustrate the Methodology, and to define the values of certain parameters used for performance evaluation. The Methodology is intended to be generally applicable, and such references should not be construed as limiting the Methodology to this edition of ASCE/SEI 7.

Regulations for New Buildings and Other Structures (Commentary to the *NEHRP Recommended Provisions*), (FEMA, 2004b), "the *Provisions* provides the minimum criteria considered prudent for protection of life safety in structures subject to earthquakes."

Design for performance other than life safety was not explicitly considered in the development of the Methodology. Accordingly, the Methodology does not address special performance or functionality objectives of ASCE/SEI 7-05 for Occupancy III and IV structures.

1.2.4 Based on Acceptably Low Probability of Structural Collapse

The Methodology achieves the primary life safety performance objective by requiring an acceptably low probability of collapse of the seismic-force-resisting system when subjected to Maximum Considered Earthquake (MCE) ground motions.

In general, life safety risk (i.e., probability of death or life-threatening injury) is difficult to calculate accurately due to uncertainty in casualty rates given collapse, and even greater uncertainty in assessing the effects of falling hazards in the absence of collapse. Collapse of a structure can lead to very different numbers of fatalities depending on variations in construction or occupancy, such as structural system type and the number of building occupants. Rather than attempting to quantify uniform protection of "life safety", the Methodology provides approximate uniform protection against collapse of the structural system.

Collapse includes both partial and global instability of the seismic-force-resisting system, but does not include local failure of components not governed by global seismic performance factors, such as localized out-of-plane failure of wall anchorage and potential life-threatening failure of non-structural systems.

Similarly, the Methodology does not explicitly address components that are not included in the seismic-force-resisting system (e.g., gravity system components and nonstructural components). It assumes that deformation compatibility and related requirements of ASCE/SEI 7-05 adequately protect such components against premature failure. Components that are not designated as part of the seismic-force-resisting system are not controlled by seismic-force-resisting system design requirements. Accordingly, they are not considered in evaluating the overall resistance to collapse.

1.2.5 Earthquake Hazard based on MCE Ground Motions

The Methodology evaluates collapse under Maximum Considered Earthquake (MCE) ground motions for various geographic regions of seismicity, as defined by the coefficients and mapped acceleration parameters of the general procedure of ASCE/SEI 7-05, which is based on the maps and procedures contained in the *NEHRP Recommended Provisions*.

While seismic performance factors apply to the design response spectrum, taken as two-thirds of the MCE spectrum, code-defined MCE ground motions are considered the appropriate basis for evaluating structural collapse. As noted in the Commentary to the *NEHRP Recommended Provisions*, "if a structure experiences a level of ground motion 1.5 times the design level, the structure should have a low likelihood of collapse."

1.2.6 Concepts Consistent with Current Seismic Performance Factor Definitions

The Methodology remains true to the definitions of seismic performance factors given in ASCE/SEI 7-05, and the underlying nonlinear static analysis (pushover) concepts described in the Commentary to the *NEHRP Recommended Provisions*. Values of the response modification coefficient, R factor, the system overstrength factor, Ω_O , and the deflection amplification factor, C_d, for currently approved seismic-force-resisting systems are specified in Table 12.2-1 of ASCE/SEI 7-05. Section 4.2 of the Commentary to the *NEHRP Recommended Provisions* provides background information on seismic performance factors.

Figures 1-1 and 1-2 are used to explain and illustrate seismic performance factors, and how they are used in the Methodology. Parameters are defined in terms of equations, which in all cases are dimensionless ratios of force, acceleration or displacement. However, in attempting to utilize the figures to clarify and to illustrate the meanings of these ratios, graphical license is taken in two ways. First, seismic performance factors are depicted in the figures as incremental differences between two related parameters, rather than as ratios of the parameters. Second, as a consequence of being depicted as incremental differences, seismic performance factors are shown on plots with units, when, in fact, they are dimensionless.

Figure 1-1, an adaptation of Figures C4.2-1 and C4.2-3 from the Commentary to the *NEHRP Recommended Provisions*, defines seismic performance factors in terms of the global inelastic response (idealized pushover curve) of the seismic-force-resisting system. In this figure, the

horizontal axis is lateral displacement (i.e., roof drift) and the vertical axis is lateral force at the base of the system (i.e., base shear).

In Figure 1-1, the term V_E represents the force level that would be developed in the seismic-force-resisting system, if the system remained entirely linearly elastic for design earthquake ground motions. The term V_{max} represents the actual, maximum strength of the fully-yielded system, and the term V is the seismic base shear required for design. As defined in Equation 1-1, the R factor is the ratio of the force level that would be developed in the system for design earthquake ground motions (if the system remained entirely linearly elastic) to the base shear prescribed for design:

$$R = \frac{V_E}{V} \tag{1-1}$$

and, as defined in Equation 1-2, the Ω_O factor is the ratio of the maximum strength of the fully-yielded system to the design base shear:

$$\Omega_O = \frac{V_{max}}{V} \tag{1-2}$$

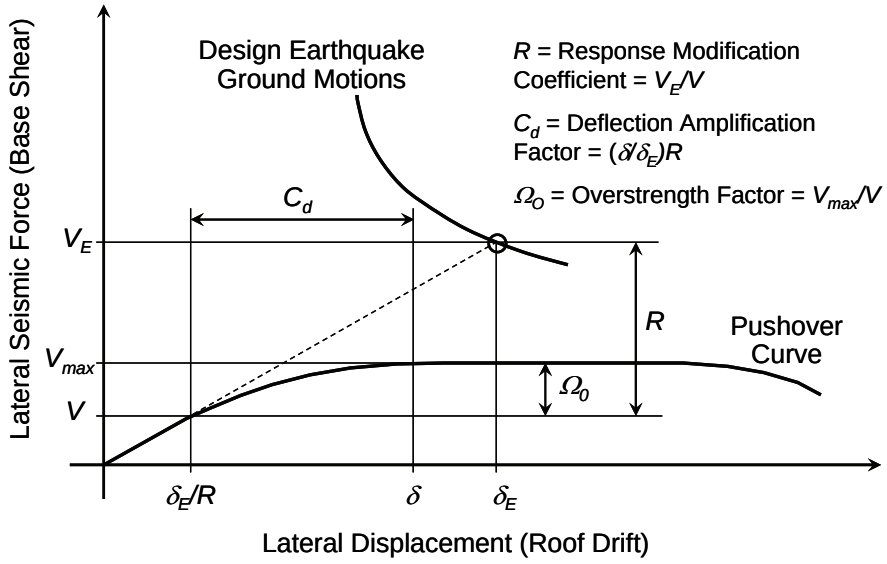

Figure 1-1 Illustration of seismic performance factors (R, Ω_O, and C_d) as defined in the Commentary to the *NEHRP Recommended Provisions* (FEMA, 2004b).

In Figure 1-1, the term δ_E/R represents roof drift of the seismic-force-resisting system corresponding to design base shear, V, assuming that the system remains essentially elastic for this level of force, and the term δ represents the assumed roof drift of the yielded system corresponding to design earthquake ground motions. As illustrated in the figure and defined

by Equation 1-3, the C_d factor is some fraction of the R factor (typically less than 1.0):

$$C_d = \frac{\delta}{\delta_E} R \tag{1-3}$$

The Methodology develops seismic performance factors consistent with the concepts and definitions described above. Figure 1-2 illustrates the seismic performance factors defined by the Methodology and their relationship to MCE ground motions.

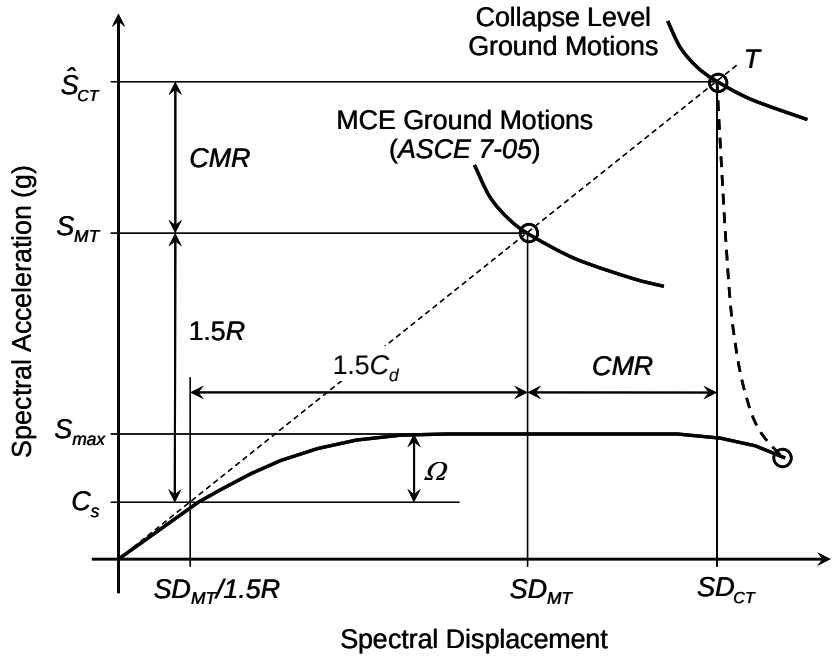

Figure 1-2 Illustration of seismic performance factors (R, Ω, and C_d) as defined by the Methodology.

Figure 1-2 parallels the "pushover" concept shown in Figure 1-1 using spectral coordinates rather than lateral force (base shear) and lateral displacement (roof drift) coordinates. Conversion to spectral coordinates is based on the assumption that 100% of the effective seismic weight of the structure, W, participates in fundamental mode at period, T, consistent with Equation 12.8-1 of ASCE/SEI 7-05:

$$V = C_s W \tag{1-4}$$

In Figure 1-2, the term S_{MT} is the Maximum Considered Earthquake (MCE) spectral acceleration at the period of the system, T, the term S_{max} represents the maximum strength of the fully-yielded system (normalized by the effective seismic weight, W, of the structure), and the term C_s is the seismic response coefficient. As defined in Equation 1-5, the ratio of the MCE

spectral acceleration to the seismic response coefficient, which is the design-level acceleration, is equal to 1.5 times the *R* factor:

$$1.5R = \frac{S_{MT}}{C_s} \tag{1-5}$$

The 1.5 factor in Equation 1-5 accounts for the definition of design earthquake ground motions in ASCE/SEI 7-05, which is two-thirds of MCE ground motions.

In Figure 1-2, the overstrength parameter, Ω, is defined as the ratio of the maximum strength of the fully-yielded system, S_{max} (normalized by W), to the seismic response coefficient, C_s:

$$\Omega = \frac{S_{max}}{C_s} \tag{1-6}$$

The Methodology calculates the overstrength parameter, Ω, based on nonlinear static (pushover) analysis. Calculated values of overstrength, Ω, are different from the overstrength factor, Ω_O, of ASCE/SEI 7-05, which is specified for design of non-ductile elements. In general, different designs of the same system will have different calculated values of overstrength, and the parameter, Ω, will vary. The single value of Ω that is considered to be most appropriate for use in design of the system of interest, is the value ultimately selected for Ω_O.

In Figure 1-2, inelastic system displacement at the MCE level is defined as $1.5C_d$ times the displacement corresponding to the design seismic response coefficient, C_s, and set equal to the MCE elastic system displacement, SD_{MT} (based on the "Newmark rule"), effectively redefining the C_d factor to be equal to the *R* factor:

$$C_d = R \tag{1-7}$$

The equal displacement assumption is reasonable for most conventional systems with effective damping approximately equal to the nominal 5% level used to define response spectral acceleration and displacement. Systems with substantially higher (or lower) levels of damping would have significantly smaller (or larger) displacements than those with 5%-damped elastic response. As one example, systems with viscous dampers have significantly higher damping than 5%. For such systems, the response modification methods of Chapter 18 of ASCE/SEI 7-05 are used to determine an appropriate value of the C_d factor, as a fraction of the *R* factor.

1.2.7 Safety Expressed in Terms of Collapse Margin Ratio

The Methodology defines collapse level ground motions as the intensity that would result in median collapse of the seismic-force-resisting system. Median collapse occurs when one-half of the structures exposed to this intensity of ground motion would have some form of life-threatening collapse. As shown in Figure 1-2, collapse level ground motions are higher than MCE ground motions. As such, MCE ground motions would result in a comparatively smaller probability of collapse. As defined in Equation 1-8, the collapse margin ratio, *CMR*, is the ratio of the median 5%-damped spectral acceleration of the collapse level ground motions, $\hat{S}_{CT}$ (or corresponding displacement, SD_{CT}), to the 5%-damped spectral acceleration of the MCE ground motions, S_{MT} (or corresponding displacement, SD_{MT}), at the fundamental period of the seismic-force-resisting system:

$$CMR = \frac{\hat{S}_{CT}}{S_{MT}} = \frac{SD_{CT}}{SD_{MT}} \tag{1-8}$$

In one sense, the collapse margin ratio, *CMR*, could be thought of as the amount S_{MT} must be increased to achieve building collapse by 50% of the ground motions. Collapse of the seismic-force-resisting system, and hence *CMR*, is influenced by many factors, including ground motion variability and uncertainty in design, analysis, and construction of the structure. These factors are considered collectively in a collapse fragility curve that describes the probability of collapse of the seismic-force-resisting system as a function of the intensity of ground motion.

1.2.8 Performance Quantified Through Nonlinear Collapse Simulation on a Set of Archetype Models

The Methodology determines the response modification coefficient, *R* factor, and evaluates the system over-strength factor, Ω, using nonlinear models of seismic-force-resisting system "archetypes." Archetypes capture the essence and variability of the performance characteristics of the system of interest. The Methodology requires nonlinear analysis of a sufficient number of archetype models, with parametric variations in design parameters, to broadly represent the system of interest.

The Methodology requires archetype models to meet the applicable design requirements of ASCE/SEI 7-05 and related standards, and additional criteria developed for the system of interest. Archetype design assumes a trial value of the *R* factor to determine the seismic response coefficient, C_s. The Methodology requires detailed modeling of nonlinear behavior of archetypes, based on representative test data sufficient to capture collapse failure modes.

Collapse failure modes that cannot be explicitly modeled are evaluated using appropriate limits on the controlling response parameter.

1.2.9 Uncertainty Considered in Performance Evaluation

The Methodology defines acceptable values of the collapse margin ratio in terms of an acceptably low probability of collapse for MCE ground motions, given uncertainty in the collapse fragility. Systems that have more robust design requirements, more comprehensive test data, and more detailed nonlinear analysis models, have less collapse uncertainty, and can achieve the same level of life safety with smaller collapse margin ratios.

Calculated values of collapse margin ratio are compared with acceptable values that reflect collapse uncertainty. If the calculated collapse margin is large enough to meet the performance objective (i.e., an acceptably small probability of collapse at the MCE), then the trial value of the *R* factor used in the archetype design is acceptable. If not, a new (lower) trial value of the *R* factor must be re-evaluated using the Methodology, or other limitations on the system of interest (e.g., height restrictions in the design requirements) must be considered.

1.3 Content and Organization

This report is written and organized to facilitate potential use and adoption by the *NEHRP Recommended Provisions.* Chapter 2 provides an overview of the Methodology, introducing the basic theory and concepts that are described in more detail in the chapters that follow.

Chapters 3 through 7 step through the elements of the Methodology, including required system information, structure archetype development, nonlinear modeling, criteria for collapse assessment, nonlinear analysis, and evaluation of seismic performance factors.

Chapter 8 defines documentation and peer review requirements, and describes recommended qualifications, expertise, and responsibilities for personnel involved with implementing the Methodology in the development and review of a proposed system.

Chapter 9 provides example applications intended to assist users in implementing the Methodology, and to validate the technical approach. Example systems include special and ordinary reinforced concrete moment frame systems, and wood light-frame systems.

Chapter 10 includes supporting studies on non-simulated collapse failure modes for steel moment frame systems, and on dynamic response

characteristics, performance properties, and collapse failure modes unique to seismically-isolated structures.

Chapter 11 provides summary conclusions, recommendations, and limitations on the use of the Methodology.

Appendices A through F provide background information supporting the development of the Methodology, and expanded guidance on key aspects of the Methodology.

A glossary of definitions and list of symbols used throughout this report, along with a list of references, are provided at the end of this report.

Chapter 2
Overview of Methodology

This chapter outlines the general framework of the Methodology and describes the overall process. It introduces the key elements of the Methodology, including required system information, development of structural system archetypes, archetype models, nonlinear analysis of archetypes, performance evaluation, and documentation and peer review requirements. These elements are specified in more detail in the chapters that follow.

2.1 General Framework

The Methodology consists of a framework for establishing seismic performance factors (SPFs) that involves the development of detailed system design information and probabilistic assessment of collapse risk. It utilizes nonlinear analysis techniques, and explicitly considers uncertainties in ground motion, modeling, design, and test data. The technical approach is a combination of traditional code concepts, advanced nonlinear dynamic analyses, and risk-based assessment techniques.

Reliable analysis requires valid ground motions and representative nonlinear models of the seismic-force-resisting system. Development of representative models requires both detailed design information and comprehensive nonlinear test data on structural components and assemblies that make up the system of interest. Figure 2-1 illustrates the key elements of the Methodology.

The Methodology includes fully defined characterizations of ground motion and methods of analysis that are generically applicable to all seismic-force-resisting systems. Design information and test data will be different for each system, and may not yet exist for new systems. The Methodology includes requirements for defining the type of design information and test data that are needed for developing representative analytical models of the seismic-force-resisting system of interest.

Rather than establishing minimum requirements for design information and test data, the use of better quality information is encouraged by rewarding systems that have "done their homework." Systems that are based on well-defined design requirements and comprehensive test data will have

inherently less uncertainty in their seismic performance. Such systems will need a lower margin against collapse to achieve an equivalent level of safety, as compared to systems with less robust data.

Due to the complexity of nonlinear dynamic analysis, the difficulty in modeling inelastic behavior, and the need to verify the adequacy and quality of design information and test data, the Methodology requires independent peer review of the entire process.

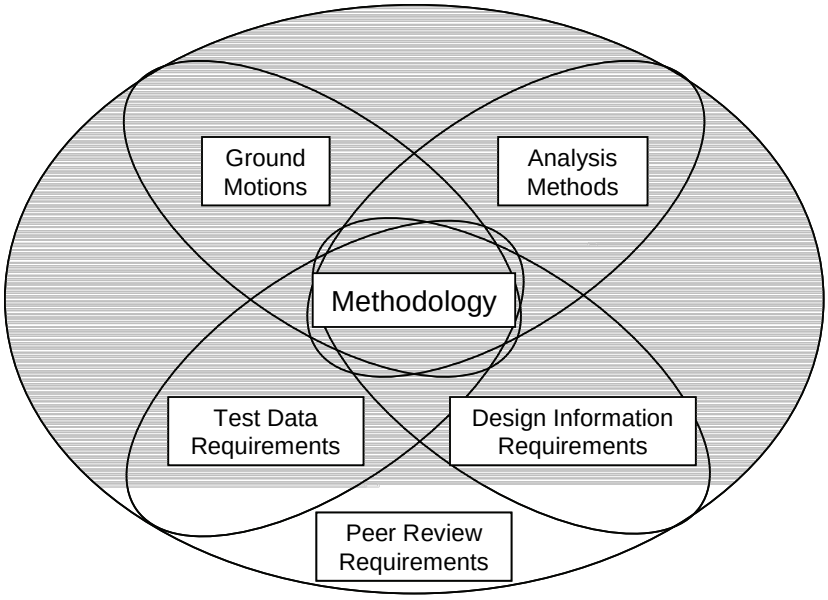

Figure 2-1 Key elements of the Methodology.

2.2 Description of Process

The steps comprising the Methodology are shown in Figure 2-2. These steps outline a process for developing system design information with enough detail and specificity to identify the permissible range of application for the proposed system, adequately simulate nonlinear response, and reliably assess the collapse risk over the proposed range of applications. Each step is linked to a corresponding chapter in this report, and described in the sections that follow.

2.3 Develop System Concept

The process begins with the development of a well-defined concept for the seismic-force-resisting system, including type of construction materials, system configuration, inelastic dissipation mechanisms, and intended range of application.

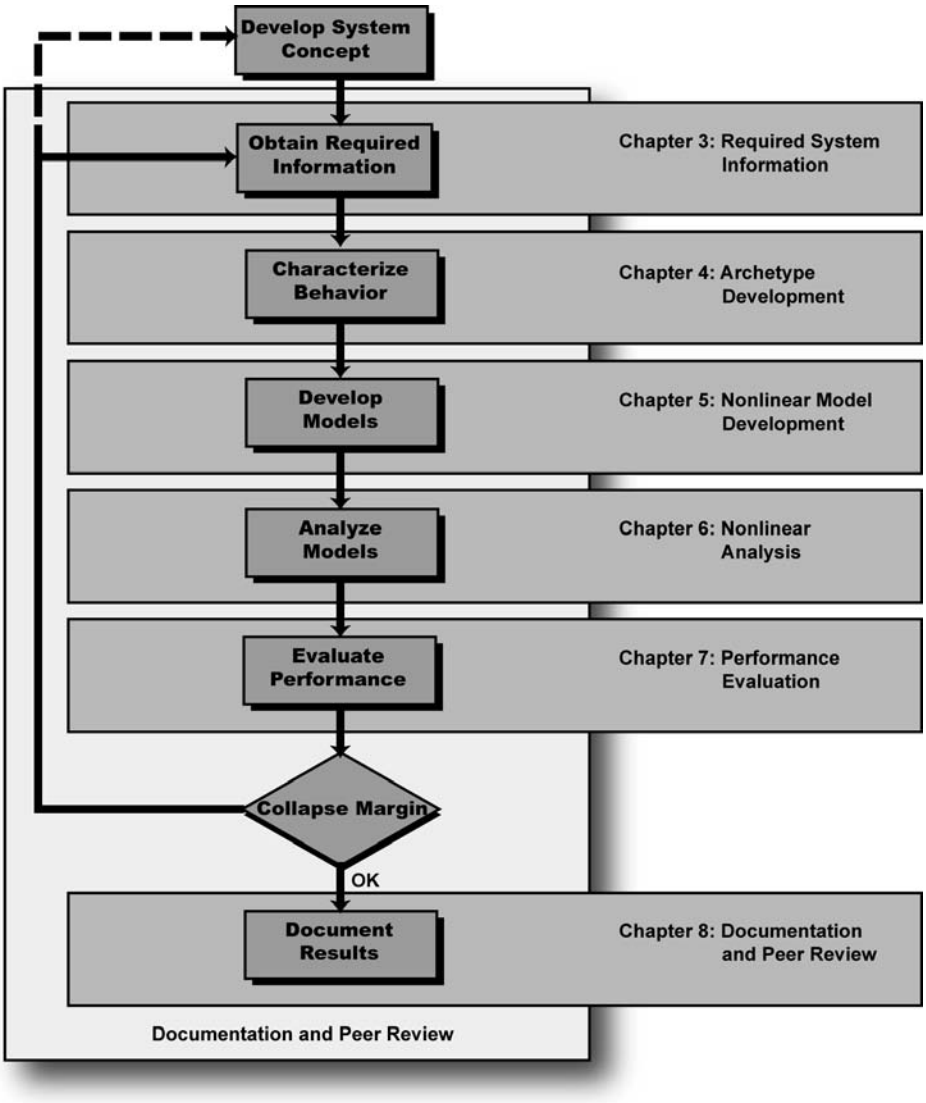

Figure 2-2 Process for quantitatively establishing and documenting seismic performance factors (SPFs).

The amount of documentation necessary to describe the system and characterize system components will vary, depending on the novelty and uniqueness of the proposed system relative to other well-established structural systems.

2.4 Obtain Required Information

Required system information is specified in Chapter 3. Required information includes detailed design requirements and results from material, component, and system testing. Design requirements include the rules that engineers will use to proportion and detail structural components of the system, and limits in the application of the system. Test results include information on

component material properties, force-deformation behavior, and nonlinear response.

Comprehensive design provisions are developed within the context of the seismic provisions of ASCE/SEI 7-05 and other applicable standards. The provisions should address all significant aspects of the design and detailing of the seismic-force-resisting system and its components. Important exceptions and deviations from established building code requirements should be clearly stipulated. Design provisions should address criteria for determining minimum strength and ensuring inelastic deformation capacity through a combination of system design requirements, component design and detailing requirements, and project-specific testing requirements. Design provisions should also specify the seismic performance factors (R , Ω_0, C_d) and other criteria (e.g., drift limits, height limits, and seismic usage restrictions) that are proposed as part of the design basis for the new system.

Test data are necessary for characterizing the strength, stiffness and ductility of the materials, members, and connections of the proposed system. Test data are also necessary for establishing properties of the nonlinear analysis models used to assess collapse risk. Test data and other substantiating evidence should be acquired as the basis of the design provisions and for calibrating analysis models. Design requirements should be documented with supporting evidence to ensure sufficient strength, stiffness and ductility of the proposed system, across the intended range of application of the system.

2.5 Characterize Behavior

System behavior is characterized through the use of structural system archetypes. The concept of an archetype is described in Chapter 4. Establishment of archetypes begins with identifying the range of features and behavioral characteristic that describe the bounds of the proposed seismic-force-resisting system.

Archetypes provide a systematic means for characterizing permissible configurations and other significant features of the proposed system. Like building code provisions, archetypical systems are intended to represent typical applications of a seismic-force-resisting system, recognizing that it is practically impossible to envision or attempt to quantify performance of all possible applications. They should, however, reflect the degree of irregularity permitted within standard building code provisions.

The challenge in defining and assessing structural system archetypes is in narrowing the range of parameters and attributes to the fewest and simplest

possible, while still being reasonably representative of the variations that would be permitted in actual structures. In addition to ground motion intensity (Seismic Design Category), the following characteristics are considered in defining structural system archetypes: (1) building height; (2) fundamental period; (3) structural framing configurations; (4) framing bay sizes or wall lengths; (5) magnitude of gravity loads; and (6) member and connection design and detailing requirements. Structural system archetypes are assembled into bins called performance groups, which reflect major divisions, or changes in behavior, within the archetype design space. The collapse safety of the proposed system is then evaluated for each performance group.

In the collapse assessment process, only framing components that are specifically designated as part of the seismic-force-resisting system are included in the archetypes. While it is recognized that other portions of the building (e.g., components of the gravity system or certain nonstructural components) can significantly affect collapse behavior, such components, which are not controlled by seismic-force-resisting system design requirements, cannot be relied upon for reducing collapse risk.

2.6 Develop Models

Development of structural models for collapse assessment is discussed in Chapter 5. Structural system archetypes provide the basis for preparing a finite number of trial designs and developing a corresponding number of idealized nonlinear models that sufficiently represent the range of intended applications for a proposed system. Index archetype models are developed to provide the most basic (generic) idealization of an archetypical configuration, while still capturing significant behavioral modes and key design features of the proposed seismic-force-resisting system.

Designs consider the range of seismic criteria for each applicable Seismic Design Category, variations in gravity loads, and other distinguishing features including alternative geometric configurations, varying heights, and different tributary areas that impact seismic design or system performance.

To the extent possible, nonlinear models include explicit simulation of all significant deterioration mechanisms that could lead to structural collapse. Recognizing that it is not always possible (or practical) to simulate all possible collapse modes, the Methodology includes provisions for assessing the effects of behaviors that are not explicitly simulated in the model, but could trigger collapse.

Nonlinear models must account for the seismic mass that is stabilized by the seismic-force-resisting system, including the destabilizing P-delta effects associated with the seismic mass. In most cases, elements are idealized with phenomenological models to simulate complicated component behavior. In some cases, however, two-dimensional or three-dimensional continuum finite element models may be required to properly characterize behavior. Models are calibrated using material, component, or assembly test data and other substantiating evidence to verify their ability to simulate expected nonlinear behavior.

2.7 Analyze Models

Collapse assessment is performed using both nonlinear static (pushover) and nonlinear dynamic (response history) analysis procedures described in Chapter 6. Nonlinear static analyses are used to help validate the behavior of nonlinear models and to provide statistical data on system overstrength and ductility capacity. Nonlinear dynamic analyses are used to assess median collapse capacities and collapse margin ratios.

Nonlinear response is evaluated for a set of pre-defined ground motions that are used for collapse assessment of all systems. Two sets of ground motion records are provided for nonlinear dynamic analysis. One set includes 22 ground motion record pairs from sites located greater than or equal to 10 km from fault rupture, referred to as the "Far-Field" record set. The other set includes 28 pairs of ground motions recorded at sites less than 10 km from fault rupture, referred to as the "Near-Field" record set. While both Far-Field and Near-Field record sets are provided, only the Far-Field record set is required for collapse assessment. This is done for reasons of practicality, and in recognition of the fact that there are many unresolved issues concerning the characterization of near-fault hazard and ground motion effects. The Near-Field record set is provided as supplemental information to examine issues that could arise due to near-fault directivity effects, if needed.

The record sets include records from all large-magnitude events in the Pacific Earthquake Engineering Research Center (PEER) Next-Generation Attenuation (NGA) database (PEER, 2006a). Records were selected to meet a number of sometimes conflicting objectives. To avoid event bias, no more than two of the strongest records have been taken from any one earthquake, yet the record sets have a sufficient number of motions to permit statistical evaluation of record-to-record (RTR) variability and collapse fragility. Strong ground motions were not distinguished based on either site condition or source mechanism. The Far-Field and Near-Field record sets are provided in Appendix A, along with background information on their selection.

For collapse evaluation, ground motions are systematically scaled to increasing earthquake intensities until median collapse is established. Median collapse is the ground motion intensity in which half of the records in the set cause collapse of an index archetype model. This process is similar to, but distinct from the concept of incremental dynamic analysis (IDA), as proposed by Vamvatsikos and Cornell (2002).

Figure 2-3 shows an example of IDA results for a single structure subjected to a suite of ground motions of varying intensities. In this illustration, sidesway collapse is the governing mechanism, and collapse prediction is based on lateral dynamic instability, or excessive lateral displacements. Using collapse data obtained from IDA results, a collapse fragility can be defined through a cumulative distribution function (CDF), which relates the ground motion intensity to the probability of collapse (Ibarra et al., 2002). Figure 2-4 shows an example of a cumulative distribution plot obtained by fitting a lognormal distribution to the collapse data from Figure 2-3.

While the IDA concept is useful for illustrating the collapse assessment procedure, the Methodology only requires calculation of the median collapse point, which can be calculated with fewer nonlinear analyses than would otherwise be required to calculate the full IDA curve. An abbreviated process for calculating the median collapse point is described in Chapter 6.

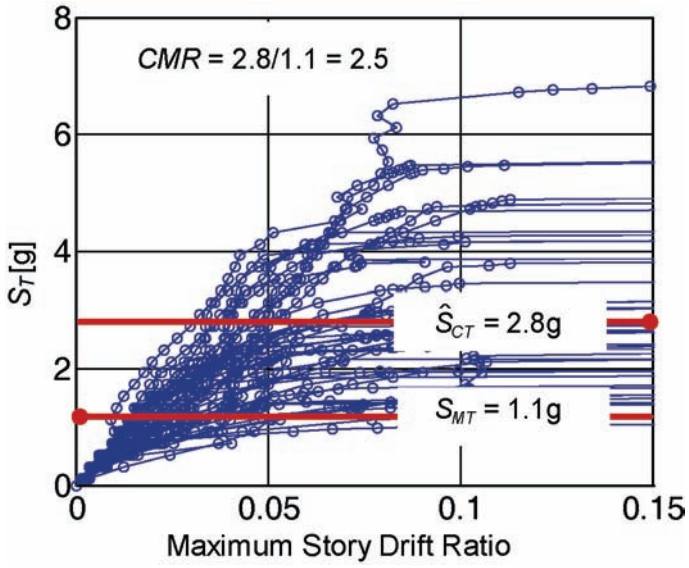

Figure 2-3 Incremental dynamic analysis response plot of spectral acceleration versus maximum story drift ratio.

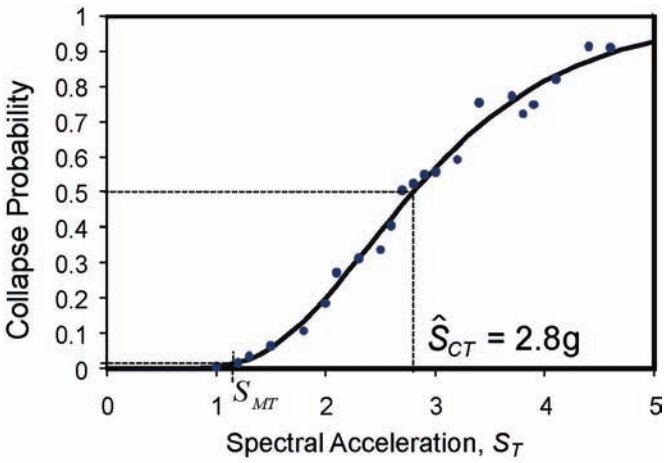

Figure 2-4 Collapse fragility curve, or cumulative distribution function.

2.8 Evaluate Performance

The performance evaluation process is described in Chapter 7. It utilizes results from nonlinear static analyses to determine an appropriate value of the system overstrength factor, Ω_O, and results from nonlinear dynamic analyses to evaluate the acceptability of a trial value of the response modification coefficient, R. The deflection amplification factor, C_d, is derived from an acceptable value of R, with consideration of the effective damping of the system of interest.

The trial value of the response modification coefficient, R, is evaluated in terms of the acceptability of a calculated collapse margin ratio, which is the ratio of the ground motion intensity that causes median collapse, to the Maximum Considered Earthquake (MCE) ground motion intensity defined by the building code. Acceptability is measured by comparing the collapse margin ratio, after some adjustment, to acceptable values that depend on the quality of information used to define the system, total system uncertainty, and established limits on acceptable probabilities of collapse.

To account for unique characteristics of extreme ground motions that lead to building collapse, the collapse margin ratio is converted to an adjusted collapse margin ratio. The adjustment is based on the shape of the spectrum of rare ground motions, and is a function of the structure ductility and period of vibration. Systems with larger ductility and longer periods benefit by larger adjustments. The background and development of this adjustment to account for the effects of spectral shape are provided in Appendix B.

Acceptable values of the collapse margin ratio are defined in terms of an acceptably low probability of collapse for MCE ground motions, considering uncertainty in collapse fragility. Systems that have more robust design

requirements, more comprehensive test data, and more detailed nonlinear analysis models, have less collapse uncertainty, and can achieve the same level of life safety with smaller collapse margin ratios. The following sources of uncertainty are explicitly considered: (1) record-to-record uncertainty; (2) design requirements-related uncertainty; (3) test data-related uncertainty; and (4) modeling uncertainty.

The probability of collapse due to MCE ground motions applied to a population of archetypes is limited to 10%, on average. Each performance group is required to meet this average limit, recognizing that some individual archetypes could have collapse probabilities that exceed this value. The probability of collapse for individual archetypes is limited to 20%, or twice the average value, to evaluate acceptability of potential "outliers" within a performance group. It should be noted that these limits were selected based on judgment. Within the performance evaluation process, these values can be adjusted to reflect different values of acceptable probabilities of collapse that are deemed appropriate by governing jurisdictions or other authorities employing this Methodology to establish seismic design requirements for a proposed system.

If the adjusted collapse margin ratio is large enough to result in an acceptably small probability of collapse at the MCE, then the trial value of R is acceptable. If not, the system must be redefined by adjusting the design requirements (Chapter 3), re-characterizing behavior (Chapter 4), or redesigning with new trial values (Chapter 5), and then re-evaluated using the Methodology. In some cases, inadequate performance could require extensive revisions to the overall system concept.

2.9 Document Results

Documentation requirements are described in Chapter 8. The results of system development efforts must be thoroughly documented for review and approval by an independent peer review panel, review and approval by an authority having jurisdiction, and eventual use in design and construction.

Documentation is required at each step of the process. It should describe seismic design rules, range of applicability of the system, testing protocols and results, rationale for the selection of structural system archetypes, results of analytical investigations, evaluation of quality of information, quantification of uncertainties, results of performance evaluations, and proposed seismic performance factors.

Documentation should be of sufficient detail and clarity to allow an unfamiliar structural engineer to properly implement the design, and an

unfamiliar reviewer to evaluate compliance with the design requirements. Documentation should also provide sufficient information to allow peer reviewers, code authorities, or material standard organizations to assess the viability of the proposed system and the reasonableness of the proposed seismic performance factors.

2.10 Peer Review

Peer review by an independent team of experts is a requirement of the Methodology, and should be an integral part of the process at each step. Implementation of the Methodology involves much uncertainty, judgment and potential for variation. Deciding on an appropriate level of detail to adequately characterize performance of a proposed system should be performed in collaboration with a peer review panel, on an ongoing basis, during developmental efforts.

The peer review panel is responsible for reviewing and commenting on the approach taken by the system development team, including the extent of the experimental program, testing procedures, design requirements, development of structural system archetypes, analytical approaches, extent of the nonlinear analysis investigation, and the final selection of the proposed seismic performance factors. Members of the peer review panel must be qualified to critically evaluate the development of the proposed system including testing, design, and analysis, and sufficiently independent from the system development team to provide an unbiased assessment of the developmental process.

The peer review panel, and their involvement, should be established early to clarify expectations for the collapse assessment. The peer review team is expected to exercise considerable judgment in evaluating all aspects of the process, from definition of the proposed system, to establishment of design criteria, scope of testing, and extent of analysis deemed necessary to adequately evaluate collapse safety.

Details on the required peer review process, and guidance on the selection of peer review panel members, are provided in Chapter 8.

Chapter 3
Required System Information

This chapter identifies information that is necessary for establishing seismic performance factors as part of the development, documentation, and review of a proposed seismic-force-resisting system. It describes the type of information that is required, and provides guidance on how it should be developed.

This information is used in the development of structural system archetypes in Chapter 4, and nonlinear analysis models in Chapter 5. It is subject to peer review as it is developed, and is an integral part of the reporting requirements in Chapter 8.

3.1 General

Seismic performance factors for a proposed system are established through nonlinear simulation of response to earthquake ground motion, and probabilistic assessment of collapse risk. Detailed system information is necessary for reliable prediction of structural response, and for development and validation of standardized engineering criteria that will lead to structures that perform as expected. Required system information includes:

- a comprehensive description of the proposed system, including its intended applications, physical and behavioral characteristics, and construction methods;
- a clear and complete set of design requirements and specifications for the system that provide information to quantify strength limit states, proportion and detail components, analyze predicted response, and confirm satisfactory behavior; and
- test data and other supporting evidence from an experimental investigation program to validate material properties and component behavior, calibrate nonlinear analysis models, and establish performance acceptance criteria.

The process for obtaining required system information is shown in Figure 3-1. It involves development of detailed system design requirements, acquisition of test data, and assessment of the quality of this information.

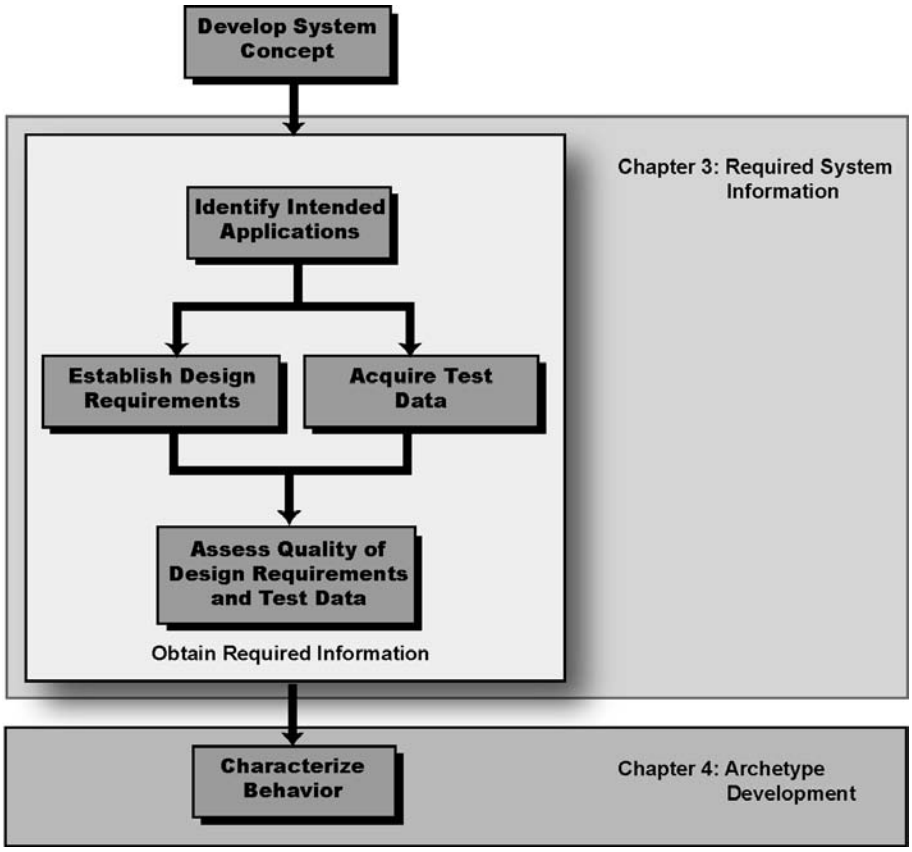

Figure 3-1 Process for obtaining required system information

Design requirements and test data are used as inputs for the development of structural system archetypes in Chapter 4. Quality ratings for design requirements and test data are used to assess total uncertainty in Chapter 7.

3.2 Intended Applications and Expected Performance

A description of the intended applications and expected performance of a proposed seismic-force-resisting system is required. This description should include: (1) the anticipated function and occupancy; (2) physical and behavioral characteristics of the system; (3) typical geometric configurations; and (4) any similarities or differences between the proposed system and current code-conforming systems. The description should also indicate how the structural system and its key components are expected to perform in an earthquake.

The following information should be used as a guide for describing the intended applications of a proposed seismic-force-resisting system:

- intended occupancies and use of facilities to be constructed using the proposed system,

- horizontal and vertical configurations (e.g., framing layout, spans, story heights, overall heights) of typical facilities to be constructed using the proposed system,
- structural gravity framing systems to be used in combination with the proposed system, including typical dead and live loads,
- geometric configurations of the proposed seismic-force-resisting system,
- expected inelastic behavior under seismic loading of varying intensity, and
- methods of construction.

3.3 Design Requirements

Design requirements establish the fundamental information that will be used to proportion and detail components, analyze the predicted response, and confirm the behavior of a proposed system. They also set boundaries in the application of the system. Design requirements are an essential input to the development of structural system archetypes in Chapter 4. Information needed to define and document system design requirements is specified in the sections that follow.

3.3.1 Basis for Design Requirements

Design requirements should be based on criteria specified in applicable sections of the latest edition of ASCE/SEI 7, *Minimum Design Loads for Buildings and Other Structures* (ASCE, 2006a), and other applicable material reference standards, such as ACI 318, *Building Code Requirements for Structural Concrete* (ACI, 2005), AISC/ANSI 341, *Seismic Provisions for Structural Steel Buildings* (AISC, 2005), ACI 530/ASCE 5/TMS 402, *Building Code Requirements for Masonry Structures* (ACI, 2002b), and ANSI/AF&PA, *National Design Specification for Wood Construction* (ANSI/AF&PA, 2005). The following statements, taken mostly from the *NEHRP Recommended Provisions for Seismic Regulations for New Buildings and Other Structures* (FEMA, 2004a), should be used as a basis for developing design requirements:

- The structure shall include complete lateral- and vertical-force-resisting systems capable of providing adequate strength, stiffness, and energy dissipation capacity to withstand the design ground motions within the prescribed limits of deformation and strength demand.
- Design ground motions shall be assumed to occur along any direction of the structure.

- Adequacy of the systems shall be demonstrated through construction of a mathematical model, and evaluation of this model for the effects of design ground motions. This evaluation shall be based on analysis in which design seismic forces are distributed and applied throughout the height of the structure in accordance with the ASCE/SEI 7-05.
- Deformations and internal forces in all members of the structure shall be determined and evaluated against acceptance criteria contained or referred to in ASCE/SEI 7-05, and as developed for the system under consideration.
- A continuous load path, or paths, shall be provided with adequate strength and stiffness to transfer all forces from the point of application to the final point of resistance.
- The foundation shall be designed to accommodate forces developed or movements imparted to the structure by design ground motions. In determining foundation design criteria, special recognition shall be given to the dynamic nature of the forces, the expected ground motions, and the design basis for strength and energy dissipation capacity of the structure.
- Design of a structure shall consider potentially adverse effects on the stability of the structure due to failure of a member, connection, or component of the seismic-force-resisting system.

3.3.2 Application Limits and Strength Limit States

The boundaries of the intended application of the proposed seismic-force-resisting system must be clearly stated, including, for example, any proposed height limitations or restrictions to certain Seismic Design Categories.

Design requirements must address material properties, components, connections, assemblies, and seismic-force-resisting system overall behavior. With generally accepted modeling criteria and good engineering judgment, design requirements should be of sufficient detail that analytical models of component behavior can be developed. They must address the details of stiffness models for members, connections, assemblies, and the overall system, recognizing that seismic performance factors will be used in the context of linear analyses and response to equivalent static forces. Where size effects are important, they must be included.

Design requirements must provide information necessary to quantify all pertinent strength limit states, including:

- tension, compression, bending, shear;
- yield, rupture, brittle fracture;

- local, member, and global instability.

Proposed systems that rely on standard structural materials, or minor modifications to existing, proven systems, can reference much of the requirements to existing standards. However, such references must be clearly justifiable and verifiable. New systems that behave outside the bounds of existing system behavior must include consideration of behavioral effects on other elements of building construction, including the gravity load system and nonstructural components.

3.3.3 Overstrength Design Criteria

It is expected that most seismic-force-resisting systems will rely on inelastic behavior somewhere within the system. Overstrength criteria should be applied to the design of components that are judged to have small inelastic deformation capacity followed by rapid deterioration in strength. This is especially important if the component is also an essential part of the gravity load system. Design requirements should be written in a manner that clearly identifies all such components so that it is not left up to the judgment of the designer to make this identification.

Design procedures utilizing linear static equivalent lateral force analyses should follow the current standard method of requiring that such components be designed for gravity loads plus Ω_0 times the seismic loads, or for the maximum forces that can be delivered to the component by other elements in the system. It is understood that the overstrength factor used for this purpose is based on judgment, and can vary by a large amount depending on system configuration. To provide adequate protection, this factor should be a high estimate of the expected ratio of maximum force to design force, particularly for systems or materials that are non-ductile or have significant variability or uncertainty in response.

3.3.4 Configuration Issues

Design requirements should comprehensively address all expected system configurations. Emphasis should be placed on criteria that protect against the occurrence of non-ductile failure modes and unintended concentration of inelastic action in limited portions of the system.

When determining the design strength of components that are affected by combined actions, such as axial-shear force interaction, consideration should be given to system configurations that might have an effect on the magnitude of combined loads. Beneficial effects of gravity loading must not be permitted in configurations that result in little or no gravity load on seismic-

force-resisting components. Similarly, possible detrimental effects of induced vertical loads should be considered in configurations that generate high axial loads on seismic-force-resisting components.

Design requirements should address issues of multi-directional loading, and simultaneous in-plane and out-of-plane loading, unless the combined load effects are demonstrated to be unimportant.

3.3.5 Material Properties

Design requirements should document all material properties that will serve as reference values for design of components, as well as criteria for determining and measuring these properties. Documentation is not needed for material properties that are prescribed in existing codes and material reference standards. To the extent possible, the experimental determination of material properties should be based on testing procedures specified in ASTM standards. Material properties of interest include:

- tensile, compressive, and shear stress and strain properties,
- friction properties between parts that might possibly slide,
- bond properties at the interface of two materials, and
- other properties on which component behavior depends strongly.

In the determination of material properties, consideration should be given to the simulation of common field conditions during testing, including confinement conditions (e.g., bi-axial or tri-axial states of stress or strain), environmental effects (e.g., temperature, moisture, solar radiation), and cyclic loading. Effects of aging should be quantified, if deemed important to seismic behavior.

Design requirements should include criteria for field testing of material properties for systems in which the reference properties depend strongly on case-specific mix proportions, placement, curing or other similar aspects of construction.

3.3.6 Strength and Stiffness Requirements

Design requirements should contain comprehensive guidance for the determination of design strength and effective elastic stiffness of structural components, and assemblies of components.

- **Stiffness requirements.** Guidance on determination of the effective elastic stiffness of structural components should be provided. The effective elastic stiffness is defined as the stiffness that, if utilized in an

analytical model, will provide a good estimate of the story drift demand at the design level.

- **Component strength requirements.** The nominal strength of a component should be expressed in terms of material properties, and quantified for the range of loads, and combinations of loads, that might be experienced as the system is subjected to collapse-level ground motions.

  Uncertainty inherent in a strength design equation, as well as the severity of the consequence of failure, should be reflected in the resistance factor (ϕ-factor) associated with the strength design equation. Resistance factors calibrated for use with common gravity load combinations are recommended for use. Although these factors may not be anchored in reliability analyses for seismic load combinations, design requirements will be utilized in conjunction with linear analyses and equivalent static forces, and the use of resistance factors will have an important effect on the overall capacity of the system.

  If the strength or deformation capacity of one component is affected significantly by interaction with other components, then this interaction should be accounted for in design equations.

  If a component is subjected to a load effect, or combination of load effects, that will cause rapid deterioration in strength in the inelastic range, then this load effect, or this combination of load effects, must be clearly identified as a non-ductile mode, and should trigger overstrength design criteria.

  Design requirements should be specific about component detailing needed to ensure adequate strength during inelastic deformation.

- **Connection strength requirements.** Design requirements should be specific about design of connections. In general, connections are considered to be non-ductile. If a proposed system is based on a ductile connection, then design requirements must clearly result in connections that will have sufficient deformation capacity to avoid significant deterioration before any of the connected components reach their expected limits.

- **Sensitivity to gravity loads.** Where the strength of a member or connection is sensitive to compression or tension from gravity loads, design requirements must account for the effect of vertical ground motions. Standard factors in existing standards for additive effects ($1.2 + 0.2S_{DS}$) and counteracting effects ($0.9 – 0.2S_{DS}$) may be used only if justified through studies on structural system archetypes.

3.3.7 *Approximate Fundamental Period*

The design requirements should include formulas for calculation of the approximate fundamental period, T_a, when the formulas of Section 12.8.2.1 of ASCE/SEI 7-05 do not apply to the system of interest (e.g., when the approximate period parameters given in Table 12.8-2 of ASCE/SEI 7-05 for "all other structural systems" are not appropriate). The formula(s) for T_a should provide an estimate of the mean minus one sigma value of the actual first mode period of buildings in which the system is utilized.

3.4 Quality Rating for Design Requirements

Quality of information is related to uncertainty, which factors into the performance evaluation for a proposed seismic-force-resisting system. The quality of the proposed design requirements is rated in accordance with the requirements of this section, and approved by the peer review panel.

Design requirements are rated between (A) Superior and (D) Poor, as shown in Table 3-1. The selection of a quality rating considers the completeness and robustness of the design requirements, and confidence in the basis for the design equations. Quantitative values of design requirements-related collapse uncertainty are: (A) Superior, $\beta_{DR} = 0.10$; (B) Good, $\beta_{DR} = 0.20$; (C) Fair, $\beta_{DR} = 0.35$; and (D) Poor, $\beta_{DR} = 0.50$. Use of these values is described in Section 7.3.

Table 3-1 Quality Rating of Design Requirements

Completeness and Robustness	Confidence in Basis of Design Requirements		
	High	**Medium**	**Low**
High. Extensive safeguards against unanticipated failure modes. All important design and quality assurance issues are addressed.	(A) Superior $\beta_{DR} = 0.10$	(B) Good $\beta_{DR} = 0.20$	(C) Fair $\beta_{DR} = 0.35$
Medium. Reasonable safeguards against unanticipated failure modes. Most of the important design and quality assurance issues are addressed.	(B) Good $\beta_{DR} = 0.20$	(C) Fair $\beta_{DR} = 0.35$	(D) Poor $\beta_{DR} = 0.50$
Low. Questionable safeguards against unanticipated failure modes. Many important design and quality assurance issues are not addressed.	(C) Fair $\beta_{DR} = 0.35$	(D) Poor $\beta_{DR} = 0.50$	--

The highest rating of (A) Superior applies to systems that include a comprehensive set of design requirements that provide safeguards against unanticipated failure modes. Therefore, for a superior rating, there must be a

high level of confidence that the design requirements produce the anticipated structural behavior. Existing code requirements for special concrete moment frames and special steel moment frames, for example, have been vetted with detailed experimental results and documented performance in earthquakes. Design and detailing provisions include capacity design requirements to safeguard against unanticipated behaviors. A set of design requirements such as these would be rated (A) Superior.

The lowest rating of (D) Poor applies to design requirements that have minimal safeguards against unanticipated failure modes, do not ensure a hierarchy of yielding and failure, and would generally be associated with systems that exhibit behavior that is difficult to predict.

3.4.1 Completeness and Robustness Characteristics

Completeness and robustness characteristics are related to how well the design requirements address issues that could potentially lead to unanticipated failure modes, as well as proper implementation of designs through fabrication, erection and final construction. Completeness and robustness characteristics are rated from high to low, as follows:

- **High.** Design requirements are extensive, well-vetted and provide extensive safeguards against unanticipated failure modes. They establish a definite hierarchy of component yielding and failure. All important issues regarding system behavior have been addressed, resulting in a high reliability in the behavior of the system. Through mature construction practices, and tightly specified quality assurance requirements, there is a high likelihood that the design provisions will be well executed through fabrication, erection and final construction.
- **Medium.** Design requirements are reasonably extensive and provide reasonable safeguards against unanticipated failure modes, leaving some limited potential for the occurrence of such modes. Design requirements establish a suggested hierarchy of component yielding and failure. While most important behavioral issues have been addressed, some have not, which somewhat reduces the reliability of the system. Quality assurance requirements are specified but do not fully address all the important aspects of fabrication, erection and final construction.
- **Low.** Design requirements provide questionable safeguards against unanticipated failure modes. Hierarchy of component yielding and failure has been only marginally addressed (if at all), and there is a likelihood of the occurrence of unanticipated failure modes. Design requirements do not address all important behaviors, resulting in

marginally reliable behavior of the system. Quality assurance is lacking, written guidance is not provided, and construction practices are not well-developed for the type of system and materials.

Simplified, but conservative, design requirements by themselves are not a reason for a low Completeness and Robustness rating as long as conservatism is quantifiable in the context of unanticipated failure modes.

3.4.2 Confidence in Design Requirements

Confidence in the basis of the design requirements refers to the degree to which the prescribed material properties, strength criteria, stiffness parameters, and design equations are representative of actual behavior and will achieve the intended result. Confidence is rated from high to low, as follows:

- **High.** There is substantiating evidence (experimental data, history of use, similarity with other systems) that results in a high level of confidence that the properties, criteria, and equations provided in the design requirements will result in component designs that perform as intended.
- **Medium.** There is some substantiating evidence that results in a moderate level of confidence that the properties, criteria, and equations provided in the design requirements will result in component designs that perform as intended.
- **Low.** There is little substantiating evidence (little experimental data, no history of use, no similarity with other systems) that results in a low level of confidence that the properties, criteria, and equations provided in the design requirements will result in component designs that perform as intended.

3.5 Data from Experimental Investigation

Analytical modeling alone is not adequate for predicting nonlinear seismic response with confidence, particularly for structural systems that have not been subjected to past earthquakes. A comprehensive experimental investigation program is necessary to establish material properties, develop design criteria, calibrate and validate component models, confirm behavior, and calibrate analyses for a proposed seismic-force-resisting system. Experimental results from other testing programs can be used to supplement an experimental investigation program, but these results must come from reliable sources, and their applicability to the system under consideration must be demonstrated.

There are practical limitations on how comprehensive an experimental testing program can be. It must be understood, however, that limitations on available experimental data will affect the uncertainty and reliability of the collapse assessment of a proposed system, and will factor directly into the performance evaluation process. The scope of an experimental investigation program should be developed in consultation with the peer review panel.

3.5.1 Objectives of Testing Program

Testing is used to develop basic information so that the combination of experimental and analytical data is sufficient to achieve the following two objectives:

- Predict the seismic response of structures in the regime of interest to the establishment of seismic performance factors, which occurs when the structure, or any portion of the structure, is subjected to large seismic demands and approaches a state of lateral dynamic instability (collapse). This implies the need to model strength and stiffness properties of important components, and reliably capture structural response, from elastic behavior through the state of lateral dynamic instability, over the entire range of possible structural configurations permitted by the design requirements.
- Develop and validate standardized engineering design criteria that can be used to design structures that perform as expected, given the specified seismic performance factors.

Achievement of these objectives requires a coordinated material, component, connection, assembly, and system testing program that will provide the following information:

- **Material test data.** Data that serve as reliable reference values for the prediction of strength, stiffness, and deformation properties of structural components and connections under earthquake loading.
- **Component and connection test data.** Information needed to develop and calibrate design criteria and analytical models of cyclic load-deformation characteristics for components and connections that form an essential part of the seismic-force-resisting system.
- **Assembly and system test data.** Information needed to quantify interactions between structural components and connections that cannot be predicted by analysis with confidence.

3.5.2 General Testing Issues

In developing a comprehensive testing program, the following issues should be considered:

- **Cumulative damage effects.** Structural materials and components experience history-dependent cumulative damage during repeated cyclic loading. The loading history used in testing should be representative of the cyclic response that a material, component, connection, or assembly would experience as part of a typical structural system subjected to a severe earthquake.
- **Size effects.** Tests should be performed on full-size specimens unless it can be shown by theory and experiment that testing of reduced-scale specimens will not significantly affect behavior.
- **Strain rate effects.** If the load-deformation characteristics of the specimen are sensitive to strain rate effects, then testing should be done at strain rates commensurate with those that would be experienced in a severe earthquake.
- **Boundary conditions.** The boundary conditions of component and assembly tests should be: (1) representative of constraints that a component or assembly would experience in a typical structural system; and (2) sufficiently general so that the results can be applied to boundary conditions that might be experienced in other system configurations. Boundary conditions should not impose beneficial effects on seismic behavior that would not exist in common system configurations.
- **Load application.** Loads should be applied to test specimens in a manner that replicates the transfer of forces to the component or assembly commonly occurring in in-situ conditions.
- **Configuration and number of component/assembly test specimens.** The configuration and number of component and assembly test specimens should be such that all common failure modes that could occur in typical system configurations are represented and evaluated. Emphasis should be on the detection and evaluation of failure modes that lead to a rapid deterioration in strength (e.g., brittle failure modes).
- **Interaction between structural components.** Test configurations should consider important interactions between structural components, unless these interactions can be predicted with confidence by analysis.
- **Direction(s) of loading.** Structural components that resist seismic forces in more than one direction (e.g., concrete core walls) should be tested

such that the combined load effects are adequately considered, unless these effects can be predicted with confidence by analysis.

- **In-plane and out-of-plane load effects.** Planar structural components (e.g., walls, diaphragms) should be subjected to simultaneous in-plane and out-of-plane loading, unless these effects can be superimposed with confidence by analysis.
- **Gravity load effects.** Effects of gravity loads should be considered in the experimental program, unless these effects can be superimposed on lateral load effects with confidence by analysis.
- **Statistical variability.** A sufficiently large number of tests should be performed so that statistical variations can be evaluated from the data directly, or can be deduced in combination with data from other sources.
- **Environmental conditions.** If environmental conditions during construction or service (e.g., temperature, humidity) will significantly affect behavior, then the range of conditions that could exist in practice should be simulated during testing.
- **Test specimen construction.** Specimens should be constructed in a setting that simulates commonly encountered field conditions. For example, if field conditions necessitate overhead welding then this type of welding should be applied in test specimen construction.
- **Quality of test specimen construction.** Construction of component, connection, assembly, and system specimens should match the level of quality that will be commonly implemented in the field. Special construction techniques or quality control measures should not be employed, unless they are part of the design requirements.
- **Past experience.** Laboratory testing cannot fully replace experience gained from observation of system behavior in actual use. A benefit should be given to structural systems whose performance has been documented in past earthquakes or other use.
- **Documentation of tests and test results.** Documentation of experiments should be comprehensive, and should include: (1) geometric data, test setup, and boundary conditions; (2) important details of the test specimen, including construction process and fabrication details; (3) type and location of instruments used for measurement of important response parameters; (4) material test data needed for performance evaluation; (5) a written record of all important events prior and during the test; (6) a comprehensive log of all important visual observations; and (7) a

comprehensive set of digital experimental data needed for performance evaluation.

The above list should be used as a guide. There may be other issues that are equally important to a given system, but cannot be placed in a general context. Assistance in the identification of important testing issues can be obtained from references available in the literature (e.g., ACI, 2001; AISC, 2005; ASTM, 2003; ATC, 1992; Clark et al., 1997; FEMA, 2007; and ICC, 2009). Specimen fabrication, testing procedures, loading protocol, and test documentation should follow guidelines established in these references as appropriate for the system being evaluated, and as approved by the peer review panel.

Testing laboratories used to conduct an experimental investigation program should comply with national or international accreditation criteria, such as the ISO/IEC 17025 *General Requirements for the Competence of Testing and Calibration Laboratories* (ISO/IEC, 2005). Testing Laboratories that are not accredited may be used for the experimental investigation program, subject to approval by the peer review panel.

3.5.3 Material Testing Program

A material testing program is required to provide reliable stress-strain relationships for the prediction of strength, stiffness, and deformation properties of structural components and connections under the type of loading experienced during an earthquake. In addition to general testing issues, materials testing should consider the following:

- low-cycle fatigue and fracture properties,
- bi-axial and tri-axial stress conditions,
- utilization of applicable ASTM Standards,
- evaluation of variability in material properties,
- effects of aging, and
- effects of environmental conditions.

Material testing programs should be performed in accordance with all applicable ASTM Standards and other testing criteria specified in nationally accepted industry standards and specifications. Material test data available from past tests that conform to all applicable standards may be used.

3.5.4 *Component, Connection, and Assembly Testing Program*

A component, connection, and assembly testing program is required to provide information for the development, calibration, and validation of analytical models of cyclic load-deformation characteristics of components and connections that form an essential part of the seismic-force-resisting system, as well as development of the design criteria for such components and connections.

Components, connections, and assemblies that have low inelastic deformation capacities (commonly referred to as non-ductile elements) must be identified, and should undergo sufficient testing to validate both the design strength of such elements as well as the strength properties used in the analytical models employed in the collapse assessment.

Testing of Structural Components

Component testing serves to identify and quantify component parameters that significantly affect seismic response. Cyclic behavior is characterized by a basic hysteresis loop, which deteriorates with the number and amplitude of cycles. It is critical that a test is continued until severe strength deterioration is evident, and all important characteristics that enter design equations and analytical models have been verified experimentally. Two hysteretic responses of a structural component (in this case a steel beam and a plywood panel) are shown in Figure 3-2. In the left figure it appears that the loops stabilize at very large amplitudes, and that more (and larger) deformation cycles can be sustained. However, the possibility of fracture at large deformations is high, and once this fracture occurs, the resistance will deteriorate, rapidly approaching zero. For this reason, no credit should be given to residual strength beyond the deformation at which the test is terminated.

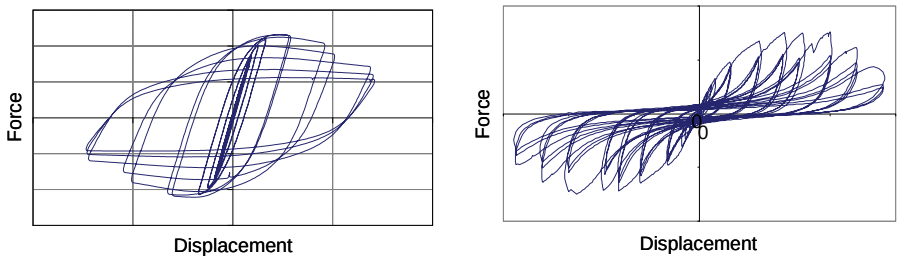

Figure 3-2 Characteristics of force-deformation response: (a) steel beam (Uang et al. 2000); (b) plywood shear wall panel (Gatto and Uang, 2002).

A sufficiently large number of tests should be performed so that important statistical variations can be evaluated from the data directly, or can be deduced in combination with data from other sources. A minimum of two tests is required for each set of primary variables in a test configuration. If rapid deterioration occurs, such as that caused by brittle fracture, a minimum of three tests should be performed. If rapid deterioration is not of concern, it is recommended that one of the tests be a monotonic loading test, which facilitates analytical modeling of the type discussed in Sections 5.4 and 5.5.

Component tests are conducted for the purpose of evaluating all force and deformation characteristics that have a significant effect on the seismic response up to the state of incipient collapse. Gravity loads should be represented, unless it can be shown that their effect is not detrimental to the seismic behavior or can be predicted with confidence from analytical models. The load application and loading history should be representative of what components will experience as part of a typical structural system subjected to a severe earthquake. Instrumentation should permit the measurement of all relevant stiffness and strength properties.

In contrast to "qualification testing", which is intended to gain approval of the use of certain components for specific applications, the main objectives of these component tests are to develop design criteria and to calibrate and validate nonlinear models that are used in collapse assessment. Types and configurations of component tests, together with the loading protocol, should be planned in conjunction with development of the nonlinear analysis models in Chapter 5.

Testing of Connections

A connection is the medium that transfers forces and deformations between adjacent components. Connections should be tested in configurations that simulate gravity load effects as well as seismic load effects, unless gravity loading results in more favorable connection behavior. Connection tests should provide all information necessary to develop connection design criteria in conformance with the latest edition of ASCE/SEI 7-05, and to permit simulation of connections in analytical models.

Testing of Assemblies

An assembly is an arrangement of structural components whose seismic behavior can be described in terms of a single response quantity, such as story drift. An assembly testing program is required if important interactions between adjacent components (or between components and connections) cannot be deduced with confidence from a combination of material,

component, and connection tests in combination with analytical modeling. Unless strain-rate effects are important, assembly tests can be performed by imposing load(s) to control point(s) in a quasi-static manner, following a predetermined loading history.

3.5.5 Loading History

Structural elements have limited strength and deformation capacities. Collapse safety depends on the ability to assess these capacities with some confidence. Strength and deformation capacities depend on cumulative damage, which implies that every component has a "memory" of past damaging events, and that all past excursions (or cycles) that have contributed to its current state of health will affect future behavior. Thus, performance depends on the history of previously applied damaging cycles, and assessing the consequences of loading history requires replication of the load and deformation cycles that a component will undergo in an earthquake (or several earthquakes, if appropriate). The objective of a loading history is to achieve this in an approximate, but consistent manner.

There is no unique or best loading history, because no two earthquakes are alike, and a specimen may be part of many different structural configurations. The overriding issue is to account for cumulative damage effects through cyclic loading. The number and amplitude of cycles applied to the specimen may be derived from analytical studies in which models of representative structural systems are subjected to representative earthquake ground motions, and the response is evaluated statistically. In analytical modeling, it should be assumed that specimen resistance deteriorates to zero following the maximum amplitude executed in the test. No credit should be given to deformation capability beyond the largest deformation that a specimen experiences in a test.

Many loading protocols have been proposed in the literature, and several have been used in multi-institutional testing programs (e.g., ATC, 1992; Clark et al., 1997; Krawinkler et al., 2000), or are contained in standards or are proposed for standards (e.g., AISC, 2005; ASTM, 2003; FEMA, 2007; ICC, 2009). These protocols recommend somewhat different loading histories, but they differ more in detail than in concept. Comprehensive discussions of loading histories and their origin and objectives are presented in Filiatrault et al. (2008), Krawinkler et al. (2000), and Krawinkler (1996).

The loading protocols referenced above have been developed with a design level or maximum considered ground motion in mind, and not for the purpose of collapse evaluation. As a result the loading histories are

symmetric with step-wise increasing deformation cycles (with the exception of the SAC near-fault loading protocol presented in Clark et al., 1997). While such histories are not representative of cyclic response approaching collapse, they do serve the purpose of quantifying deterioration properties for analytical modeling, particularly if a cyclic test is complemented with a monotonic loading test that provides information on the force-displacement capacity boundary (FEMA, 2009).

Loading history should be deformation-controlled, with the following two exceptions:

- Force-control may be applied for small excursions in which a component will remain essentially elastic. Force-control is encouraged for stiff specimens tested in a relatively flexible test set-up, in order to facilitate measurements and test control in the early stages of testing.
- Force-control may be necessary to test components that are an essential part of the load path, but are fully force-controlled in the in-situ condition, and have no reliable inelastic deformation capacity. One such example would be an anchor controlled by the maximum force exerted by a connected component. In such a case, the loading history should be determined based on the strength and deformation capacities of the connected component. Criteria for a force-controlled loading history are presented in FEMA 461 *Interim Testing Protocols for Determining the Seismic Performance Characteristics of Structural and Nonstructural Components* (FEMA, 2007).

3.5.6 System Testing Program

Testing of an essentially complete structural system should be performed if important response characteristics or important interactions between components and connections cannot be evaluated with good confidence by analytical models that have been calibrated through material, component, connection, or assembly tests.

System tests should be used as a validation tool for a proposed analytical model rather than as an exploratory test from which analytical models will be developed. System tests should not be used to replace any testing at the material, component, connection, or assembly level.

Dynamic System Tests

A dynamic system test should be performed if the response near collapse depends strongly on dynamic characteristics that cannot be predicted with good confidence by analytical models or from component or assembly tests.

Such a test should be performed on an earthquake simulator (shake table) utilizing realistic MCE-level (or collapse level) ground motions, unless it can be demonstrated that equivalent response evaluation can be achieved through alternative means.

Quasi-Static System Tests

Quasi-static cyclic testing consists of loads that are applied to one or more control points by means of hydraulic actuators whose displacement or load values are varied in a cyclic manner in accordance with a predetermined loading history. The loading history used in testing should be representative of the cyclic response that a material, component, connection, or assembly would experience as part of a typical structural system subjected to a severe earthquake.

A quasi-static system test should be performed if important behaviors or interactions between components and connections cannot be evaluated with good confidence by means of calibrated analytical models. Examples include interactions between horizontal and vertical components (floor diaphragms and vertical seismic-force-resisting units) and between vertical components that resist seismic forces in orthogonal directions.

3.6 Quality Rating of Test Data

Quality of test data is related to uncertainty, which factors into the performance evaluation for a proposed seismic-force-resisting system. The quality of test data obtained from an experimental investigation program is rated in accordance with the requirements of this section, and approved by the peer review panel.

Test data are rated between (A) Superior and (D) Poor, as shown in Table 3-2. This rating depends not only on the quality of the testing program, but on how well the tests address key parameters and behavioral issues. The selection of a quality rating for test data considers the completeness and robustness of the overall testing program, and confidence in the test results. Quantitative values of test data-related collapse uncertainty are: (A) Superior, $\beta_{TD} = 0.10$; (B) Good, $\beta_{TD} = 0.20$; (C) Fair, $\beta_{TD} = 0.35$; and (D) Poor, $\beta_{TD} = 0.50$. Use of these values is described in Section 7.3.

Table 3-2 Quality Rating of Test Data from an Experimental Investigation Program

Completeness and Robustness	Confidence in Test Results		
	High	Medium	Low
High. Material, component, connection, assembly, and system behavior well understood and accounted for. All, or nearly all, important testing issues addressed.	(A) Superior $\beta_{TD} = 0.10$	(B) Good $\beta_{TD} = 0.20$	(C) Fair $\beta_{TD} = 0.35$
Medium. Material, component, connection, assembly, and system behavior generally understood and accounted for. Most important testing issues addressed.	(B) Good $\beta_{TD} = 0.20$	(C) Fair $\beta_{TD} = 0.35$	(D) Poor $\beta_{TD} = 0.50$
Low. Material, component, connection, assembly, and system behavior fairly understood and accounted for. Several important testing issues not addressed.	(C) Fair $\beta_{TD} = 0.35$	(D) Poor $\beta_{TD} = 0.50$	--

3.6.1 Completeness and Robustness Characteristics

Completeness and robustness characteristics are related to: (1) the degree to which relevant testing issues have been considered in the development of the testing program; and (2) the extent to which the testing program and other documented experimental evidence quantify the necessary material, component, connection, assembly, and system properties and important behavior and failure modes. Completeness and robustness characteristics are rated from high to low, as follows:

- **High.** All, or nearly all, important general testing issues of Section 3.5.2 are addressed comprehensively in the testing program and other supporting evidence. Experimental evidence is sufficient so that all, or nearly all, important behavior aspects at all levels (from material to system) are well understood, and the results can be used to quantify all important parameters that affect design requirements and analytical modeling.
- **Medium.** Most of the important general testing issues of Section 3.5.2 are addressed adequately in the testing program and other supporting evidence. Experimental evidence is sufficient so that all, or nearly all, important behavior aspects at all levels (from material to system) are generally understood, and the results can be used to quantify or deduce most of the important parameters that significantly affect design requirements and analytical modeling.
- **Low.** Several important general testing issues of Section 3.5.2 are not addressed adequately in the testing program and other supporting

evidence. Experimental evidence is sufficient so that the most important behavior aspects at all levels (from material to system) are fairly well understood, but the results are not adequate to quantify or deduce, with high confidence, many of the important parameters that significantly affect design requirements and analytical modeling.

3.6.2 Confidence in Test Results

Confidence in test results is related to the reliability and repeatability of the results obtained from the testing program, and corroboration with available results from other relevant testing programs. It includes consideration as to whether or not experimental results consistently record performance to failure for all modes of behavior (limited ductility to large ductility), and if sufficient information is provided to assess uncertainties in the design requirements (e.g., ϕ factors) and analytical models. Confidence in test results is rated from high to low, as follows:

- **High.** Reliable experimental information is produced on all important parameters that affect design requirements and analytical modeling. Comparable tests from other testing programs have produced results that are fully compatible with those from the system-specific testing program. A sufficient number of tests are performed so that statistical variations in important parameters can be assessed. Test results are fully supported by basic principles of mechanics.
- **Medium.** Moderately reliable experimental information is produced on all important parameters that affect design requirements and analytical modeling. Comparable tests from other testing programs do not contradict, but do not fully corroborate, results from the system-specific testing program. A measure of uncertainty in important parameters can be estimated from the test results. Test results are supported by basic principles of mechanics.
- **Low.** Experimental information produced on many of the important parameters that affect design requirements and analytical modeling is of limited reliability. Comparable tests from other testing programs do not support the results from the system-specific testing program. Insufficient data exists to assess uncertainty in many important parameters. Basic principles of mechanics do not support some of the results of the testing program.

Chapter 4
Archetype Development

This chapter describes the development of structural system *archetypes*, which provide a systematic means for characterizing key features and behaviors related to collapse performance of a proposed seismic-force-resisting system. It defines how archetype descriptions and performance characteristics are used to develop a set of building configurations (*index archetype configurations*) that together describe the overall range of permissible configurations (*archetype design space*) of a system, which is then separated into groups sharing common features or behavioral characteristics (*performance groups*) for assessing collapse performance. Specific structural designs (*index archetype designs*) are then developed for each configuration based on the specified design criteria, and these designs then form the basis of nonlinear analysis models (*index archetype models*) that are analyzed to assess collapse performance. Guidelines related to index archetype designs and index archetype models are presented in Chapter 5.

4.1 Development of Structural System Archetypes

Behavior of a proposed seismic-force-resisting system is investigated through the use of archetypes. An *archetype* is a prototypical representation of a seismic-force-resisting system. Archetypes are intended to reflect the range of design parameters and system attributes that are judged to be reasonable representations of the feasible design space and have a measurable impact on system response. They are used to bridge the gap between collapse performance of a single specific building and the generalized predictions of behavior needed to quantify performance for an entire class of buildings.

An *index archetype configuration* is a prototypical representation of a seismic-force-resisting system configuration that embodies key features and behaviors related to collapse performance when the system is subjected to earthquake ground motions. Given that building codes permit significant latitude with respect to system configurations within a building class, index archetype configurations are not intended to represent every conceivable configuration of the system of interest. Rather, the intent is to investigate a reasonably broad range of parameters that are permitted by the specified design requirements and represent conditions that are feasible in design and construction practice.

Collectively, the set of index archetype configurations describe the *archetype design space*, which defines the overall range of permissible configurations, structural design parameters, and other properties that define the application limits for a seismic-force-resisting system. For performance evaluation, the archetype design space is divided into *performance groups*, which are groups of index archetype configurations that share a common set of features or behavioral characteristics.

Development of structural system archetypes follows the process outlined in Figure 4-1. Using the design requirements and test data developed under Chapter 3 as inputs, the development of structural system archetypes considers both structural configuration issues and seismic behavioral effects.

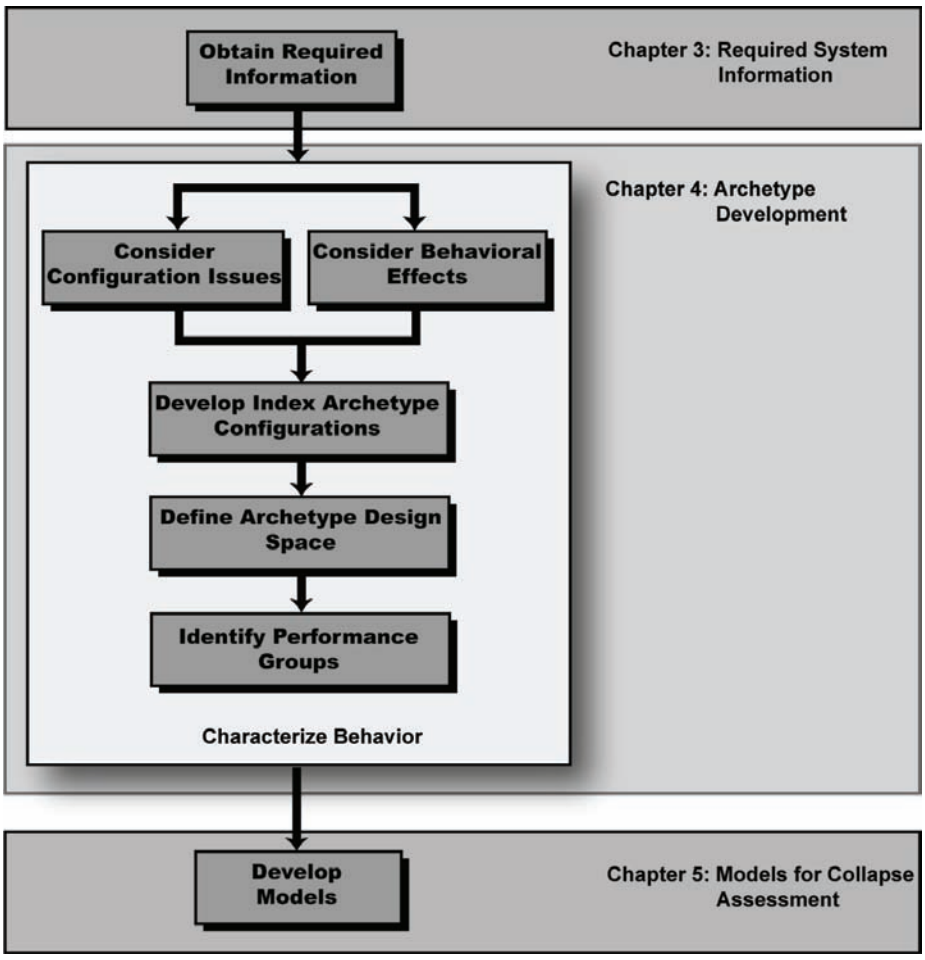

Figure 4-1 Process for development of structural system archetypes.

4.2 Index Archetype Configurations

Index archetype configurations must be sufficiently broad in scope to capture the range of situations that are feasible under the design requirements, but sufficiently limited to be practical to evaluate. The intent is to both: (1)

assess situations that will be generally representative of practice that meets minimum specified requirements for seismic design and construction of a proposed seismic-force-resisting system; and (2) assess designs that are at the limits of the range of design configurations that are allowable based on the design requirements.

While index archetype configurations are not intended to represent every conceivable combination of design parameters, the archetype configurations must encompass the full design space permitted by the design requirements. An exception to this occurs when the collapse safety trends for the assessed archetype designs show that certain configurations will not control the system performance assessment.

Index archetype configurations should not incorporate "standard" practices that may routinely exceed minimum code requirements. For example, use of one member size at multiple locations in a building is a design and construction practice that can result in member overstrengths, which exceed minimum design requirements, and should not be built into index archetype configurations.

It is expected that the set of index archetype configurations will generally include about twenty to thirty specific structural configurations, though the specific number will depend on the characteristics of the seismic-force-resisting system and the limits of the archetype design space. Where the seismic design requirements are relatively loose and cover a broad range of possible design situations, the number of required index archetype configurations may be significantly larger than for systems with more limited applications. The final selection of index archetype configurations, and their corresponding design parameters, should be reviewed and approved by the peer review panel.

The development of index archetype configurations involves the following steps:

- Identify key design variables and related physical properties based on structural configuration issues summarized in Section 4.2.1. Investigate physical properties that affect collapse performance to identify critical design variables that should be reflected in index archetype configurations.
- Establish bounds for key design variables that define the archetype design space. The design space is limited primarily by the seismic design requirements and practical constraints on design and construction.

- Identify behavioral issues and related design considerations based on behavioral effects summarized in Section 4.2.2. Investigate possible deterioration modes that could result in local and global collapse scenarios, and assess the likelihood of those scenarios.
- Develop a set of index archetype configurations based on key design variables and behavioral effects that are likely to result in local or global collapse scenarios.

4.2.1 Structural Configuration Issues

Structural configuration issues include occupancy and program influences, framing type and geometric variations, and gravity and lateral load intensities. Typical configuration design variables that can affect the behavior of a seismic-force-resisting system are summarized in Table 4-1. These structural issues should be used as a guide in establishing index archetype configurations, as follows:

- **Occupancy and Use.** Building occupancy and use can influence the structural layout, framing system, configuration, and loading intensity. Framing spans, story heights, and live loads for seismic-force-resisting systems intended for residential occupancies are usually quite different from office occupancies. Similarly, steel moment frames and associated gravity framing used for industrial occupancies can be different from those used for office or institutional buildings. Occupancies with large live load demands may have larger inherent overstrength in comparison with systems for other occupancies. Major changes in structural configuration resulting from different occupancies and use should be reflected in the index archetype configurations.
- **Elevation and Plan Configuration.** The range of elevation and plan configurations permitted by the system design requirements should be reflected in the index archetype configurations. This could include, for example: (1) the range of framing span lengths of the seismic-force-resisting system; (2) alternative configurations of steel bracing (e.g., chevron versus x-bracing); (3) variations in shear wall aspect ratios that result in flexure- versus shear-dominated behavior; (4) floor diaphragm characteristics that are addressed in the seismic system designation; and (5) the extent of gravity loading tributary to the system. The extent to which such factors are significant will vary depending on the type of seismic-force-resisting system.
- **Building Height.** The range of story heights and number of stories permitted by the system design requirements should be reflected in the index archetype configurations to the extent that these parameters affect

the structural period and the localization of inelastic deformations. Since the inelastic response of structures with short periods (in the constant acceleration region of the hazard spectrum) tends to be different from structures with longer periods (in the constant velocity region of the hazard spectrum), the response of short-period and long-period structures are characterized separately. Due to significant differences in the response characteristics of very tall buildings, and limited low frequency content in the ground motions specified for collapse assessment, use of this Methodology should be limited to buildings with a fundamental period of $T \leq 0.4$ seconds (i.e., building heights of about 20 to 30 stories for moment frame systems, and 30 to 40 stories for braced frame and shear wall systems).

Table 4-1 Configuration Design Variables and Related Physical Properties

Design Variable	Related Physical Properties
Occupancy and Use	• Typical framing layout • Distribution of seismic-force-resisting system components • Gravity load intensity • Component overstrength
Elevation and Plan Configuration	• Distribution of seismic-force-resisting components • Typical framing layout • Permitted vertical (strength and stiffness) irregularities • Beam spans, number of framing bays, system regularity • Wall length, aspect ratio, plan geometry, wall coupling • Braced bay size, number of braced bays, bracing configuration • Diaphragm proportions, strength, and stiffness (or flexibility) • Ratio of seismic mass to seismic-force-resisting components • Ratio of tributary gravity load to seismic load
Building Height	• Story heights • Number of stories
Structural Component Type	• Moment frame connection types • Bracing component types • Shear wall sheathing and fastener types • Isolator properties and types
Seismic Design Category	• Design ground motion intensity • Special design/detailing requirements • Application limits
Gravity Load	• Gravity load intensity • Typical framing layout • Ratio of tributary gravity load to seismic load • Component overstrength

- **Structural Component Type.** The extent that structural component types can vary within a given seismic-force-resisting system should be reflected in index archetype configurations. Examples include different types of moment connection details (e.g., welded, bolted, or reduced-beam section), steel bracing members (e.g., HSS, pipe, or W-shape), and light-frame wood shear wall sheathing, framing, and fasteners.
- **Seismic Design Category.** Systems should be evaluated for the highest (most severe) Seismic Design Category for which they are proposed, and then verified in lower Seismic Design Categories. Index archetype configurations within a Seismic Design Category should consider spectral intensities corresponding to the maximum and minimum values for that category, associated design and detailing requirements, and any restrictions on use that are keyed to Seismic Design Category.
- **Gravity Load.** Large gravity load demands can result in overstrength with respect to seismic demands. For some components (e.g., columns in moment frames) axial load ratio can significantly impact inelastic deformation capacity. The nature, magnitude and variation of gravity loads, including structure self weight, occupancy-related superimposed dead loads, and occupancy-related live loads should be considered, and design parameters that affect tributary gravity load, such as bay sizes and building height, should be reflected in the index archetype configurations. It is anticipated that, for most systems, two levels of gravity load (high and low) would be sufficient.

An example of how configuration issues are considered in the development of index archetype configurations for a special reinforced concrete moment frame system conforming to design requirements contained in ASCE/SEI 7-05 is provided in Appendix C.

4.2.2 Seismic Behavioral Effects

Consideration of seismic behavioral effects includes identifying dominant deterioration and collapse mechanisms that are possible, and assessing the likelihood that they will occur. How a component or system behaves under seismic loading is often influenced by configuration decisions, so behavioral effects and configuration issues should be considered concurrently in the development of index archetype configurations.

Seismic collapse resistance depends on the strength, stiffness, and deformation capacity of individual structural components and the overall seismic-force-resisting system. Each of these properties can be addressed directly through system design requirements, but each are also influenced by

aspects of the configuration that could change the way a system behaves across the range of an archetype design space. For example, requirements for ductile confinement of reinforced concrete columns will directly affect inelastic deformation capacity, but the magnitude of column axial load, which is influenced by elevation and plan configurations, also has a large impact.

Consideration of behavioral effects is used to help identify major changes in system behavior as the configuration varies. Once potential deterioration and collapse mechanisms are identified, they are addressed through one of the following methods: (1) by ruling out failure modes that are unlikely to occur based on system design and detailing requirements; (2) explicit simulation of failure modes through nonlinear analyses; or (3) evaluation of "non-simulated" failure modes using alternative limit state checks on demand quantities from nonlinear analyses.

Typical behavioral issues and related design considerations that can have an effect on the behavior of a seismic force-resisting system are summarized in Table 4-2.

Table 4-2 Seismic Behavioral Effects and Related Design Considerations

Behavioral Issue	Related Design Considerations
Strength	• Minimum design member forces • Calculated member forces • Capacity design requirements • Component overstrength
Stiffness	• Design member forces • Drift limits • Plan and elevation configuration • Calculated inter-story drifts • Diaphragm stiffness (or flexibility) • Foundation stiffness (or flexibility)
Inelastic deformation capacity	• Component detailing requirements • Member geometric proportions • Capacity design requirements • Calculated member forces • Redundancy of the seismic force-resisting system
Seismic Design Category	• Design ground motion intensity • Special design/detailing requirements
Inelastic system mobilization	• Building height and period • Diaphragm strength and stiffness • Permitted strength and stiffness irregularities • Capacity design requirements

These behavioral issues should be used as a guide in establishing index archetype configurations, as follows:

- **Strength.** Differences between design strength and calculated seismic demands should be reflected in the index archetype configurations. Design strength is a function of the design earthquake intensity, component detailing requirements, capacity design requirements, and overstrength resulting from gravity loads and other minimum load requirements. Calculated demands are a function of the structural configuration and gravity load (dead and live load) intensity. In cases where gravity load, minimum seismic or wind loads, other minimum loads, or stiffness considerations control, there can be significant overstrength relative to seismic design forces. Capacity design provisions control yielding by requiring strengths of certain components to be greater than would otherwise be required by minimum seismic design forces to protect them from inelastic demands.
- **Stiffness.** The elastic lateral stiffness of the seismic-force-resisting system affects the dynamic behavior, sensitivity to sidesway stability (P-delta) effects, and induced deformation demands on critical components. Stiffness is a function of the design earthquake intensity and imposed drift limits, system configuration, and relative stiffness (or flexibility) of certain key components, such as diaphragms or foundations. Index archetype configurations should take into account system types that are more sensitive to drift limits than others, and should identify configurations that probe limits on minimum stiffness within the system design requirements. Where behavior of certain elements (e.g., diaphragm or foundation flexibility), is likely to influence the performance of the system, these effects should be considered in the development of index archetype configurations. For example, in low-rise industrial structures with large floor plans and stiff seismic-force-resisting elements, flexibility of the floor and roof diaphragms could significantly alter the period of vibration of the system, and should, therefore, be considered.
- **Inelastic Deformation Capacity.** Inelastic deformation capacity of components is a function of design requirements, including detailing rules and capacity design provisions, member geometric proportions, and calculated member forces that can vary with structural configuration. Where the inelastic deformation capacity of components is influenced by the force distribution (such as differences in the level of axial forces in walls or columns), factors that influence force distribution (such as plan configuration) should be considered in the index archetype

configurations. The impact of structural redundancy on the distribution of inelastic deformations should also be reflected in the index archetype configurations.

- **Seismic Design Category.** Applicable Seismic Design Categories establish the design ground motion intensities, which influence seismic-force-resisting system strength and stiffness. Seismic Design Category designations can also trigger special design and detailing requirements that will influence component inelastic deformation capacity. Index archetype configurations should reflect behavioral effects that are influenced by the Seismic Design Categories for which a system is being proposed.
- **Inelastic System Mobilization.** Inelastic system mobilization is the extent to which inelastic action is distributed throughout the seismic-force-resisting system. Inelastic system mobilization is influenced by limits on stiffness and strength irregularities and other system design requirements such as strong-column-weak-beam criteria. Design and configuration decisions can affect whether yielding is distributed vertically across many stories or tends to concentrate in just a few stories. To the extent that the diaphragm design is specified as part of the lateral system, diaphragm strength and stiffness will influence the dynamic response and distribution of forces among the seismic-force-resisting elements. Index archetype configurations should identify and test configurations that are permitted by system design requirements, and will result in a lower bound of inelastic system mobilization.

An example of how behavioral effects are considered in the development of index archetype configurations for a special reinforced concrete moment frame system conforming to design requirements contained in ASCE/SEI 7-05 is provided in Appendix D.

4.2.3 Load Path and Components Not Designated as Part of the Seismic-Force-Resisting System

The complete load path of the seismic-force-resisting system should be considered when defining index archetype configurations. Only those components that are either specified in the design requirements of the seismic-force-resisting system, or otherwise have a significant effect on the system, should be incorporated in the archetype assessment. Portions of the structure that comprise the gravity load system, but are not specifically designed to resist seismic forces, should not be included as part of the index archetype configuration. However, the seismic mass and destabilizing

P-delta effects of the gravity system should be included in the index archetype models.

Conversely, potential failure modes of the gravity system, floor diaphragms, and collector elements need not be reflected in the index archetype configurations, unless those elements are specifically defined in the design requirements for the seismic-force-resisting system. While it is recognized that failure of gravity elements may trigger collapse, their design is usually considered through separate code requirements that are common to many seismic-force-resisting systems and specific to none. If the deformation demands at collapse of a proposed seismic-force-resisting system, however, are excessive relative to those normally experienced by other systems, typical controls for deformation compatibility of gravity framing may not be adequate. In such cases, special deformation criteria for gravity system components should be included in the design requirements for the proposed seismic-force-resisting system.

4.2.4 Overstrength Due to Non-Seismic Loading

Index archetype designs should reflect the inherent overstrength that results from earthquake and gravity load design requirements in addition to any other minimum force requirements that are specified by building code provisions that will always be applicable to a structure. For example, the minimum wind load requirements specified in ASCE/SEI 7-05 (10 psf on the projected surface area exposed to wind) are required in all structures, and should be considered when evaluating potential overstrength. Similarly, minimum seismic design force requirements, which are specified generally for all seismic force resisting systems, should be incorporated in index archetype designs.

Overstrength from design loading that could exist, but is not assured in all cases, should not be considered in the development of index archetype configurations. Such an example could include hurricane wind forces, or other similar location- or use-specific non-seismic loads, that would not apply to all buildings everywhere. Only non-seismic requirements that apply universally to all structures should be considered when evaluating potential overstrength relative to earthquake loading.

4.3 Performance Groups

Index archetype configurations are assembled into performance groups (or bins) that reflect major differences in configuration, design gravity and seismic load intensity, structural period, and other factors that may significantly affect seismic behavior within the archetype design space.

Performance groups should contain multiple index archetype configurations that reflect the expected range of permissible variation in size and other key parameters defined by the archetype design space. For example, each performance group should contain index archetype configurations that cover the range of building heights (up to the limits that can be assessed using the specified ground motions) permitted by the system design requirements.

Binning of index archetype configurations into performance groups provides the basis for statistical assessment of minimum and average collapse margin ratios for performance evaluation in Chapter 7. Performance group populations should not be made larger than necessary, biased towards certain configurations, or otherwise manipulated to bias the average collapse statistics for the bin. Binning of index archetype configurations into performance groups should be reviewed and approved by the peer review panel.

4.3.1 Identification of Performance Groups

As illustrated by the generic performance group table shown in Table 4-3, performance groups should be organized to consider: (1) basic structural configuration; (2) gravity load level; (3) seismic design category; and (4) period domain. The number of basic structural configurations will vary by system (i.e., 1 through N), and variation in gravity load levels may (or may not) affect the performance of certain systems. As a minimum, assuming one basic structural configuration and no dependence on gravity loads, all systems will have at least four performance groups based on combinations of two seismic design levels and two period domains. These parameters should be used as a guide in establishing performance groups, as follows:

- **Basic Structural Configuration.** Changes in the basic structural configuration are intended to capture major variations in the seismic-force-resisting system that are permissible within the design requirements and are likely to affect the structural response. Examples of alternative configurations that could be separated into performance groups include: (1) variations in bracing configurations (e.g., X-bracing versus chevron bracing) in steel concentrically braced frames; (2) variations in framing spans and story heights in moment frames; and (3) variations in shear wall aspect ratios that may influence whether a wall responds in shear or flexural behavior.
- **Gravity Load Level.** To the extent that the gravity load intensity and distribution of gravity loads affect the response of a seismic-force-resisting system, gravity loads should be varied in the index archetype configurations and separated into different performance groups.

Variation in gravity load level is related to the intensity of the gravity load (as affected by the type of gravity framing and use of the structure) and the amount of seismic mass that is tributary to the seismic-force-resisting system in the form of directly applied gravity loads. In moment frames, tributary gravity loads can be distinguished through the use of perimeter frames versus space frame configurations. In wall systems, differences can be distinguished through the use of bearing walls (where most of the gravity loads are directly supported by the walls) versus non-bearing walls (where gravity loads are supported by other means, such as frames).

Table 4-3 Generic Performance Group Matrix

Performance Group Summary					
Group No.	Grouping Criteria				Number of Archetypes
	Basic Configuration	Design Load Level		Period Domain	
		Gravity	Seismic		
PG-1	Type 1	High	Max SDC	Short	≥ 3
PG-2				Long	≥ 3
PG-3			Min SDC	Short	≥ 3
PG-4				Long	≥ 3
PG-5		Low	Max SDC	Short	≥ 3
PG-6				Long	≥ 3
PG-7			Min SDC	Short	≥ 3
PG-8				Long	≥ 3
PG-9	Type 2	High	Max SDC	Short	≥ 3
PG-10				Long	≥ 3
PG-11			Min SDC	Short	≥ 3
PG-12				Long	≥ 3
PG-13		Low	Max SDC	Short	≥ 3
PG-14				Long	≥ 3
PG-15			Min SDC	Short	≥ 3
PG-16				Long	≥ 3
PG-17	Type N	High	Max SDC	Short	≥ 3
PG-18				Long	≥ 3
PG-19			Min SDC	Short	≥ 3
PG-20				Long	≥ 3
PG-21		Low	Max SDC	Short	≥ 3
PG-22				Long	≥ 3
PG-23			Min SDC	Short	≥ 3
PG-24				Long	≥ 3

- **Seismic Design Category.** In concept, the full range of Seismic Design Categories for which the seismic-force-resisting system will be permitted

should be reflected in the index archetype configurations and separated into different performance groups. Generally, however, it should suffice to check a system for the maximum and minimum spectral intensities of the highest Seismic Design Category (SDC) in which the system will be permitted. For example, systems intended for SDC D should be designed and assessed for the maximum and minimum spectral acceleration values (SDC D_{max} and SDC D_{min}) as given in Table 5-1A and Table 5-1B of Chapter 5. Usually, designs for the maximum spectral acceleration of the highest Seismic Design Category will control the collapse performance of the system, which is an indication that assessment of performance in lower Seismic Design Categories will not be required. If, however, the minimum spectral acceleration of the highest Seismic Design Category controls performance, then the system should also be designed and assessed for the minimum spectral acceleration of the next lowest Seismic Design Category.

- **Period Domain.** Differences in fundamental period, *T*, between short-period and long-period systems should be reflected in the index archetype configurations and separated into different performance groups. Period domain is described in Chapter 5, and defined by the boundary between the constant acceleration and constant velocity regions of the design spectrum. Since, within a given structural system, building period varies with the building height, bins of short-period and long-period archetypes will typically be distinguished by building height (or number of stories). The range of index archetypes should generally extend from short-period configurations for one-story buildings up to long-period configurations for the tallest practical buildings within the archetype design space. For the potentially limited number of short-period building archetypes, development of index archetypes should consider variations in both the number of stories and the story height.

Each performance group should include at least three index archetypes. There is no maximum number of archetypes in each performance group, but it is expected that each group will typically have three to six index archetype configurations. This minimum requirement may be waived if it is infeasible to have three alternative designs within a specific performance group. For example, in the case of flexible moment frame systems, it may not be possible to have three distinct index archetype configurations within the short-period domain. Further guidance on the minimum number of performance groups, and index archetype configurations in each group, is provided in Chapter 7.

Chapter 5
Nonlinear Model Development

This chapter describes the development of analytical models for collapse assessment of a proposed seismic-force-resisting system. It first defines how *index archetype designs* are prepared from index archetype configurations using the proposed design requirements for the system of interest. It then outlines how *index archetype models* are developed using nonlinear component properties and limit state criteria developed and calibrated with test data. Index archetype models are based on structural system archetypes defined in Chapter 4, and are used to perform nonlinear analyses described in Chapter 6.

5.1 Development of Nonlinear Models for Collapse Simulation

Since the index archetype configurations are developed with explicit consideration of features to be investigated through nonlinear collapse simulation, the development of nonlinear models and structural system archetypes is interdependent. Nonlinear model development includes preparation of: (1) *index archetype designs*, which are index archetype configurations that have been proportioned and detailed using the design requirements for a proposed seismic-force-resisting system; and (2) *index archetype models*, which are idealized mathematical representations of index archetype designs used to simulate collapse in nonlinear static and dynamic analyses.

Development of nonlinear models for collapse simulation follows the process outlined in Figure 5-1. Using system design requirements (Chapter 3) and structural system archetypes (Chapter 4), design criteria and material test data are applied to each index archetype configuration to develop index archetype designs based on trial values of R, C_d, and Ω_o. Each design is then idealized into an index archetype model for nonlinear analysis (Chapter 6). Model parameters and collapse assessment criteria are calibrated to component, connection, assembly, and system tests. Quality ratings for index archetype models are used to assess modeling uncertainty in Chapter 7.

5.2 Index Archetype Designs

Index archetype designs for a seismic-force-resisting system are prepared by applying the proposed design requirements, substantiated by test data, to a set

of index archetype configurations. Index archetype designs should include all significant design features that are likely to affect structural response and collapse behavior. All seismic-force-resisting components and connections should be designed in strict accordance with the minimum requirements of the seismic design provisions for the proposed system. Designs should also meet applicable provisions of ASCE/SEI 7-05 (or other model building code) and any other referenced standards.

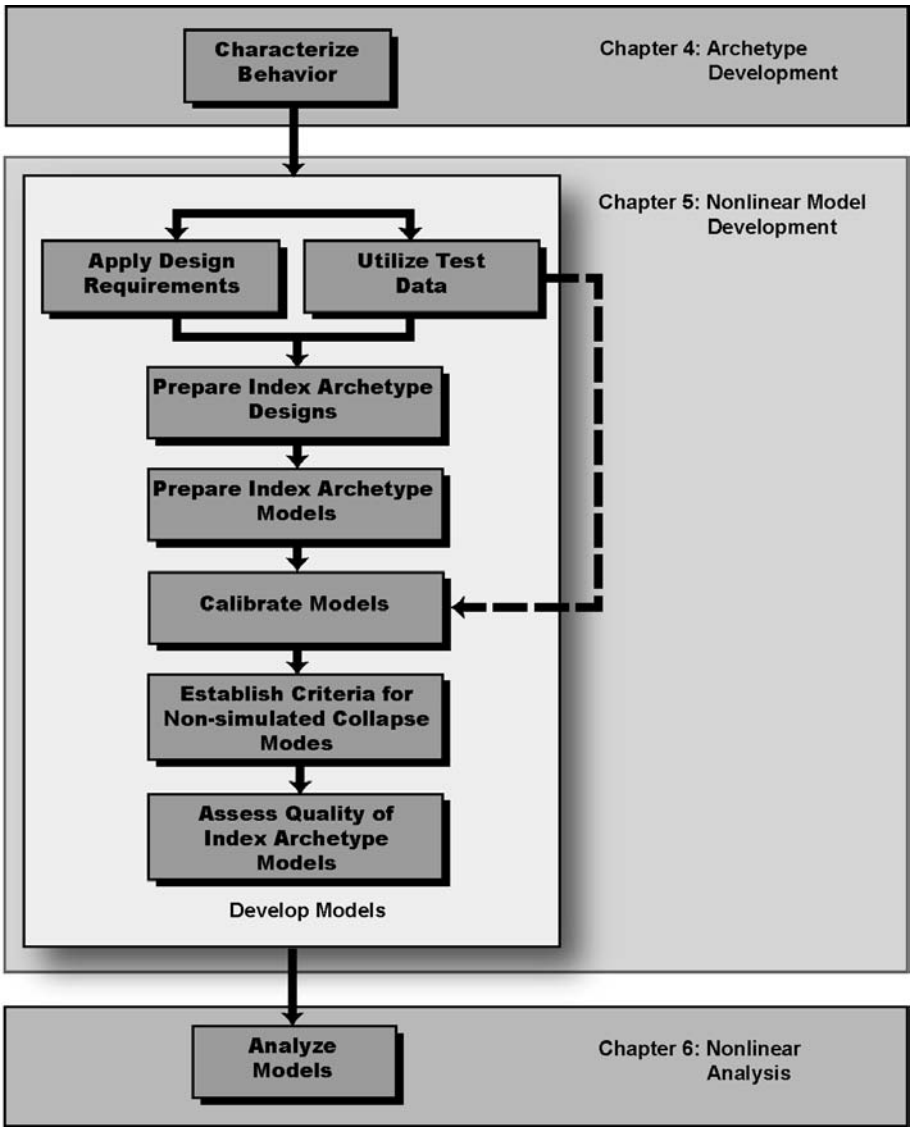

Figure 5-1 Process for development of index archetype models.

While index archetype designs are intended to interrogate the feasible range of the archetype design space, they are not intended to capture all feasible "outliers" of superior or poor seismic performance. Nor are they intended to interrogate seismic design criteria that are common across all seismic-force-resisting systems.

Explicit assessment of redundancy, structural irregularities, soil-structure interaction, importance factors, and other general seismic design criteria are not addressed in the Methodology. It is assumed that such generic design requirements of ASCE/SEI 7-05 (or other applicable building codes) are equally effective for all seismic-force-resisting systems. It is, therefore, important that index archetype designs comply with all relevant limitations in ASCE/SEI 7-05 provisions that are generic to all systems.

The following sections describe design methods, seismic criteria, design loads, load combinations and related requirements for preparing index archetype designs. They are included here to illustrate how seismic design base shears are calculated relative to the Maximum Considered Earthquake (MCE) spectrum used to assess collapse margin, and to highlight specific aspects of seismic design criteria that are relevant to the Methodology.

These criteria are primarily based on the design requirements contained within ASCE/SEI 7-05, modified as appropriate for design of index archetypes. While the specific requirements discussed here are based on ASCE/SEI 7-05, this is not meant to imply a limitation on the application of the Methodology, which is intended to be generally applicable to any set of comprehensive seismic design procedures.

5.2.1 Seismic Design Methods

In general, the Equivalent Lateral Force (ELF) method of Section 12.8, ASCE/SEI 7-05, should be used to develop index archetype designs, except as noted below:

- The Response Spectrum Analysis (RSA) method of Section 12.9, ASCE/SEI 7-05, should be used to develop archetype designs when the ELF method is not permitted by ASCE/SEI 7-05, or by the specific design requirements of the system of interest. For example, the ELF method is not permitted for the design of taller structures in Seismic Design Category D that have a fundamental period, T, greater than $3.5T_s$ (Table 12.6-1, ASCE/SEI 7-05).
- Response history analysis (RHA) methods should be used to develop archetype designs when ELF and RSA methods are not permitted by ASCE/SEI 7-05, or by the specific design requirements of the system of interest. For example, response history methods are required for design of seismically isolated structures with certain performance characteristics (Section 17.4.2.2, ASCE/SEI 7-05).

- The RSA method (or RHA methods) may be used to develop index archetype designs when such methods are (or are expected to be) commonly used in practice in lieu of the ELF method.

5.2.2 Criteria for Seismic Design Loading

The provisions of ASCE/SEI 7-05 specify seismic loads and design criteria in terms of Seismic Design Category (SDC), which is a function of the level of design earthquake (DE) ground motions and the Occupancy Category of the structure. The Methodology is based on life safety performance and assumes all structures to be either Occupancy Category I or II (i.e., structures that do not have special functionality requirements) with a corresponding importance factor equal to unity. Seismic Design Categories for Occupancy I and II structures vary from SDC A to SDC E in regions of the lowest and highest seismicity, respectively.

The Methodology defines MCE and DE ground motions for structures in Seismic Design Categories B, C, and D. The Methodology ignores both SDC A structures, which are not subject to seismic design (other than the minimum, 1% lateral load specified by Section 11.7.2 of ASCE/SEI 7-05), and SDC E structures which are located in deterministic MCE ground motion regions near active faults.

The provisions of ASCE/SEI 7-05 define MCE demand in terms of mapped values of short-period spectral acceleration, S_S, and 1-second spectral acceleration, S_1, site coefficients, F_a and F_v, and a standard response spectrum shape. For seismic design of the structural system, ASCE/SEI 7-05 defines the DE demand as two-thirds of the MCE demand. The Methodology requires archetypical systems to be designed for DE seismic criteria, and then evaluated for collapse with respect to MCE demand.

For Seismic Design Categories B, C, and D, maximum and minimum ground motions are based on the respective upper-bound and lower-bound values of MCE and DE spectral acceleration, as given in Table 11.6-1 of ASCE/SEI 7-05, for short-period response, and in Table 11.6-2 of ASCE/SEI 7-05, for 1-second response. MCE spectral accelerations are derived from DE spectral accelerations for site coefficients corresponding to Site Class D (stiff soil) following the requirements of Section 11.4 of ASCE/SEI 7-05. For the purpose of assessing performance across all possible site classifications, the Methodology uses values based on the default Site Class D uniformly for design of all archetypes.

Tables 5-1A and 5-1B list values of maximum and minimum spectral acceleration, site coefficients, and design parameters for Seismic Design

Categories B, C, and D. Figure 5-2 shows DE response spectra for ground motions associated with these parameters, based on the standard shape of the design response spectrum shown in Figure 11.4-1 of ASCE/SEI 7-05.

Table 5-1A Summary of Mapped Values of Short-Period Spectral Acceleration, Site Coefficients and Design Parameters for Seismic Design Categories B, C, and D

Seismic Design Category		Maximum Considered Earthquake			Design
Maximum	Minimum	S_S (g)	F_a	S_{MS} (g)	S_{DS} (g)
D		1.5	1.0	1.5	1.0
C	D	0.55	1.36	0.75	0.50
B	C	0.33	1.53	0.50	0.33
	B	0.156	1.6	0.25	0.167

Table 5-1B Summary of Mapped Values of 1-Second Spectral Acceleration, Site Coefficients and Design Parameters for Seismic Design Categories B, C, and D

Seismic Design Category		Maximum Considered Earthquake			Design
Maximum	Minimum	S_1 (g)	F_v	S_{M1} (g)	S_{D1} (g)
D		0.60[1]	1.50	0.90	0.60
C	D	0.132	2.28	0.30	0.20
B	C	0.083	2.4	0.20	0.133
	B	0.042	2.4	0.10	0.067

1. Value of 1-second MCE spectral acceleration rounded to 0.60 g.

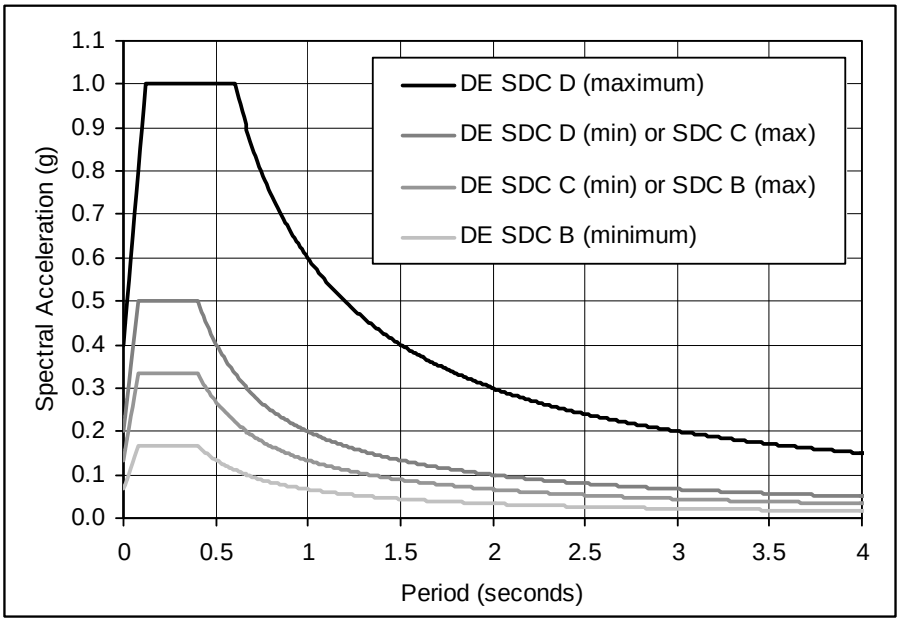

Figure 5-2 Plots of design earthquake (DE) response spectral accelerations used for design of Seismic Design Category D, C and B structure archetypes, respectively.

Maximum values of spectral acceleration for SDC D (S_s = 1.5 g and S_1 = 0.60 g) are based on the effective boundary between deterministic (near-source) and probabilistic regions of MCE ground motions, as defined in Section 21.2 of ASCE/SEI 7-05. The Methodology purposely excludes SDC D structures at deterministic (near-source) sites defined by 1-second spectral acceleration equal to or greater than 0.60 g, although Section 11.6 of ASCE/SEI 7-05 defines SDC D structures as having 1-second spectral acceleration values as high as 0.75 g. The 1-second value of MCE spectral acceleration shown in Table 5-1B, S_1 = 0.60, is rounded upward slightly for convenience, and should be taken as $S_1 < 0.60$g, for the purpose of evaluating minimum base shear design requirements. This is done to avoid triggering Equation 12.8-6 of ASCE-SEI 7-05 for design of index archetypes.

An internal study, documented in Appendix A, found that the collapse margin ratio (*CMR*) was somewhat smaller in systems designed using SDC E seismic criteria and evaluated using near-field ground motions, than in systems designed using SDC D seismic criteria and evaluated using far-field ground motions. By ignoring SDC E structures, the Methodology implicitly accepts a somewhat greater collapse risk for buildings located close to active faults. This is consistent with the approach in ASCE/SEI 7-05, which implicitly accepts greater risk for buildings near active faults by limiting MCE ground motions to deterministic values of seismic hazard.

5.2.3 Transition Period, T_s

The Methodology requires statistical evaluation of short-period archetypes separately from long-period archetypes, and distinguishes between them on the basis of the transition period, T_s. The transition period defines the boundary between the region of constant acceleration and the region of constant-velocity of the design (or MCE) response spectrum, as illustrated in Figure 5-2. The transition period, T_s, is defined as:

$$T_s = \frac{S_{D1}}{S_{DS}} = \frac{S_{M1}}{S_{MS}} \tag{5-1}$$

where the values of S_{D1} and S_{DS} (and S_{M1} and S_{MS}) are given in Table 5-1A and Table 5-1B, respectively, for each Seismic Design Category. The value of T_s is 0.6 seconds for the upper bound of Seismic Design Category D (SDC D_{max}), 0.4 seconds for the lower bound of Seismic Design Category D (SDC D_{min}), and 0.4 seconds for the upper and lower bounds of the other Seismic Design Categories.

5.2.4 Seismic Base Shear, V

Index archetypes are designed using the seismic base shear, V, as defined by Equation 12.8-1 of ASCE/SEI 7-05:

$$V = C_s W \tag{5-2}$$

where C_s is the seismic response coefficient and W is the effective seismic weight. This base shear equation is used as the basis of the applied forces when the Equivalent Lateral Force procedure is used for design, and to scale design values in accordance with Section 12.9.4 of ASCE/SEI 7-05 when the Response Spectrum Analysis procedure is used for design. The seismic coefficient, C_s, is defined for short-period archetypes ($T \leq T_s$) as:

$$C_s = \frac{S_{DS}}{R} \tag{5-3}$$

and for long-period archetypes ($T > T_s$) as:

$$C_s = \frac{S_{D1}}{T\,R} \geq 0.44\,S_{DS} \tag{5-4}$$

where S_{D1} and S_{DS} are given in Tables 5-1A and 5-1B, respectively, R is the trial value of the response modification factor, and T is the fundamental period of the index archetype.

Equations 5-3 and 5-4 have an implied occupancy importance factor of I=1.0, since the index archetype designs are defined for Occupancy Categories I and II. These equations are also constrained by the minimum seismic coefficient, C_s = 0.01, required by Equation 12.8-5 of ASCE/SEI 7-05 and by the minimum static lateral force, $F_x = 0.01 w_x$, required by Equation 11.7-1 of ASCE/SEI 7-05 for design of all structures. Note that Equation 12.8-6 of ASCE-SEI 7-05 does not apply since the Methodology defines 1-second MCE spectral acceleration as $S_1 < 0.60$ g, in all cases.

ASCE/SEI 7-05 reduces the value of C_s for very long period structures that have a fundamental period, $T > T_L$, where T_L is the transition period between the constant velocity and constant displacement response domains. Values of T_L range from 4 seconds to 16 seconds, as defined in Section 11.4.5 of ASCE/SEI 7-05. Reduced values of C_s for very long period structures do not apply, since the Methodology limits index archetype designs to configurations with fundamental periods less than 4 seconds (due to possible limitations on the low frequency content of ground motion records used for the nonlinear dynamic analysis).

5.2.5 Fundamental Period, T

The fundamental period, *T*, is used within the Methodology in two ways. First, it is used in establishing the design base shear through Equation 5-4. Second, it is used in defining the ground motion spectral intensity to establish the collapse margin ratio (*CMR*) in nonlinear dynamic analysis procedures (Chapter 6). In both cases, the Methodology defines the fundamental period, *T*, as:

$$T = C_u T_a = C_u \quad C_t \quad h_n^{\,x} \geq \ 0.25 \text{ seconds} \tag{5-5}$$

where h_n is the building height, the values of the coefficient, C_u, are given in Table 12.8-1 of ASCE/SEI 7-05, and values of period parameters C_t and x are given in Table 12.8-2 of ASCE/SEI 7-05. The approximate fundamental period, T_a, is based on regression analysis of actual building data, and represents lower-bound (mean minus one standard deviation) values of building period (Chopra et al., 1998). The value of the coefficient, C_u, ranges from 1.4 in high seismic regions to 1.7 in low seismic regions, and the product, $C_u T_a$, approximates the average value of building period. Alternative formulas for estimating the approximate fundamental period of masonry or concrete shear wall structures are given in Section 12.8.2.1 of ASCE/SEI 7-05, and may be used in lieu of T_a in Equation 5-5. Alternative formulas for the approximate fundamental period of proposed seismic-force-resisting systems with different dynamic characteristics should be specified as part of the design requirements for such systems.

Use of Equation 5-5 provides a consistent basis for determining the building period for the purpose of calculating the design base shear and evaluating the MCE spectral intensity at collapse. Based on scatter in ground motion spectra at small periods, the fundamental period, *T*, as calculated by Equation 5-5 (or other alterative formulas) includes a lower limit of 0.25 seconds for the purpose of evaluating the *CMR*.

5.2.6 Loads and Load Combinations

Index archetype designs should be prepared considering gravity and seismic loading, in accordance with the seismic load effects and load combinations of Section 12.4 of ASCE/SEI 7-05 and guidance provided in this section. Basic seismic load combinations for strength design (ignoring snow load, *S*, and foundation load, *H*) are:

$$\left(1.2 + 0.2S_{DS}\right) D + Q_E + L \tag{5-6a}$$

$$\left(0.9 - 0.2S_{DS}\right) D + Q_E \tag{5-6b}$$

where D includes the structural self weight and superimposed dead loads, L is the live load (including appropriate live load reduction factors), and Q_E is the effect of horizontal seismic forces resulting from the base shear, V. The basic load combinations, defined above, purposely do not include the redundancy factor, ρ, which is conservatively assumed to be 1.0 in all cases. Seismic loads, and hence capacity of index archetype designs, should not be increased for a possible lack of redundancy that may not exist in all applications of the proposed system.

Where the seismic load effect with overstrength is required, basic load combinations for strength design (ignoring snow load, S, and foundation load, H) are:

$$\left(1.2 + 0.2S_{DS}\right)D + \Omega_O Q_E + L \tag{5-7a}$$

$$\left(0.9 - 0.2S_{DS}\right)D + \Omega_O Q_E \tag{5-7b}$$

where Ω_o is the overstrength factor. Snow load, S, and foundations loads, H, are not required for design of index archetypes. Snow load is an environmental load that varies independently of seismic intensity, and is not considered to be a primary factor affecting seismic performance. Foundation loads, H, are not typical and when present, generally apply to design of structural components that do not affect performance of the seismic-force-resisting system.

Wind load is also not required for design of index archetypes, since wind load does not occur (in load combinations) with earthquake load. However, index archetypes may be designed for minimum values of wind load in lieu of earthquake load when minimum values of wind load exceed earthquake load. If wind load is used for archetype design, minimum values of wind load should be based on the lowest basic wind speed in Chapter 6 of ASCE/SEI 7-05 for all regions of the United States, and consider building (plan) configurations which minimize lateral forces due to wind load.

5.2.7 Trial Values of Seismic Performance Factors

Preparation of index archetype designs requires selection of trial values of the response modification coefficient, R, displacement amplification coefficient, C_d, and overstrength factor, Ω_o. Initial values of R, C_d, and Ω_o may need to be revised, and the index archetypes redesigned, based on the outcome of the performance evaluation process in Chapter 7.

A trial value of the response modification factor, R, is required for all index archetype designs to determine seismic base shear, V, and the related effect

of horizontal seismic force, Q_E. For certain archetypes, Equations 5-7a and 5-7b require a trial value of the overstrength factor, Ω_O, for design of structural components that are subject to rapid deterioration and are sensitive to overload conditions. For index archetype designs governed by drift, Section 12.8.6 of ASCE/SEI 7-05 requires a trial value of the deflection amplification factor, C_d, to determine story drift. Guidance on initial selection of trial values may be found in the acceptance criteria of Chapter 7.

5.2.8 Performance Group Design Variations

As described in Chapter 4, performance groups for each archetype configuration include design load variations based on Seismic Design Category and gravity load intensity, and design height variations that influence the fundamental period of the structure.

Maximum and Minimum Seismic Loads. Strictly speaking, index archetype designs should reflect all Seismic Design Categories for which the seismic-force-resisting system will be permitted. Typically, however, the highest SDC will have the smallest collapse margin ratios, and govern system performance. To reasonably cover the design space, the performance groupings (Chapter 4) require assessment of index archetypes that are designed for both the maximum and minimum spectral intensities of the highest SDC in which the system is allowed. For example, index archetypes for systems permitted in all SDCs must be designed for SDC D_{max} and SDC D_{min}. Similarly, index archetypes for systems permitted in SDC A or SDC B must be designed for SDC B_{max} and SDC B_{min}.

In certain cases, performance might be controlled by lower SDCs. For example, if collapse margin ratios calculated for index archetypes designed using SDC D_{max} are not consistently larger than those for index archetypes designed using SDC D_{min}, then lower SDCs might control collapse performance. In such cases, index archetypes should also be designed and assessed for minimum spectral accelerations corresponding to the next lowest SDC. If index archetypes designed for the next lower SDC are found to have even lower collapse margin ratios, then additional index archetypes designs should be prepared to confirm whether or not lower SDCs control system performance.

High and Low Gravity Loads. Where gravity loads tributary to the seismic-force-resisting system significantly influence collapse behavior, index archetype designs must be prepared for high gravity and low gravity load intensities. High and low gravity load intensities reflect differences in the self weight of alternative gravity framing components (e.g., metal deck

versus concrete slabs) as well as framing configurations (e.g., space frame versus perimeter frame configurations or bearing wall versus non-bearing wall components). Where gravity load effects are significant, design dead load, *D*, and live load, *L*, intensities should be established considering different building occupancies and the range of likely gravity load intensities in the archetype design space.

Building Height. Index archetypes must be designed to populate performance groups in the short-period ($T \leq T_s$) and long-period ($T > T_s$) ranges. Equation 5-5 can be used to relate building height to number of stories and story heights. Ideally, each performance group should have at least 3 index archetype designs. However, flexible systems (e.g., steel moment frames) can have relatively long fundamental periods, *T*, greater then T_s, potentially limiting the number of index archetype designs in short-period performance groups. Conversely, systems with building height limits may have few archetypes with fundamental periods, *T*, greater than T_s, limiting the number of archetypes in long-period performance groups. In such cases, performance groups are permitted to have less than three archetypes, provided that the group has at least one index archetype design for each feasible building height (combination of number of stories and story heights).

Unless restricted by height, long-period performance groups should contain index archetypes of different heights (number of stories) that have fundamental periods ranging from about T_s to about 4 seconds. Index archetypes should be designed such that the fundamental periods of the performance group are well distributed over the full range of periods. It should be noted that more than three archetypes per long-period performance group may be required to properly evaluate the performance of taller systems.

5.3 Index Archetype Models

General considerations for developing index archetype models are summarized in Table 5-2. These considerations should be used as a guide in establishing index archetype models, as follows:

- **Model Idealization.** Definition of index archetype models includes selection of the type of idealization used to represent structural behavior. At the one extreme are nonlinear continuum finite element models, which, in theory, are capable of representing the underlying structural mechanics most directly. At the other extreme are phenomenological models, which represent the overall force-deformation response through concentrated nonlinear springs. A nonlinear beam-column hinge model

is an example of such a phenomenological model, in which moment-rotation behavior is related to beam-column design parameters through semi-empirical models that are calibrated to beam-column subassembly tests.

In between these two extremes are models that utilize both continuum and phenomenological representations. A "fiber-type" model of a reinforced concrete shear wall is an example of such a combined model, where flexural effects are modeled with uniaxial stress-strain behavior for reinforcing steel and concrete, and where shear behavior (or combined shear-flexural behavior) is represented through a stress-resultant (force-based) phenomenological model. Regardless of type, models must be validated against test data and other substantiating evidence to assess how accurately they capture nonlinear response and critical limit state behavior.

Table 5-2 General Considerations for Developing Index Archetype Models

Model Attributes	Considerations
Mathematical Idealization	• Continuum (physics-based) versus phenomenological elements
Plan and Elevation Configurations	• Number of moment frame bays, regularity. • Planar versus 3-D wall representations, openings, coupling beams, regularity. • Number of bracing bays, bracing configuration, regularity. • Variations to reflect diaphragm effects on stiffness and 3-D force distributions
2-D versus 3-D Component Behavior	• Prevalence of 2-D versus 3-D systems in design practice • Impact on structural response, including provisions for 3-D (out-of-plane failures) in 2-D models
2-D versus 3-D System Behavior	• Characteristics of index archetype configurations, such as diaphragm flexibility • Impact on structural response that is specific to certain structural systems

- **Elevation and Plan Configurations.** Representation of elevation and plan configurations in index archetype models will depend on both the index archetype configurations and the structural system behavior. While vertical and horizontal irregularities will certainly influence collapse, for the purpose of evaluating general design provisions, currently permissible elevation and plan irregularities in ASCE/SEI 7-05

are not addressed in index archetype models. As illustrated by examples in Chapter 9, two-dimensional, three-bay frames of regular proportions are judged sufficient to represent typical behavior of reinforced concrete moment frame systems. The extent to which this type of model will suffice for studies of other moment frame types should be established based on the specific behavioral effects of the specific moment frame system. For walls, the issue of planar versus three-dimensional response is a key consideration, as is the presence of wall openings, boundary elements, and coupling beams. For example, reinforced concrete walls with large boundary members (e.g., flanged walls) are likely to exhibit more shear-critical behavior than planar walls without boundary members. For braced frame systems, one or two bays of framing are likely to be sufficient unless the system relies on the specific interaction between two adjacent bays. Representation of alternative brace configurations is likely to be a dominant variable in collapse assessment of braced-frame systems. Where diaphragm flexibility has a significant effect on the lateral system response and performance, this flexibility should be incorporated in the index archetype model.

- **Two-Dimensional versus Three-Dimensional Component Behavior.** The need for models that simulate two-dimensional versus three-dimensional behavior will generally depend on: (1) the type of structural configurations common in the design space; and (2) the expected influence of three-dimensional effects on structural response. For most structural framing types, two-dimensional models are likely to be sufficient. However, there may be cases where three-dimensional behavior (e.g., out-of-plane torsional-flexural instability of laterally unbraced beam-columns or braces) or three-dimensional geometry (e.g., reinforced-concrete C-shaped core walls) are important to simulate. For wall systems, two-dimensional wall models may be sufficiently accurate for some system configurations (e.g., wooden shear walls, planar reinforced concrete walls) but less accurate and perhaps inappropriate for others (e.g., C-shaped and I-shaped reinforced concrete core walls).
- **Two-Dimensional versus Three-Dimensional System Behavior.** System behavior involves the interaction of multiple seismic-force-resisting components distributed spatially within a structure. Introduction of different spatial combinations, however, could lead to an intractable number of index archetype configurations and corresponding index archetype models. Building code provisions regarding plan configuration and three-dimensional effects (e.g., redundancy, accidental torsion) are usually not system specific, so in most cases, a two-dimensional system representation should be adequate. Diaphragm

flexibility may require three-dimensional index archetype model configurations if important diaphragm effects cannot be suitably incorporated in two-dimensional models.

5.3.1 Index Archetype Model Idealization

Index archetype models should provide the most basic (generic) representation of an index archetype configuration that is still capable of distinguishing between significant behavioral modes and key design features of the proposed seismic-force-resisting system. Index archetype models should be developed in cooperation with the peer review panel.

The mathematical idealization of index archetype models should capture all significant nonlinear effects related to the collapse behavior of the system. This can be done through: (1) explicit simulation of failure modes through nonlinear analyses; or (2) evaluation of non-simulated[1] failure modes using alternative limit state checks on demand quantities from nonlinear analyses.

Analytical models are generally distinguished by overall topology and element type. Topology refers to two-dimensional or three-dimensional modeling configurations. The choice of topology (2-D or 3-D) is largely a function of the index archetype configurations. The choice of element type depends on structural component behavior and the nature of component degradation. Two-dimensional topologies (e.g., planar frames or walls) do not preclude the modeling of three-dimensional effects (e.g., out-of-plane instabilities). Conversely, three-dimensional topologies (e.g., space frames or C-shaped walls) do not necessarily employ element types that capture all three-dimensional behavioral effects. Thus, the modeling decisions should be made on a case-by-case basis, depending on the specific features of the structure system archetypes.

For simulating collapse, component models must capture strength and stiffness degradation under large deformations. Structural components are usually idealized as a combination of one-dimensional line-type elements (beam-columns or axial struts) and two-dimensional continuum elements (plane-stress or plate/shell finite elements). Three-dimensional continuum elements (brick finite elements) may be appropriate and necessary in some cases. Within each element type, element formulations can be further distinguished by the extent to which the underlying structural behavior is modeled explicitly or through phenomenological representations. For

[1] The term “non-simulated” is used to describe potential modes of collapse failure that are not explicitly captured by the index archetype model (i.e., not explicitly simulated), but is evaluated by alternative methods of analysis and included in the evaluation of collapse performance.

example, nonlinear beam-column elements can range in sophistication from fiber-type continuum elements, in which the geometry and materials in the cross section are modeled explicitly, to concentrated spring models, in which the inelastic response is idealized through uni-axial or multi-axial springs.

Provided that they are accurately calibrated to the appropriate range of design and behavioral parameters, concentrated spring models will usually be sufficient for simulating nonlinear response of columns, beams, and beam-column connections in frame systems. These models have the practical advantage of providing a straight-forward approach to characterizing strength and inelastic deformation characteristics. However, concentrated spring models generally cannot represent behavioral effects beyond those present in the underlying data. Continuum models, which generally model the physical behavior at a more fundamental level, can, if properly formulated and validated, represent a broader range of behavioral effects that do not rely as much on tests to represent the specific parameters of the index archetype designs.

Wall systems will typically require two-dimensional continuum models that can capture significant nonlinear stress and strain variations within the walls. Continuum models may include traditional two-dimensional plane stress/strain finite elements, or alternative formulations that utilize combinations of formal finite element approaches and engineering assumptions to represent the nonlinear behavior (including the effects of strength and stiffness degradation).

In the case of moment frame systems, for example, an index archetype model might consist of the two-dimensional, three-bay frame shown in Figure 5-3. This model incorporates one-dimensional line-type elements with either concentrated spring or discrete component models to simulate the nonlinear degrading response of beams, columns, beam-column connections, and panel zones. Significant frame behaviors are captured in a two-dimensional representation, and the three-bay configuration captures differences between interior and exterior columns. The additional leaning column elements capture P-delta effects of the seismic mass that is not tributary to the frame.

For shear wall systems, an index archetype model might be as simple as a cantilever element that accounts for inelastic flexure and shear behavior at the base of the wall. However, where punched shear wall geometries are included in the index archetype configurations, then the corresponding index archetype models would need to be more complicated.

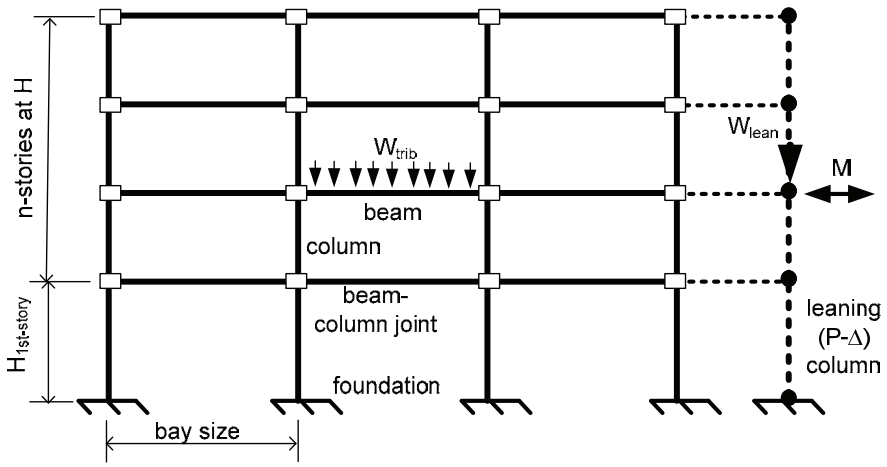

Figure 5-3 Example of index archetype model for moment resisting frame systems

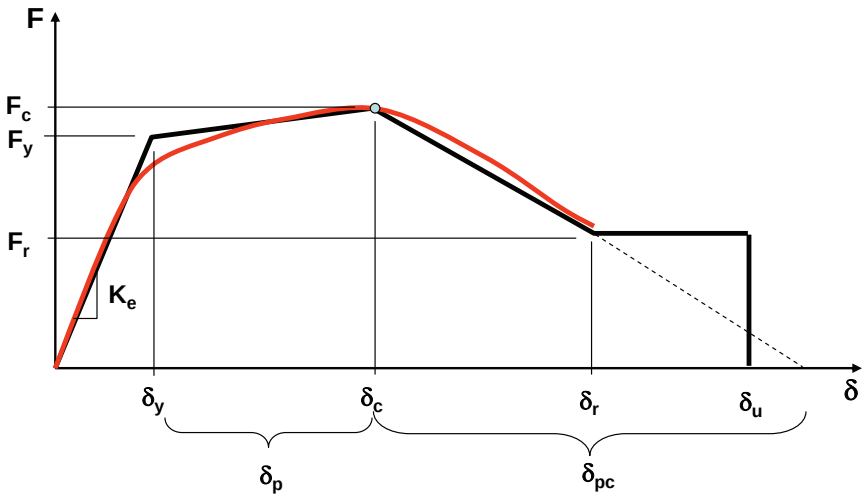
5.4 Simulated Collapse Modes

To the extent possible, index archetype models should directly simulate all significant deterioration modes that contribute to collapse behavior. Typically, this is accomplished through structural component models that simulate stiffness, strength, and inelastic deformation under reverse cyclic loading. Research has demonstrated that the most significant factors influencing collapse response are the strength at yield, F_y, maximum strength (at capping point), F_c, plastic deformation capacity, δ_p, the post-capping tangent stiffness, K_{pc}, and the residual strength, F_r (Ibarra et al., 2005). These parameters can be used to define a component backbone curve, such as the one shown in Figure 5-4. Recently, such a curve has been designated a force-displacement capacity boundary (FEMA, 2009).

Cyclic deterioration, which reduces stiffness values and lowers the force-displacement capacity boundary established by the monotonic backbone curve, should also be included to the extent that it influences the collapse response in nonlinear dynamic analyses. An example of degrading hysteretic response is shown in Figure 5-5. Characterization of component backbone curves and hysteretic responses should represent the median response properties of structural components. While illustrated in an aggregate sense in Figure 5-4 and Figure 5-5, the behavior can be modeled through elements of varying degrees of sophistication using phenomenological or physics-based approaches.



Effective yield strength and deformation (F_y and δ_y)
Effective elastic stiffness, $K_e = F_y/\delta_y$
Strength cap and associated deformation for monotonic loading (F_c and δ_c)
Pre-capping plastic deformation for monotonic loading, δ_p
Effective post-yield tangent stiffness, $K_p = (F_c\text{-}F_y)/\ \delta_p$

Ultimate deformation, δ_u

Figure 5-4 Parameters of an idealized component backbone curve

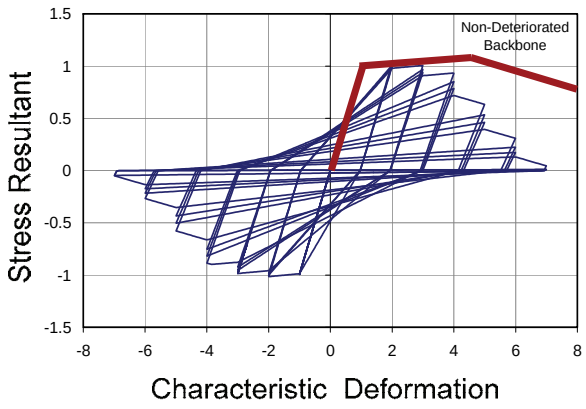

Figure 5-5 Idealized inelastic hysteretic response of structural components with cyclic strength and stiffness degradation.

While of lesser importance than the definition of the maximum force and deformation at the capping point, the initial stiffness can have a significant effect on the ductility capacity. Element-level initial stiffness should reflect all important contributors to deformation (e.g., flexure, bond-slip, and shear), and should be validated against component and assembly test data. An effective initial stiffness defined as the secant stiffness from the origin through the point of 40% of the yield strength of the element should be

considered in phenomenological concentrated spring models. In continuum models, initial stiffness is usually modeled directly. Where results are sensitive to initial stiffness, attention should be given to effects related to initiation of cracking or yielding that may not be considered in the model, such as shrinkage cracking due to concrete curing and residual stresses due to fabrication.

Figure 5-4 and Figure 5-5 are intentionally portrayed in a generic sense, since critical response parameters will vary for each specific component and configuration. For example, in ductile reinforced concrete components (i.e., special moment frames), nonlinear response is typically associated with moment-rotation in the hinge regions where degradation occurs at large deformations through a combination of concrete crushing, confinement tie yielding/rupture, and longitudinal bar buckling. However, in less ductile reinforced concrete components (i.e., ordinary moment frames), nonlinear response may include shear failures and axial failure following shear failure. Where the seismic-force-resisting system carries significant gravity load, characteristic force and deformation quantities may need to represent vertical deformation effects as well as horizontal response effects.

The development of analytical models is case specific, and no single model is universally applicable. For many steel, reinforced concrete, and wood components, the deterioration model proposed by Ibarra et al. (2005) satisfactorily matches experimental results and analytical predictions. However, this model should be utilized for a proposed system only if it can be justified based on experimental evidence.

Referring to Figure 5-5, the backbone curve defines a boundary within which hysteresis loops are confined. The implication is that in the analytical model, the load-deformation response is not permitted to move outside this curve. Such boundaries can be based on monotonic behavior, but ideally they should be based on series of tests including monotonic loading and cyclic loading with different loading protocols (FEMA, 2009). If such boundaries are fixed in the analytical model (i.e., cyclic deterioration is not incorporated explicitly), then estimates of the backbone curve parameters should account for average cyclic deterioration, to produce a modified backbone curve. If the initial stiffness is very different from the effective elastic stiffness, then it may affect the response close to collapse, and should become part of the modeling effort.

Figure 5-6 illustrates the effect of cyclic loading relative to a backbone curve obtained from monotonic loading. In almost all cases, the plastic deformation capacity, δ_p, is reduced by cyclic loading, and in many cases it is

reduced by a considerable amount from the monotonic loading case. A backbone curve is difficult to construct from a cyclic test (unless experience exists from other similar specimens) and often necessitates the execution of an additional monotonic test. If monotonic tests are not available, a curve enveloping the cyclic test (cyclic envelope) may be used as a conservative estimate of the modified backbone curve.

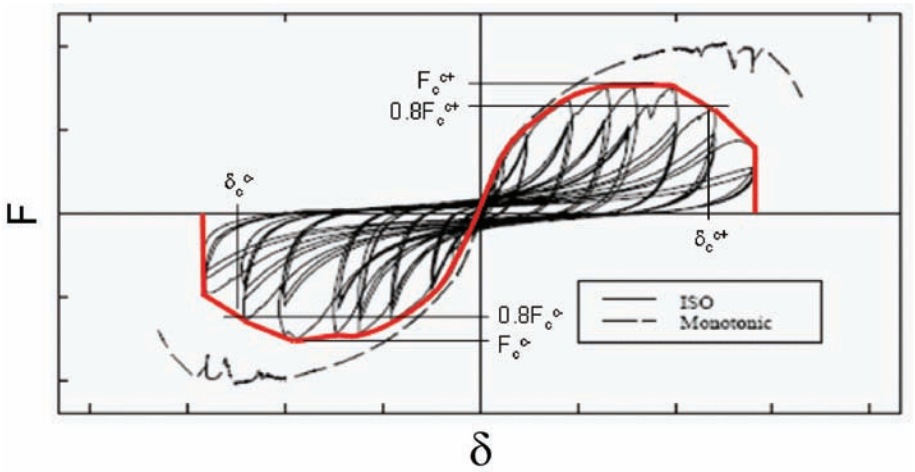

Figure 5-6 Comparison of monotonic and cyclic response, along with a cyclic envelope curve (adapted from Gatto and Uang 2002).

If the backbone curve is obtained from a monotonic test (or is deduced based on a cyclic deterioration model), then cyclic deterioration must be built into the analytical model representing component behavior. Most cyclic deterioration models are energy based (e.g., Ibarra et al., 2005; Sivaselvan and Reinhorn, 2000). Validity of the component model must be demonstrated through satisfactory matching of component, connection, or assembly test date from the experimental program.

Figure 5-6 also illustrates a simplified measure of performance, which is the deformation associated with a force value of 80% of the maximum strength measured in the test, F_c^c. In the figure, the deformation value, δ_c^c, which is obtained from the intersection of a horizontal line at $0.8F_c^c$ with the cyclic envelope, can be viewed as a conservative estimate of the ultimate deformation capacity of a component. In simplified analytical models it can be assumed that no deterioration occurs up to this value of deformation, provided that the strength of the component is assumed to drop to zero at deformations larger than this value. Both F_c^c and δ_c^c may be different in the positive and negative directions.

The monotonic backbone curve of Figures 5-4 and 5-6 is similar but distinct from the generalized force-displacement curves specified in ASCE/SEI 41,

Seismic Rehabilitation of Existing Buildings, (ASCE, 2006b). In ASCE/SEI 41-06, generalized force-displacement curves utilize cyclic envelopes that incorporate some degree of cyclic degradation and, in most cases, result in conservative estimates of median response. In this Methodology, backbone curves are intended to represent median properties of monotonic loading response, where cyclic strength and stiffness degradation are directly modeled in the analysis, and statistical variations of the component response are explicitly accounted for in the assessment process.

The type of backbone curve and cyclic hysteretic model used will also impact the amount of equivalent viscous damping used in the model. Models that have backbone curves with a large initial elastic region (which do not dissipate energy under cyclic loading) will generally use higher equivalent viscous damping than models with small initial elastic regions (which do dissipate energy under small cycles).

While component models are expected to be rigorously calibrated to test data, available data may not be comprehensive enough to fully calibrate the models. Data are often particularly scarce for evaluating the capping point and post-capping behavior that occurs at large deformations in ductile components. In such cases, test data should be augmented by engineering analysis and judgment to establish the modeling parameters.

An example of the development and calibration of nonlinear component models for reinforced concrete moment frame systems is provided in Appendix E.

5.5 Non-Simulated Collapse Modes

In cases where it is not possible (or not practical) to directly simulate all significant deterioration modes contributing to collapse behavior, non-simulated collapse modes can be indirectly evaluated using alternative limit state checks on structural response quantities measured in the analyses. Examples of possible non-simulated collapse modes might include shear failure and subsequent axial failure in reinforced concrete columns, fracture in the connections or hinge regions of steel moment frame components, or failure of tie-downs in light-frame wood shear walls. Component failures such as these may be difficult to simulate directly.

In Figure 5-7, a non-simulated collapse (NSC) limit state is shown to occur prior to the deformation at peak strength (and subsequent deterioration) that is directly simulated in the model. Non-simulated limit state checks are similar to the assessment approach of ASCE/SEI 41-06, in which component acceptance criteria are used to evaluate specific performance targets based on

demand quantities extracted from the analyses. This approach is more of an approximation to the actual behavior of the system. It increases the uncertainty in analytical results and tends to provide conservative estimates of collapse limit states. While not ideal, it is a practical approach that provides a consistent method for evaluating the effects of deterioration and collapse mechanisms that are otherwise difficult (or impossible) to incorporate directly in the analytical model.

Compared to collapse that is simulated directly, non-simulated limit state checks will generally result in lower estimates of median collapse. Non-simulated collapse modes are usually associated with component failure modes, and a commonly applied assumption is that the first occurrence of this failure mode will lead to collapse of the structure. Collapse of an entire structure predicated on the failure of a single component can, in many cases, be overly conservative. For this reason, local failure modes should be directly simulated, if at all possible, to permit redistribution of forces to other components after a limit state has been reached. Alternatively, local limit state checks can be redefined to indirectly account for possible redistribution of forces that is known to occur prior to collapse.

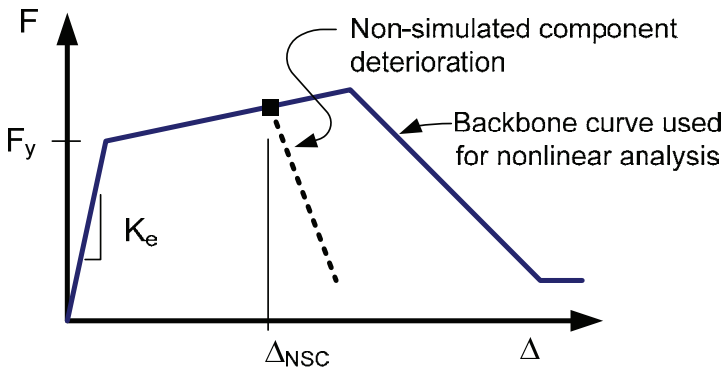

Figure 5-7 Component backbone curve showing a deterioration mode that is not directly simulated in the analysis model.

When considered in the context of incremental dynamic analyses, non-simulated component limit state checks are essentially stipulating a collapse limit prior to the point where an analysis would otherwise simulate collapse. Figure 5-8 shows a plot of the results from an incremental dynamic analysis of an index archetype model, which is subjected to a single ground motion that is scaled to increasing intensities. The point denoted SC corresponds to the collapse limit that is directly simulated in the model. The point denoted NSC represents the collapse limit as determined by applying a component limit state check on a potential collapse mode that is not directly simulated in the model. In this example, the limit state check is based on story drift, but

non-simulated collapse checks could be based on any other structural response parameter measured in the analysis, such as peak force demand in an element, or peak plastic hinge rotation demand.

Limit state checks for non-simulated collapse modes should be established based on test data and other supporting evidence, and should be calibrated to represent the median value of the governing response parameter that is associated with the collapse response. When establishing limit state checks, judgment should be exercised in relating the critical condition of a component to the collapse response of the building system, since there are many cases where critical limit states for isolated components will not immediately trigger overall system collapse. Non-simulated collapse limit states should be developed in cooperation with the Methodology peer review panel.

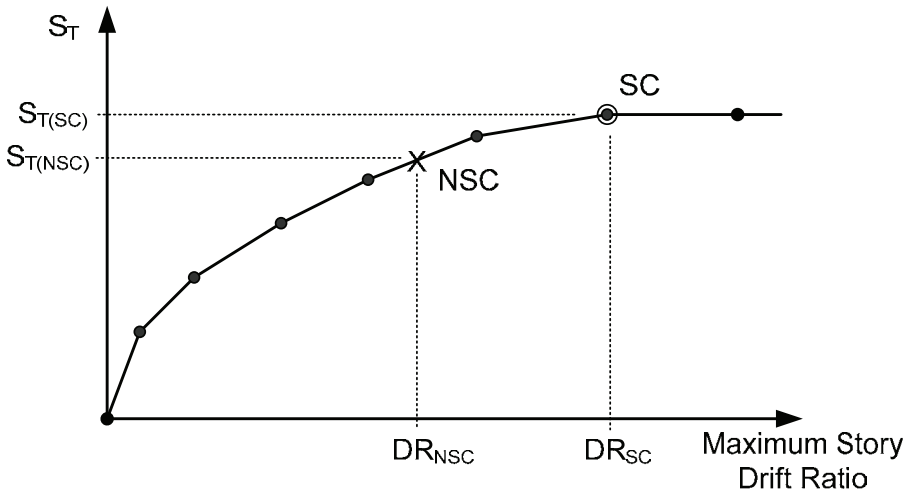

Figure 5-8 Incremental dynamic analysis results showing simulated (SC) and non-simulated (NSC) collapse modes.

5.6 Characterization of Modeling Uncertainties

In this Methodology, nonlinear analysis is used to determine the median ground motion intensity associated with collapse of a proposed seismic-force-resisting system. Index archetype models should, therefore, represent the median response of structural components that constitute the proposed system. Variability in collapse response, due to ground motion variability, modeling, and other uncertainties, is factored into the performance evaluation process in Chapter 7. When a model calibrated to median properties is used, nonlinear dynamic analysis under multiple ground motions is intended to provide a median estimate of the collapse capacity of an index archetype.

5.7 Quality Rating of Index Archetype Models

Quality of index archetype models is related to uncertainty, which factors into the performance evaluation for a proposed seismic-force-resisting system. The quality of index archetype models is rated in accordance with the requirements of this section, and approved by the peer review panel.

Index archetype models are rated between (A) Superior and (D) Poor, as shown in Table 5-3. This rating is a combined assessment of: (1) how well index archetype models represent the range of structural collapse characteristics and associated design parameters of the archetype design space; and (2) how well the analysis models capture structural collapse behavior through both direct simulation and non-simulated limit state checks. The quantitative values of modeling-related collapse uncertainty are: (A) Superior, $\beta_{MDL} = 0.10$; (B) Good, $\beta_{MDL} = 0.20$; (C) Fair, $\beta_{MDL} = 0.35$; and (D) Poor, $\beta_{MDL} = 0.50$. Use of these values is described in Section 7.3.

Table 5-3 Quality Rating of Index Archetype Models

Representation of Collapse Characteristics	Accuracy and Robustness of Models		
	High	**Medium**	**Low**
High. Index models capture the full range of the archetype design space and structural behavioral effects that contribute to collapse.	(A) Superior $\beta_{MDL} = 0.10$	(B) Good $\beta_{MDL} = 0.20$	(C) Fair $\beta_{MDL} = 0.35$
Medium. Index models are generally comprehensive and representative of the design space and behavioral effects that contribute to collapse.	(B) Good $\beta_{MDL} = 0.20$	(C) Fair $\beta_{MDL} = 0.35$	(D) Poor $\beta_{MDL} = 0.50$
Low. Significant aspects of the design space and/or collapse behavior are not captured in the index models.	(C) Fair $\beta_{MDL} = 0.35$	(D) Poor $\beta_{MDL} = 0.50$	--

The highest rating of (A) Superior applies to instances in which the index archetype models represent the complete range of structural configuration and collapse behavior, there is a high confidence in the ability of established models to simulate behavior, and the nonlinear model is of high-fidelity. The combination of low quality representation of collapse characteristics along with low quality modeling in terms of accuracy and robustness is not permitted.

An adaptation of the Methodology to assess building-specific collapse performance of an individual building is presented in Appendix F.

Differences in assigning quality ratings for an analytical model of an individual building are discussed there.

5.7.1 Representation of Collapse Characteristics

Representation of collapse characteristics refers to how completely and comprehensively the index archetype models capture the full range of design parameters and associated structural collapse behavior that is envisioned within the archetype design space. The quality of the representation is characterized as follows:

- **High.** The set of index archetype configurations and associated archetype models provides a complete and comprehensive representation of the full range of structural configurations, design parameters and behavioral characteristics that affect structural collapse. The index archetype models cover a comprehensive range of building heights, lateral system configurations, and design alternatives that are permitted by the design requirements. To the extent that 3-D component and system effects are significant, they are reflected in the index archetype models, as are other significant system effects such as diaphragm flexibility,
- **Medium.** The set of index archetype models provides a reasonably broad and complete representation of the design space. Where the complete design space is not fully represented in the set of models, there is reasonable confidence that the range of response captured by the models is indicative of the primary structural behavior characteristics that affect collapse.
- **Low.** The set of index archetype models does not capture the full range of structural configurations and collapse behavior for the system due to the combined effects of a loosely defined design space and a less than complete set of index archetype configurations. Loosely defined limits on system configurations and design parameters present a challenge in that the number of possible alternative configurations and structural design parameters are so large as to preclude systematic interrogation with a manageable number of index archetype configurations. Seismic-force-resisting systems permitted in low Seismic Design Categories that have limited requirements on design (e.g., steel ordinary moment frame systems) may fall into this category. Even for well controlled design criteria, however, representation of collapse characteristics may be low if the number and variety of index archetype configurations are not insufficient to capture the possible range in collapse behavior.

5.7.2 Accuracy and Robustness of Models

Accuracy and robustness is related to the degree to which nonlinear behaviors are directly simulated in the model, or otherwise accounted for in the assessment. Use of non-simulated collapse limit state checks will lower the accuracy and robustness of a nonlinear model. If conservatively applied, however, non-simulated collapse checks should not necessarily lower the overall quality rating of the assessment procedure. Model accuracy and robustness are characterized as follows:

- **High.** Nonlinear models directly simulate all predominate inelastic effects, from the onset of yielding through strength and stiffness degradation causing collapse. Models employ either concentrated hinges or distributed finite elements to provide spatial resolution appropriate for the proposed system. Computational solution algorithms are sufficiently robust to accurately track inelastic force redistribution, including cyclic loading and unloading, without convergence problems, up to the point of collapse.
- **Medium.** Nonlinear models capture most, but not all, nonlinear deterioration and response mechanisms leading to collapse. Models may not be sufficiently robust to track the full extent of deterioration, so that some component-based limit state checks are necessary to assess collapse.
- **Low.** Nonlinear models capture the onset of yielding and subsequent strain hardening, but do not simulate degrading response. Onset of degradation is primarily evaluated using non-simulated component limit state checks. Overall uncertainty in response quantities is increased due to inability to capture the effects of deterioration and redistribution.

Chapter 6
Nonlinear Analysis

This chapter describes nonlinear analysis procedures for collapse assessment of a proposed seismic-force-resisting system. It defines the set of input ground motions, and specifies how nonlinear static analyses and nonlinear dynamic analyses are conducted on index archetype models developed in Chapter 5. Nonlinear analyses are used to define the median collapse capacity and other parameters that are needed for performance evaluation in Chapter 7.

6.1 Nonlinear Analysis Procedures

Nonlinear analysis for collapse assessment follows the process outlined in Figure 6-1.

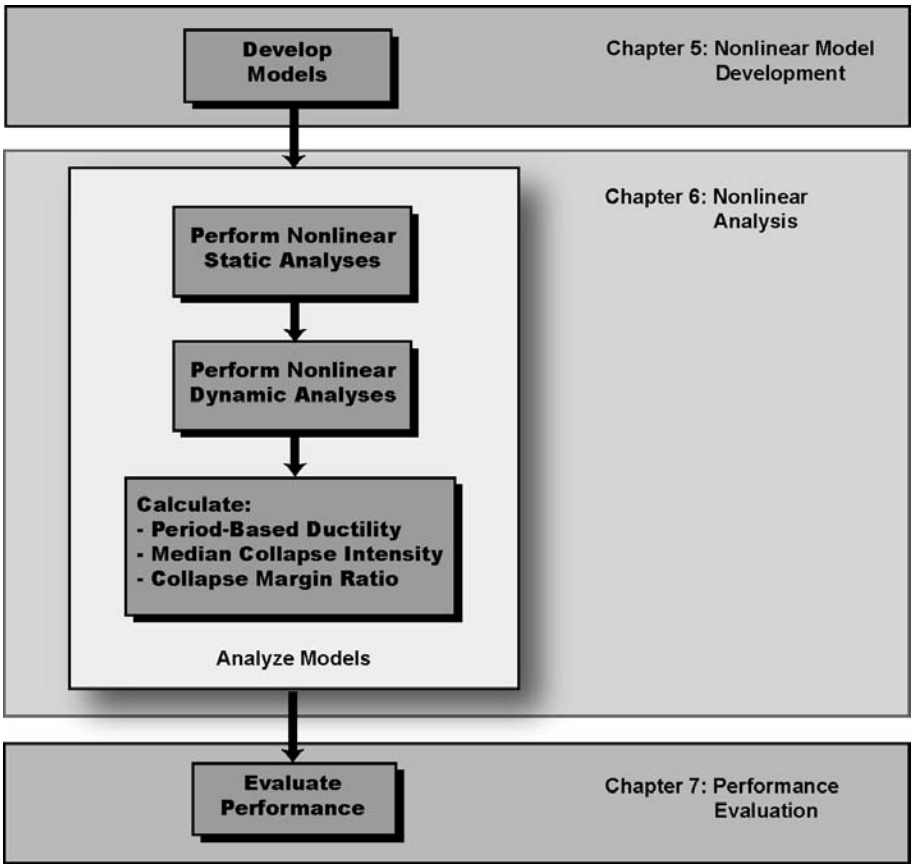

Figure 6-1 Process for performing nonlinear analyses for collapse assessment.

Nonlinear static (pushover) and dynamic (response history) analyses of all index archetype models are performed to obtain statistics for system overstrength, period elongation, and collapse capacity. Nonlinear static analyses are performed first, to help validate the model and to provide statistical data on system overstrength, Ω, and period-based ductility, μ_T. Nonlinear dynamic analyses are then performed to assess median collapse capacities, $\hat{S}_{CT}$, and collapse margin ratios, *CMR*. Median collapse capacity is defined as the ground motion intensity where half of the ground motions in the record set cause collapse of an index archetype model.

In all cases, modeling parameters, including the seismic mass and imposed gravity loads, should represent the median values of the structure and its components. The gravity loads for analysis are different from design gravity loads, and are given by the following load combination:

$$1.05D + 0.25L \tag{6-1}$$

where D is the nominal dead load of the structure and the superimposed dead load, and L is the nominal live load. Load factors in Equation 6-1 are based on expected values (equivalent to median values for normally distributed random variables) reported in a study on the development of a predecessor document to ASCE/SEI 7-05 (Ellingwood et al., 1980). The nominal live load in Equation 6-1 can be reduced by reduction factors based on influence area (subject to the limitations in ASCE/SEI 7-05), but should not be reduced by additional reduction factors.

As described in Chapter 5, index archetype models should account for all seismic mass and P-delta effects associated with gravity loads that are stabilized by the seismic-force-resisting system. This includes gravity loads that are directly tributary to the components of the seismic-force-resisting system, as well as gravity loads that rely on the seismic-force-resisting system for lateral stability. Models should also account, either directly or indirectly, for stiffness and strength degradation leading to the onset of collapse along with energy dissipated by the building.

6.1.1 Nonlinear Analysis Software

Software for nonlinear analysis can be of any type that is: (1) capable of static pushover and dynamic response history analyses; and (2) capable of capturing strength and stiffness degradation in structural components at large deformations. A significant computational challenge is to accurately capture the negative post-peak response, sometimes referred to as strain-softening response, in component backbone curves. Strain-softening response leads to the need for robust iterative numerical solution strategies to minimize errors

and achieve convergence at large inelastic deformations. Problems with strain-softening response have the potential for non-unique solutions and damage localization that is sensitive to numerical issues. While most modern analysis software can overcome these issues, care must be taken to investigate the sensitivity of the solution to modeling parameters and numerical aspects of the computational solution algorithms.

6.2 Input Ground Motions

Nonlinear dynamic response of index archetypes is evaluated for a set of pre-defined ground motions that are systematically scaled to increasing intensities until median collapse is established. The ratio between median collapse intensity, $\hat{S}_{CT}$, and Maximum Considered Earthquake (MCE) ground motion intensity, S_{MT}, is defined as the collapse margin ratio, *CMR*, which is the primary parameter used to characterize the collapse safety of the structure.

6.2.1 MCE Ground Motion Intensity

Collapse performance is evaluated relative to ground motion intensity associated with the MCE, as defined in ASCE/SEI 7-05, and related to the seismic criteria used for design of index archetypes in Chapter 5.

As described in Chapter 5, the Methodology defines DE and MCE ground motion intensities for three ranges of spectral acceleration associated with Seismic Design Categories B, C and D. Table 6-1 summarizes MCE spectral acceleration for maximum and minimum ground motions for these Seismic Design Categories, and Figure 6-1 shows MCE response spectra for the corresponding ground motion intensities.

Table 6-1 Summary of Maximum Considered Earthquake Spectral Accelerations And Transition Periods Used for Collapse Evaluation of Seismic Design Category D, C, and B Structure Archetypes, Respectively

Seismic Design Category		Maximum Considered Earthquake		Transition Period
Maximum	Minimum	S_{MS} (g)	S_{M1} (g)	T_s (sec.)
D		1.5	0.9	0.6
C	D	0.75	0.30	0.4
B	C	0.50	0.20	0.4
	B	0.25	0.10	0.4

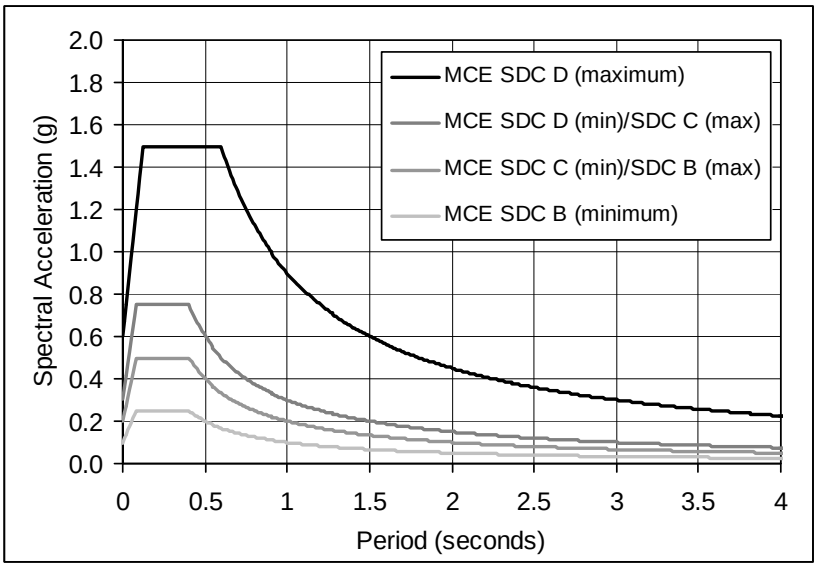

Figure 6-2 MCE response spectra required for collapse evaluation of index archetypes designed for Seismic Design Category (SDC) B, C, and D.

MCE ground motion intensity, S_{MT}, is defined for short-period archetypes ($T \leq T_s$) as:

$$S_{MT} = S_{MS} \tag{6-2}$$

and for long-period archetypes ($T > T_s$) as:

$$S_{MT} = \frac{S_{M1}}{T} \tag{6-3}$$

where values of S_{M1} and S_{MS} are given in Table 6-1, and T is the fundamental period of an index archetype as defined in Equation 5-5.

6.2.2 Ground Motion Record Sets

The Methodology provides two sets of ground motion records for collapse assessment using nonlinear dynamic analysis, referred to as the Far-Field record set and the Near-Field record set. The Far-Field record set includes twenty-two component pairs of horizontal ground motions from sites located greater than or equal to 10 km from fault rupture. The Near-Field record set includes twenty-eight component pairs of horizontal ground motions recorded at sites less than 10 km from fault rupture. The record sets do not include the vertical component of ground motion since this direction of earthquake shaking is not considered of primary importance for collapse evaluation, and is not required by the Methodology for nonlinear dynamic analysis.

The ground motion record sets each include a sufficient number of records to permit evaluation of record-to-record (*RTR*) variability and calculation of median collapse intensity, $\hat{S}_{CT}$. Explicit calculation of record-to-record variability, however, is not required for collapse evaluation of index archetypes. Instead, an estimate of record-to-record variability, based on previous research and developmental studies, is built into the process for calculating total system collapse uncertainty in Chapter 7. The record sets, along with selection criteria and background information on their selection, are provided in Appendix A.

The Methodology specifies use of the Far-Field record set for collapse evaluation of index archetypes designed for Seismic Design Category (SDC) B, C or D criteria (i.e., structures at sites that are located away from active faults). The Near-Field record set is provided as supplemental information, and is used in special studies of Appendix A to evaluate potential differences in the *CMR* for SDC E structures. Figure 6-3 shows the 44 individual response spectra (i.e., 22 records, 2 components each) of the Far-Field record set, the median response spectrum, and spectra representing one standard deviation and two-standard deviations above the median.

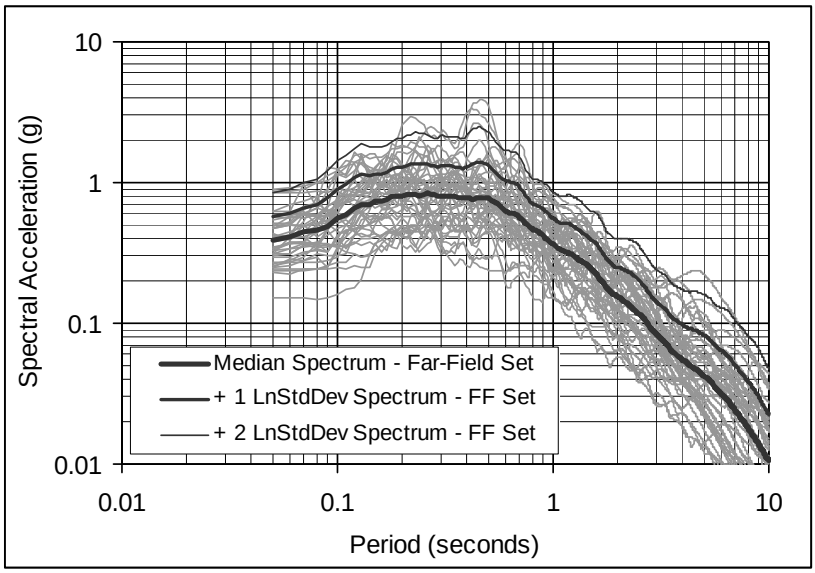

Figure 6-3 Far-Field record set response spectra.

Both ground motion record sets include strong-motion records (i.e., records with PGA > 0.2 g and PGV > 15 cm/sec) from all large-magnitude (M > 6.5) events in the Pacific Earthquake Engineering Research Center (PEER) Next-Generation Attenuation (NGA) database (PEER, 2006a). Large-magnitude events dominate collapse risk and generally have longer durations of shaking, which is important for collapse evaluation of nonlinear degrading models.

The sets include records from soft rock and stiff soil sites (predominantly Site Class C and D conditions), and from shallow crustal sources (predominantly strike-slip and thrust mechanisms). To avoid event bias, no more than two of the strongest records are taken from each earthquake.

The primary function of the Far-Field record set is to provide a fully-defined set of records for use in a consistent manner to evaluate collapse across all applicable Seismic Design Categories, located in any seismic region, and founded on any soil site classification. Actual earthquake records are used, in contrast with artificial or synthetic records, recognizing that regional variation of ground motions would not be addressed. In the United States, strong-motion records date back to the 1933 Long Beach Earthquake, with only a few records obtained from each event until the 1971 San Fernando Earthquake. Large magnitude events are rare, and few existing earthquake ground motion records are strong enough to collapse a large percentage of modern, code-compliant buildings.

Even with many instruments, existing strong motion instrumentation networks (e.g., Taiwan and California) provide coverage for only a small fraction of all regions of high seismicity. Considering the size of the earth and period of geologic time, the available sample of strong motion records from large-magnitude earthquakes is still quite limited, and potentially biased by records from more recent, relatively well-recorded events. Due to the limited number of very large earthquakes, and the frequency ranges of ground motion recording devices, the ground motion record sets are primarily intended for buildings with natural (first-mode) periods less than or equal to 4 seconds. Thus, the record set is not necessarily appropriate for tall buildings with long fundamental periods of vibration greater than 4 seconds.

6.2.3 Ground Motion Record Scaling

Ground motion records are scaled to represent a specific intensity (e.g., the collapse intensity of the index archetypes of interest). Record scaling involves two steps. First, individual records in each set are "normalized" by their respective peak ground velocities, as described in Appendix A. This step is intended to remove unwarranted variability between records due to inherent differences in event magnitude, distance to source, source type and site conditions, without eliminating overall record-to-record variability. Second, normalized ground motions are collectively scaled (or "anchored") to a specific ground motion intensity such that the median spectral acceleration of the record set matches the spectral acceleration at the fundamental period, T, of the index archetype that is being analyzed.

The first step was performed as part of the ground motion development process, so the record sets contained in Appendix A already reflect this normalization. The second step is performed as part of the nonlinear dynamic analysis procedure. This two-step scaling process parallels the ground motion scaling requirements of Section 16.1.3.2 of ASCE/SEI 7-05. Figure 6-4 shows the median spectrum of the Far-Field record set anchored to maximum and minimum MCE response spectra of Seismic Design Categories B, C and D, at a period of 1 second.

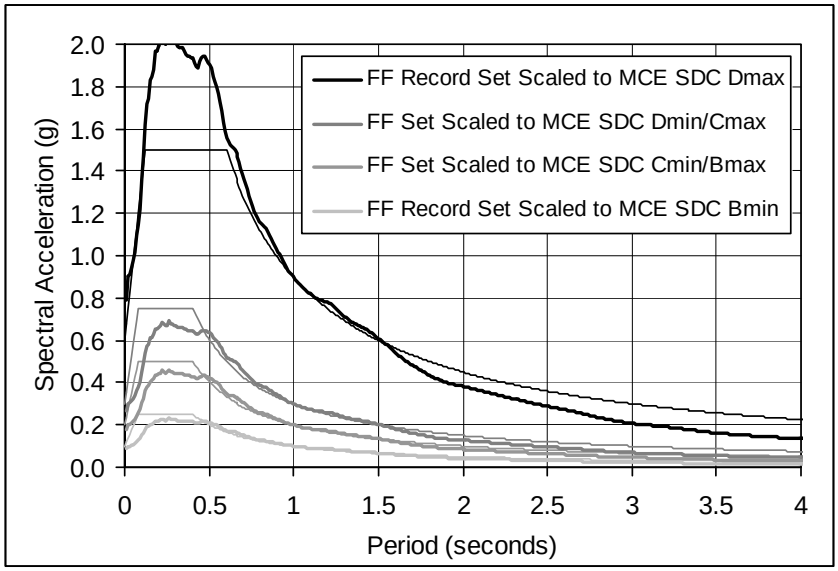

Figure 6-4 Median spectrum of the Far-Field record set anchored to maximum and minimum MCE response spectra of Seismic Design Categories B, C and D, at a period of 1 second.

6.3 Nonlinear Static (Pushover) Analyses

Nonlinear static (pushover) analyses are conducted under the factored gravity load combination of Equation 6-1 and static lateral forces. In general, pushover analysis should be performed following the nonlinear static procedure (NSP) of Section 3.3.3 of ASCE/SEI 41-06.

The vertical distribution of the lateral force, F_x, at each story level, x, should be in proportion to the fundamental mode shape of the index archetype model:

$$F_x \propto m_x \phi_{1,x} \tag{6-4}$$

where m_x is the mass at level x; and $\phi_{1,x}$ is the ordinate of the fundamental mode at level x.

Figure 6-5 shows an idealized pushover curve and definitions of the maximum base shear capacity, V_{max} and the ultimate displacement, δ_u. V_{max} is taken as the maximum base shear strength at any point on the pushover curve, and δ_u is taken as the roof displacement at the point of 20% strength loss ($0.8V_{max}$).

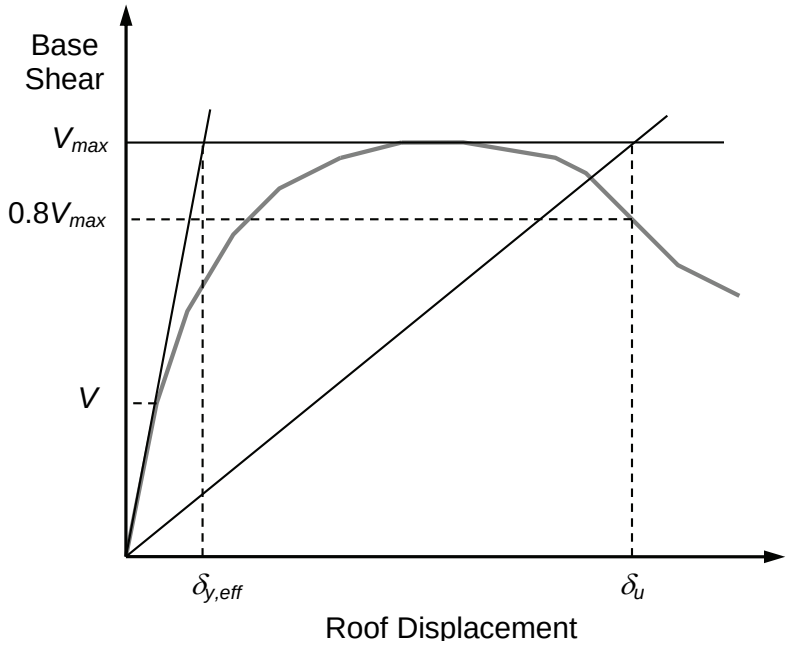

Figure 6-5 Idealized nonlinear static pushover curve

A nonlinear static pushover analysis is used to quantify V_{max} and δ_u, which are then used to compute archetype overstrength, Ω, and period-based ductility, μ_T. In order to quantify these values, the lateral loads are applied monotonically until a loss of 20% of the base shear capacity ($0.8V_{max}$) is achieved.

The overstrength factor for a given index archetype model, Ω, is defined as the ratio of the maximum base shear resistance, V_{max}, to the design base shear, V:

$$\Omega = \frac{V_{max}}{V} \tag{6-5}$$

The period-based ductility for a given index archetype model, μ_T, is defined as the ratio of ultimate roof drift displacement, δ_u, (defined as shown in Figure 6-5) to the effective yield roof drift displacement $\delta_{y,eff}$:

$$\mu_T = \frac{\delta_u}{\delta_{y,eff}} \tag{6-6}$$

The effective yield roof drift displacement is as given by the formula:

$$\delta_{y,eff} = C_O \frac{V_{\max}}{W} \left[\frac{g}{4\pi^2}\right] (\max(T, T_1))^2 \quad (6\text{-}7)$$

where C_0 relates fundamental-mode (SDOF) displacement to roof displacement, V_{max}/W is the maximum base shear normalized by building weight, g is the gravity constant, T is the fundamental period ($C_u T_a$, defined by Equation 5-5), and T_1 is the fundamental period of the archetype model computed using eigenvalue analysis.

The coefficient C_0 is based on Equation C3-4 of ASCE/SEI 41-06, as follows:

$$C_0 = \phi_{1,r} \frac{\sum_1^N m_x \phi_{1,x}}{\sum_1^N m_x \phi_{1,x}^2} \quad (6\text{-}8)$$

where m_x is the mass at level x; and $\phi_{1,x}$ ($\phi_{1,r}$) is the ordinate of the fundamental mode at level x (roof), and N is the number of levels. Additional background on period-based ductility is included in Appendix B.

Since pushover analyses are intended to verify the models and provide a conservative bound on the system overstrength factor, checks for non-simulated collapse modes are not incorporated directly. Non-simulated collapse modes should be considered when evaluating ultimate roof drift displacement, δ_u.

Where three-dimensional analyses are used, separate nonlinear static analyses should be performed to evaluate overstrength and ultimate roof drift displacement independently along the two principle axes of the index archetype model. The resulting values for overstrength and ultimate roof drift displacement are then calculated by averaging the values from each of the principle loading directions.

6.4 Nonlinear Dynamic (Response History) Analyses

Nonlinear dynamic (response history) analyses are conducted under the factored gravity load combination of Equation 6-1 and input ground motions from the Far-Field record set in Appendix A. Nonlinear dynamic analyses are used to establish the median collapse capacity, $\hat{S}_{CT}$, and collapse margin ratio, *CMR*, for each of the index archetype models. Ground motion intensity, S_T, is defined based on the median spectral intensity of the Far-

Field record set, measured at the fundamental period of the structure ($C_u T_a$, defined by Equation 5-5). Determination of the collapse margin ratio for each index archetype model is expected to require approximately 200 nonlinear response history analyses (approximately 5 analyses of varying intensity for each component of the 22 pairs of earthquake ground motion records).

The following sections present background on the collapse assessment methodology followed by specific guidelines for conducting nonlinear dynamic analyses to calculate the collapse parameters, $\hat{S}_{CT}$ and *CMR*, for index archetype models.

6.4.1 Background on Assessment of Collapse Capacity

The median collapse intensity can be visualized through the concept of incremental dynamic analysis (IDA) (Vamvatsikos and Cornell, 2002), in which individual ground motions are scaled to increasing intensities until the structure reaches a collapse point. Results from a set of an incremental dynamic analyses are illustrated in Figure 6-6, where each point in the figure corresponds to the results of one nonlinear dynamic analysis of one index archetype model subjected to one ground motion record that is scaled to one intensity level.

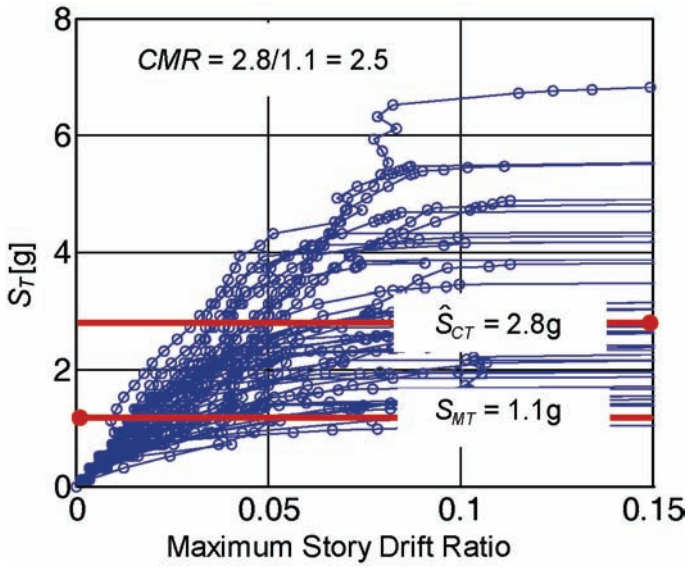

Figure 6-6 Incremental dynamic analysis response plot of spectral acceleration versus maximum story drift ratio.

In Figure 6-6, the results of each analysis are plotted in terms of the spectral intensity of the ground motion (on the vertical axis) versus maximum story drift ratio recorded in the analysis (on the horizontal axis). Each line in Figure 6-6 connects results for a given ground motion scaled to increasing

spectral intensities. Differences between the lines reflect differences in the response of the same index archetype model when subjected to different ground motions with different frequency characteristics. Collapse under each ground motion is judged to occur either directly from dynamic analysis results as evidenced by excessive lateral displacements (lateral dynamic instability) or assessed indirectly through non-simulated component limit state criteria. In Figure 6-6, the median collapse capacity of $\hat{S}_{CT}$ = 2.8g is defined as the spectral intensity when half of the ground motions cause the structure to collapse.

Using collapse data from IDA results, a collapse fragility curve can be defined through a cumulative distribution function (CDF), which relates the ground motion intensity to the probability of collapse (Ibarra et al., 2002). Figure 6-7 shows an example of a cumulative distribution plot obtained by fitting a lognormal distribution through the collapse data points from Figure 6-6.

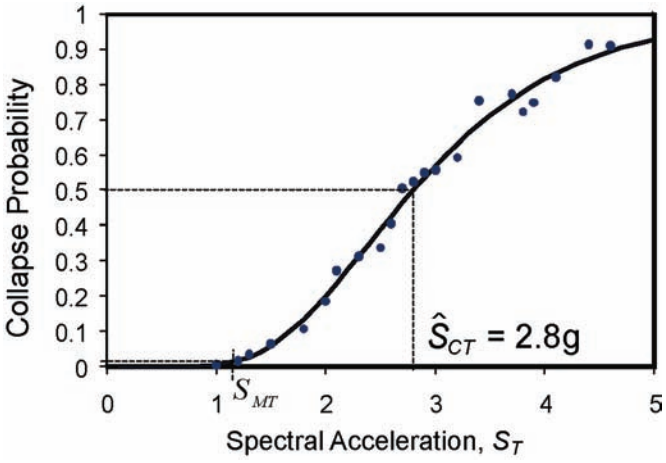

Figure 6-7 Collapse fragility curve, or cumulative distribution function.

The lognormal collapse fragility is defined by two parameters, which are the median collapse intensity, $\hat{S}_{CT}$, and the standard deviation of the natural logarithm, β_{RTR}. The median collapse capacity ($\hat{S}_{CT}$ = 2.8g in the figure) corresponds to a 50% probability of collapse. The slope of the lognormal distribution is measured by β_{RTR}, and reflects the dispersion in results due to record-to-record (*RTR*) variability (uncertainty). In this Methodology only the median collapse intensity, $\hat{S}_{CT}$, is calculated, and record-to-record variability, β_{RTR}, is set to a fixed value (i.e., β_{RTR} = 0.4 for systems with period-based ductility ≥ 3).

Values of record-to-record variability are fixed for several reasons. First, previous studies have shown that the record-to-record variability is fairly constant for different structural models and record sets. Second, more

precise calculation of record-to-record variability would not significantly affect calculation of the *CMR* when combined with other sources of collapse uncertainty. Finally, record-to-record variability is fixed because accurate calculation of β_{RTR} would require collapse data from a larger number of ground motions than is necessary to calculate an accurate median collapse intensity, $\hat{S}_{CT}$.

6.4.2 Calculation of Median Collapse Capacity and CMR

While the IDA concept is useful for illustrating the collapse assessment procedure, the Methodology only requires identification of the median collapse intensity, $\hat{S}_{CT}$, which can be calculated with fewer nonlinear analyses than would otherwise be necessary for developing the full IDA curve. Referring to Figure 6-6, $\hat{S}_{CT}$ can be obtained by scaling all the records in the Far-Field record set to the MCE intensity, S_{MT}, and then increasing the intensity until just over one-half of the scaled ground motion records cause collapse. The lowest intensity at which one-half of the records cause collapse is the median collapse intensity, $\hat{S}_{CT}$. Judicious selection of earthquake intensities close to and approaching the median collapse intensity leads to a significant reduction in the number of analyses that are required. As a result, nonlinear response history analyses for median collapse assessment are computationally much less involved than the full IDA approach. While the full IDA curve is not required, a sufficient number of response points should be plotted at increasing intensities to help validate the accuracy in calculating the median collapse intensity.

The MCE intensity is obtained from the response spectrum of MCE ground motions at the fundamental period, *T*. In Figure 6-6, the MCE intensity, S_{MT}, is 1.1 g, taken directly from the response spectrum for SDC D_{max} in Figure 6-4. The ratio between the median collapse intensity and the MCE intensity is the collapse margin ratio, *CMR*, which is the primary parameter used to characterize the collapse safety of the structure.

$$CMR = \frac{\hat{S}_{CT}}{S_{MT}} \tag{6-9}$$

6.4.3 Ground Motion Record Intensity and Scaling

In the Methodology, ground motion intensities are defined in terms of the median spectral intensity of the Far-Field record set, rather than the spectral intensity of each individual record. Conceptually, this envisions the Far-Field record set as representative of a suite of records from a characteristic earthquake in which spectral intensities of individual records will exhibit

dispersion about the median value of the set. Thus, the median collapse capacity of the structure is equal to the median capacity of the Far-Field record set at the point where half of the records in the set cause collapse of the index archetype model.

The spectral scaling intensity for the ground motion records is determined based on the median spectral acceleration of the Far-Field record set at the fundamental period, T, of the building. For purposes of scaling the spectra and calculating the corresponding MCE hazard spectra, the value of fundamental period is the same as that required for archetype design ($C_u T_a$, defined by Equation 5-5). The spectral acceleration of the record set at the specified period is S_T, and the intensity at the collapse point for each record is S_{CT} (i.e., S_T of the average spectra corresponding to the point when the specified record triggers collapse). The median collapse intensity for the entire record set (the median of 44 records) is $\hat{S}_{CT}$. The spectral acceleration of the MCE hazard, S_{MT}, is given in Table 6-1.

6.4.4 Energy Dissipation and Viscous Damping

To the extent that index archetype models are accurately calibrated for the loading histories encountered in the dynamic analysis, most of the structural damping will be modeled directly in the analysis through hysteretic response of the structural components. Thus, assumed viscous damping for nonlinear collapse analyses should be less than would typically be used in linear dynamic analyses. Depending on the type and characteristics of the nonlinear model, additional viscous damping may be used to simulate the portion of energy dissipation arising from both structural and nonstructural components (e.g., cladding, partitions) that is not otherwise incorporated in the model. When used, viscous damping should be consistent with the inherent damping in the structure that is not already captured by the nonlinear hysteretic response that is directly simulated in the model.

For nonlinear dynamic analyses, equivalent viscous damping is typically assumed to be in the range of 2% to 5% of critical damping for the first few vibration modes that tend to dominate the response. Care should be taken to ensure that added viscous damping does not increase beyond acceptable levels as the model yields. The appropriate amount of damping, and strategies to incorporate it in the assessment, should be confirmed with the peer review panel.

6.4.5 Guidelines for CMR Calculation using Three-Dimensional Nonlinear Dynamic Analyses

For two-dimensional analyses, all forty-four ground motion records (twenty-two pairs) are applied as independent events to calculate the median collapse intensity, $\hat{S}_{CT}$, for each index archetype model. For three-dimensional analyses, the twenty-two record pairs are applied twice to each model, once with the ground motion records oriented along one principal direction, and then again with the records rotated 90 degrees.

Because ground motions records are applied in pairs in three-dimensional nonlinear dynamic analyses, collapse behavior of each index archetype model resulting from each ground motion component is coupled. Notwithstanding other variations between the two-dimensional and three-dimensional analyses, studies have shown that the median collapse intensity resulting from three-dimensional analyses is on average about 20% less than the median collapse intensity resulting from two-dimensional analyses. Thus, the application of pairs of ground motion records in three-dimensional analyses introduces a conservative bias as compared to results from two-dimensional analyses.

To achieve parity with the two-dimensional analyses, an adjustment should be made when calculating the collapse margin ratio using three-dimensional analyses. The *CMR* calculated based on median collapse intensity, $\hat{S}_{CT}$, obtained from three-dimensional analyses should be multiplied by a factor of 1.2. This multiplier is applied in addition to the spectral shape factor, *SSF*, which is used to calculate the adjusted collapse margin ratio, *ACMR*, as part of the performance evaluation in Chapter 7.

6.4.6 Summary of Procedure for Nonlinear Dynamic Analysis

Nonlinear dynamic analysis of each index archetype model includes the following steps:

1. Using the normalized Far-Field earthquake record set in Appendix A, scale all records to an initial scale factor. A suggested initial scale factor is $S_T = 1.3S_{MT,}$, which can be adjusted up or down based on the results of initial analyses.

2. Perform nonlinear response history analyses on each index archetype model using all twenty-two pairs of records in the Far-Field record set. For two-dimensional analyses, models should be analyzed separately for each ground motion component in each pair, for a total of forty-four analyses. For three-dimensional analyses, the twenty-two record pairs should be applied twice to each model, once with the ground motion

records oriented along one principal direction, and then again with the records rotated 90 degrees. Process results to check for simulated collapse (lateral dynamic instability or excessive lateral deformations signaling a sidesway collapse mechanism) or non-simulated collapse (demands that exceed certain component limit state criteria applied external to the analysis).

3. Based on results from the first set of analyses, adjust the ground motion scale factor, and perform additional analyses until collapse is detected for twenty-two of the forty-four ground motions. The median collapse intensity, $\hat{S}_{CT}$, should be taken as the collapse spectral intensity, S_T, observed for the set of analyses where twenty-two records caused collapse. To reduced the number of analyses, the median collapse intensity, $\hat{S}_{CT}$, can be conservatively estimated from the collapse spectral intensity, S_T, observed for any set of analyses where less than twenty-two records cause collapse. This may expedite the assessment for index archetype designs whose actual median collapse intensity (based on 22 records) exceeds the acceptance criteria by a significant margin.

Other strategies can be used for systematically scaling the records to determine the median collapse capacity. The most straightforward approach is to systematically scale up the entire record set, in specified increments, until collapse is detected for twenty-two of the records (or record pairs).

6.5 Documentation of Analysis Results

Nonlinear analysis results serve as the basis for performance evaluation in Chapter 7, and are subject to review by the peer review panel. As a minimum, information on model development, and data from nonlinear static and dynamic analyses, should be documented in accordance with this section.

6.5.1 Documentation of Nonlinear Models

The following information should be reported on the development of the nonlinear index archetype models:

- Description of index archetype models, including graphical representations of idealized models showing support and loading conditions and member types
- Summary of modeling parameters and substantiating test data including material strengths and stress-strain properties, component

and connection strengths and deformation capacities, gravity loads and masses, and damping parameters

- Summary of criteria and substantiating test data for non-simulated collapse modes
- General documentation of analysis software

6.5.2 Data from Nonlinear Static Analyses

The following information should be reported from nonlinear static (pushover) and eigenvalue analyses of each index archetype model:

- Fundamental period of vibration, T, model period of vibration, T_1, and design base shear, V
- Distribution of lateral (pushover) loads
- Plot of base shear versus roof drift
- Fully yielded strength, V_{max}, and static overstrength factor $\Omega = V_{max}/V$
- The effective yield, $\delta_{y,eff}$, ultimate roof displacements, δ_u, and period-based ductility, μ_T
- Story drift ratios at the design base shear, the maximum load V_{max}, and $0.8V_{max}$ (used to gage system behavior)

6.5.3 Data from Nonlinear Dynamic Analyses

The following information should be reported from nonlinear dynamic (response history) analyses of each index archetype model:

- MCE ground motion intensity (MCE spectral acceleration), S_{MT}, and the period used to calculate this value
- Median collapse intensity, $\hat{S}_{CT}$, and collapse margin ratio, *CMR*
- Data used to compute the median collapse capacity, $\hat{S}_{CT}$, along with the response parameter used to identify the collapse condition (e.g., maximum story drift ratio for simulated collapse, and limit-state criteria for non-simulated collapse). Accompanying notes, plots, or narratives describing the governing mode(s) of failure
- Representative plots of hysteresis curves for selected structural components up to the collapse point

Chapter 7
Performance Evaluation

This chapter describes the process for evaluating the performance of a proposed seismic-force-resisting system, assessing the acceptability of a trial value of the response modification coefficient, R, and determining appropriate values of the system overstrength factor, Ω_O, and the deflection amplification factor, C_d.

Performance evaluation is based on the results of nonlinear static and dynamic analyses conducted in accordance with Chapter 6. It requires judgment in interpreting analytical results, assessing uncertainty, and rounding of values for design. Performance evaluation, and selection of appropriate seismic performance factors, requires the concurrence of the peer review panel.

7.1 Overview of the Performance Evaluation Process

The performance evaluation process utilizes results from nonlinear static (pushover) analyses to determine an appropriate value of the system overstrength factor, Ω_O, and results from nonlinear static and nonlinear dynamic (response history) analyses to evaluate the acceptability of a trial value of the response modification coefficient, R. The deflection amplification factor, C_d, is derived from an acceptable value of R, with consideration of the effective damping of the system of interest.

The trial value of the response modification coefficient, R, used to design index archetypes, is evaluated in terms of the acceptability of the collapse margin ratio. Acceptability is measured by comparing the collapse margin ratio, after adjustment for the effects of spectral shape, to acceptable values that depend on the quality of the information used to define the system, total system uncertainty, and established limits on collapse probability.

Performance evaluation follows the process outlined in Figure 7-1, and includes the following steps:

- Obtain calculated values of system overstrength, Ω, period-based ductility, μ_T, and collapse margin ratio, CMR, for each index archetype, from results of nonlinear analyses (Chapter 6).

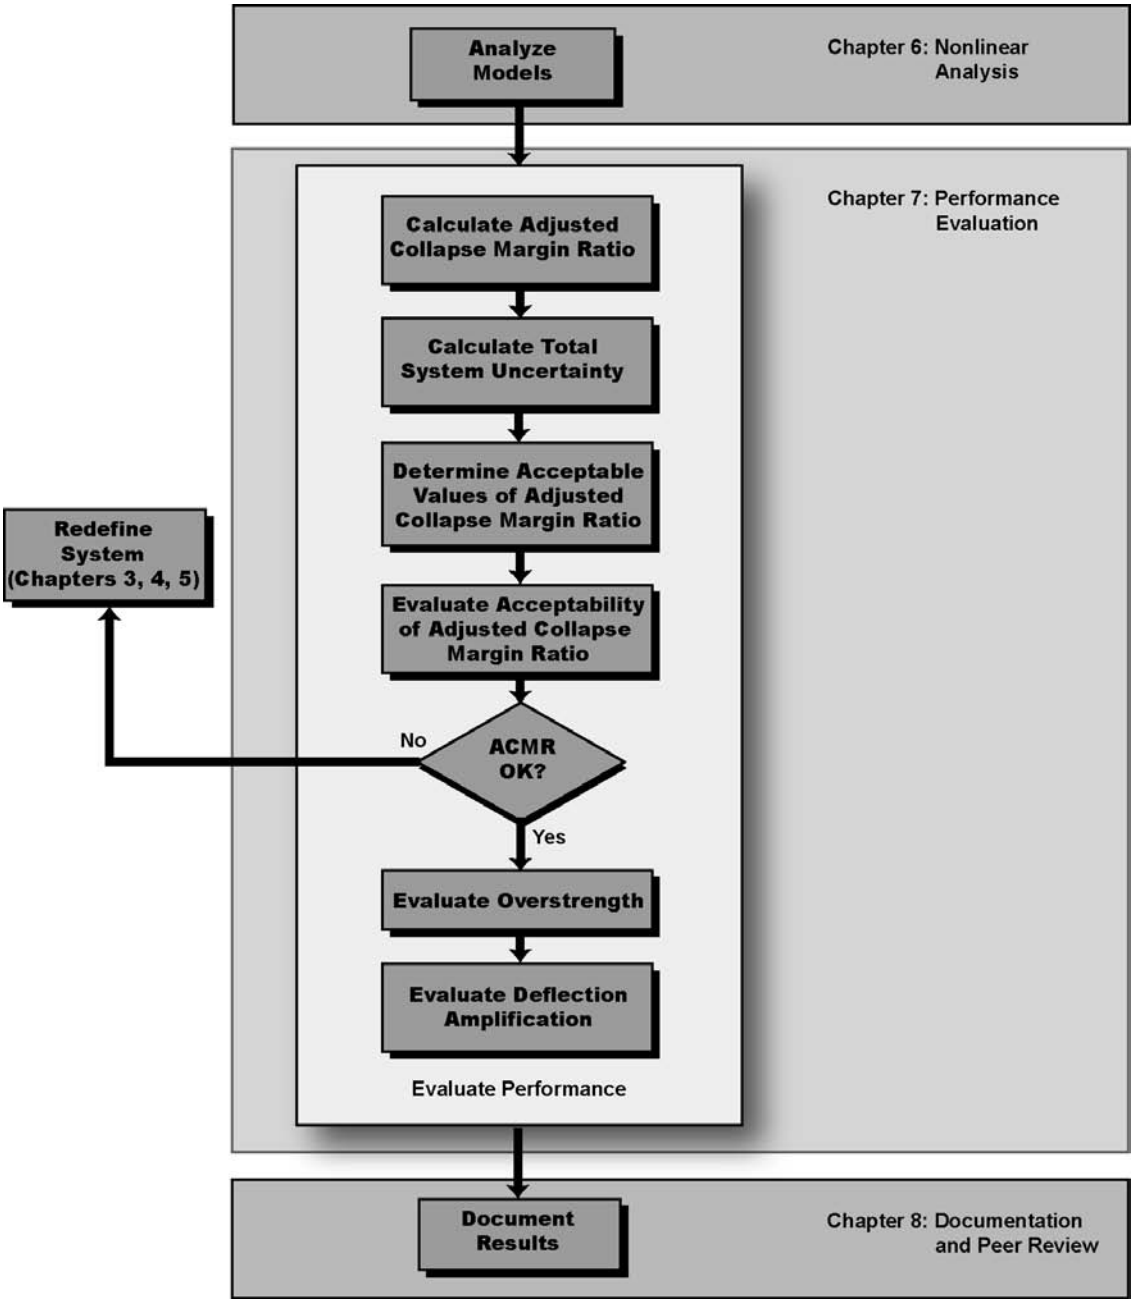

Figure 7-1 Process for performance evaluation

- Calculate the adjusted collapse margin ratio, *ACMR*, for each archetype using the spectral shape factor, *SSF*, which depends on the fundamental period, *T*, and period-based ductility, μ_T, as provided in Section 7.2.
- Calculate total system collapse uncertainty, β_{TOT}, based on the quality ratings of design requirements and test data (Chapter 3), and the quality rating of index archetype models (Chapter 5), as provided in Section 7.3.

- Determine acceptable values of adjusted collapse margin ratio, $ACMR_{10\%}$ and $ACMR_{20\%}$, respectively, based on total collapse system uncertainty, β_{TOT}, as provided in Section 7.4.
- Evaluate the adjusted collapse margin ratio, *ACMR*, for each archetype and average values of *ACMR* for each archetype performance group relative to acceptable values as provided in Section 7.5.
- Evaluate the system overstrength factor, Ω_O, as provided in Section 7.6.
- Evaluate the displacement amplification factor, C_d, as provided in Section 7.7.

If the evaluation of *ACMR* finds trial values of seismic performance factors to be unacceptable, then the system should be redefined and reanalyzed, as needed, and then re-evaluated by repeating performance evaluation process. Systems could be redefined by adjusting the design requirements (Chapter 3), re-characterizing behavior (Chapter 4), or redesigning with new trial values of seismic performance factors (Chapter 5). In general, it is expected that more than one iteration of the evaluation process will be required to determine optimal (and acceptable) values of the seismic performance factors for the system of interest.

7.1.1 Performance Group Evaluation Criteria

In Chapter 4, index archetype configurations are assembled into performance groups that reflect major differences in configuration, design and seismic load intensity and structural period. The binning of index archetype configurations provides the basis for statistical assessment of minimum and average properties of seismic performance factors.

In general, trial values of seismic performance factors are evaluated for each performance group. Results within each performance group are averaged to determine the value for the group, which is the primary basis for judging acceptability of each trial value. The trial value of the response modification factor, *R*, must be found acceptable for all performance groups. The system overstrength factor, Ω_O, is based on the largest average value of overstrength, Ω, for all performance groups (subject to certain limits). The deflection amplification factor, C_d, is derived from the acceptable value of *R* and consideration of the effective damping of the system.

The governing performance group for the response modification factor, *R*, is the one with the smallest average value of *ACMR*. The governing performance group for the overstrength factor, Ω_O, is the one with the largest average value of Ω. It is likely that the response modification factor, *R*, and

the system overstrength factor, Ω_O, will be governed by different performance groups.

Results are also evaluated to identify potential outliers within each performance group (i.e., individual index archetypes that perform significantly worse than the average performance of the group). Outliers can be accommodated by adopting more conservative values of seismic performance factors, or they can be eliminated from the archetype design space by revising the design requirements (e.g., implementation of height limits or other restrictions on use). Revision of seismic performance factors or design requirements will necessitate re-design and re-analysis of index archetypes, and re-evaluation of system performance.

It is not required that all index archetype configurations be used for evaluation, if it can be shown by selective analysis that certain design combinations (configurations) are not critical and do not control the performance evaluation. Caution should be exercised in removing non-critical index archetype configurations from a governing performance group since their removal could adversely affect the average value of the group used in the evaluation.

7.1.2 Acceptable Probability of Collapse

The fundamental premise of the performance evaluation process is that an acceptably low, yet reasonable, probability of collapse can be established as a criterion for assessing the collapse performance of a proposed system.

In this Methodology, it is suggested that the probability of collapse due to Maximum Considered Earthquake (MCE) ground motions be limited to 10%. Each performance group is required to meet this collapse probability limit, on average, recognizing that some individual archetypes could have collapse probabilities that exceed this value. A limit of twice that value, or 20%, is suggested as a criterion for evaluating the acceptability of potential "outliers" within a performance group.

It should be noted that these limits were selected based on judgment. Within the performance evaluation process, these values could be adjusted to reflect different values of acceptable probabilities of collapse that are deemed appropriate by governing jurisdictions, or other authorities employing this Methodology to establish seismic design requirements and seismic performance factors for a proposed system.

7.2 Adjusted Collapse Margin Ratio

Collapse capacity, and the calculation of collapse margin ratio, can be significantly influenced by the frequency content (spectral shape) of the ground motion record set. To account for the effects of spectral shape, the collapse margin ratio, *CMR*, is modified to obtain an adjusted collapse margin ratio, *ACMR*, for each index archetype, *i*:

$$ACMR_i = SSF_i \times CMR_i \tag{7-1}$$

This adjustment is in addition to the adjustment of the *CMR* made to account for three-dimensional nonlinear dynamic analysis effects specified in Chapter 6.

7.2.1 Effect of Spectral Shape on Collapse Margin

Baker and Cornell (2006) have shown that rare ground motions in the Western United States, such as those corresponding to the MCE, have a distinctive spectral shape that differs from the shape of the design spectrum used for structural design in ASCE/SEI 7-05. In essence, the shape of the spectrum of rare ground motions is peaked at the period of interest, and drops off more rapidly (and has less energy) at periods that are longer or shorter than the period of interest. Where ground motion intensities are defined based on the spectral acceleration at the first-mode period of a structure, and where structures have sufficient ductility to inelastically soften into longer periods of vibration, this peaked spectral shape, and more rapid drop at other periods, causes rare records to be less damaging than would otherwise be expected based on the shape of the standard design spectrum.

The most direct approach to account for spectral shape would be to select a unique set of ground motions that have the appropriate shape for each site, hazard level, and structural period of interest. This, however, is not feasible in a generalized procedure for assessing the collapse performance of a class of structures, with a range of possible configurations, located in different geographic regions, with different soil site classifications. To remove this conservative bias, simplified spectral shape factors, *SSF*, which depend on fundamental period and period-based ductility, are used to adjust collapse margin ratios. Background and development of spectral shape factors are described in Appendix B.

7.2.2 Spectral Shape Factors

Spectral shape factors, *SSF*, are a function of the fundamental period, *T*, the period-based ductility, μ_T, and the applicable Seismic Design Category.

Table 7-1a and Table 7-1b provide values of *SSF* for use in adjusting the collapse margin ratio, *CMR*.

Table 7-1a Spectral Shape Factor (*SSF*) for Archetypes Designed for SDC B, SDC C, or SDC D_{min}

T (sec.)	Period-Based Ductility, μ_T							
	1.0	1.1	1.5	2	3	4	6	≥ 8
≤ 0.5	1.00	1.02	1.04	1.06	1.08	1.09	1.12	1.14
0.6	1.00	1.02	1.05	1.07	1.09	1.11	1.13	1.16
0.7	1.00	1.03	1.06	1.08	1.10	1.12	1.15	1.18
0.8	1.00	1.03	1.06	1.08	1.11	1.14	1.17	1.20
0.9	1.00	1.03	1.07	1.09	1.13	1.15	1.19	1.22
1.0	1.00	1.04	1.08	1.10	1.14	1.17	1.21	1.25
1.1	1.00	1.04	1.08	1.11	1.15	1.18	1.23	1.27
1.2	1.00	1.04	1.09	1.12	1.17	1.20	1.25	1.30
1.3	1.00	1.05	1.10	1.13	1.18	1.22	1.27	1.32
1.4	1.00	1.05	1.10	1.14	1.19	1.23	1.30	1.35
≥ 1.5	1.00	1.05	1.11	1.15	1.21	1.25	1.32	1.37

Table 7-1b Spectral Shape Factor (*SSF*) for Archetypes Designed using SDC D_{max}

T (sec.)	Period-Based Ductility, μ_T							
	1.0	1.1	1.5	2	3	4	6	≥ 8
≤ 0.5	1.00	1.05	1.1	1.13	1.18	1.22	1.28	1.33
0.6	1.00	1.05	1.11	1.14	1.2	1.24	1.3	1.36
0.7	1.00	1.06	1.11	1.15	1.21	1.25	1.32	1.38
0.8	1.00	1.06	1.12	1.16	1.22	1.27	1.35	1.41
0.9	1.00	1.06	1.13	1.17	1.24	1.29	1.37	1.44
1.0	1.00	1.07	1.13	1.18	1.25	1.31	1.39	1.46
1.1	1.00	1.07	1.14	1.19	1.27	1.32	1.41	1.49
1.2	1.00	1.07	1.15	1.2	1.28	1.34	1.44	1.52
1.3	1.00	1.08	1.16	1.21	1.29	1.36	1.46	1.55
1.4	1.00	1.08	1.16	1.22	1.31	1.38	1.49	1.58
≥ 1.5	1.00	1.08	1.17	1.23	1.32	1.4	1.51	1.61

Since spectral shape factors are considerably different between SDC D_{max} and other Seismic Design Categories, the governing performance group for the adjusted collapse margin ratio, *ACMR*, may not be the same as the governing performance group for the collapse margin ratio, *CMR*, before adjustment.

7.3 Total System Collapse Uncertainty

Many sources of uncertainty contribute to variability in collapse capacity. Larger variability in the overall collapse prediction will necessitate larger collapse margins in order to limit the collapse probability to an acceptable level at the MCE intensity. It is important to evaluate all significant sources of uncertainty in collapse response, and to incorporate their effects in the collapse assessment process.

7.3.1 Sources of Uncertainty

The following sources of uncertainty are considered in the collapse assessment process:

- **Record-to-Record Uncertainty (*RTR*).** Record-to-record uncertainty is due to variability in the response of index archetypes to different ground motion records. Record-to-record variability is evident in incremental dynamic response plots (as shown in Figure 6-5). Variability in response is due to the combined effects of: (1) variations in frequency content and dynamic characteristics of the various records; and (2) variability in the hazard characterization as reflected in the Far-Field ground motion record set. Values of record-to-record variability, β_{RTR}, ranging from 0.35 to 0.45 are fairly consistent among various building types (Haselton, 2006; Ibarra and Krawinkler, 2005a and 2005b; Zareian et al., 2006; Zareian, 2006). Based on available research and studies of example archetype evaluations using the Far-Field ground motion record set in Appendix A, a fixed value of $\beta_{RTR} = 0.40$ is assumed in the performance evaluation of systems with significant period elongation (i.e., period-based ductility, $\mu_T \geq 3$). Most systems, even those with limited ductile capacity, have significant period elongation before collapse, and are appropriately evaluated using this value.

  Studies in Appendix A also found that record-to-record variability can be significantly less than $\beta_{RTR} = 0.40$ for systems that have little, or no, period elongation (e.g., systems with very limited ductility and certain base-isolated systems). For these systems, values of record-to-record variability can be reduced as follows:

$$\beta_{RTR} = 0.1 + 0.1\mu_T \leq 0.40 \qquad (7\text{-}2)$$

  where β_{RTR} must be greater than or equal to 0.20.

- **Design Requirements Uncertainty (*DR*).** Design requirements uncertainty is related to the completeness and robustness of the design requirements, and the extent to which they provide safeguards against

unanticipated failure modes. Design requirements-related uncertainty is quantified in terms of the quality of design requirements, rated in accordance with the requirements in Chapter 3.

- **Test Data Uncertainty (*TD*).** Test data uncertainty is related to the completeness and robustness of the test data used to define the system. Uncertainty in test data is closely associated with, but distinct from, modeling-related uncertainty. Test data-related uncertainty is quantified in terms of the quality of test data, rated in accordance with the requirements in Chapter 3.
- **Modeling Uncertainty (*MDL*).** Modeling uncertainty is related to how well index archetype models represent the full range of structural response characteristics and associated design parameters of the archetype design space, and how well the analysis models capture structural collapse behavior through direct simulation or non-simulated component checks. Modeling-related uncertainty is quantified in terms of the quality of index archetype models, rated in accordance with the requirements in Chapter 5.

7.3.2 Combining Uncertainties in Collapse Evaluation

The total uncertainty is obtained by combining *RTR, DR, TD,* and *MDL* uncertainties. Formally, the collapse fragility of each index archetype is defined by the random variable, S_{CT}, assumed to be equal to the product of the median value of the collapse ground motion intensity, $\hat{S}_{CT}$, as calculated by nonlinear dynamic analysis, and the random variable, λ_{TOT}:

$$S_{CT} = \hat{S}_{CT}\lambda_{TOT} \tag{7-3}$$

where λ_{TOT} is assumed to be lognormally distributed with a median value of unity and a lognormal standard deviation of $\beta_{TOT.}$ The lognormal random variable, λ_{TOT}, is defined as the product of four component random variables as:

$$\lambda_{TOT} = \lambda_{RTR}\lambda_{DR}\lambda_{TD}\lambda_{MDL} \tag{7-4}$$

where λ_{RTR}, $\lambda_{MDL,}$ $\lambda_{DR,}$ and λ_{TD} are assumed to be independent and lognormally distributed with median values of unity, and lognormal standard deviation parameters, β_{RTR}, $\beta_{DR,}$ β_{TD}, and $\beta_{MDL,}$ respectively. Since the four component random variables are assumed to be statistically independent, the lognormal standard deviation parameter, β_{TOT}, describing total collapse uncertainty, is given by:

$$\beta_{TOT} = \sqrt{\beta_{RTR}^2 + \beta_{DR}^2 + \beta_{TD}^2 + \beta_{MDL}^2} \qquad (7\text{-}5)$$

Where: β_{TOT} = total system collapse uncertainty (0.275 - 0.950)
β_{RTR} = record-to-record collapse uncertainty (0.20 - 0.40)
β_{DR} = design requirements-related collapse uncertainty (0.10 – 0.50)
β_{TD} = test data-related collapse uncertainty (0.10 – 0.50)
β_{MDL} = modeling-related collapse uncertainty (0.10 – 0.50).

The performance evaluation process does not require explicit calculation of the lognormal distribution given by Equation 7-3 and Equation 7-4. Acceptance criteria, however, are based on the composite uncertainty, β_{TOT}, developed on the basis of Equation 7-5.

7.3.3 Effect of Uncertainty on Collapse Margin

Uncertainty influences the shape of a collapse fragility curve plotted from incremental dynamic analysis results. Figure 7-2 shows two collapse fragility curves reflecting two different levels of uncertainty. The dashed curve "a" reflects a β_{RTR} = 0.4, and the solid curve "b" reflects a β_{TOT} = 0.65. As indicated in the figure, additional uncertainty has the effect of flattening the curve. While the median collapse intensity, $\hat{S}_{CT}$, is unchanged, additional uncertainty causes a large increase in the probability of collapse at the MCE intensity, S_{MT}.

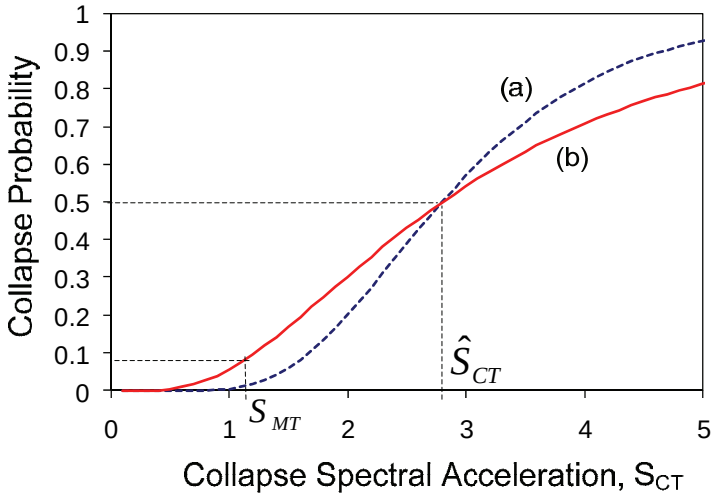

Figure 7-2 Collapse fragility curves considering (a) ground motion record-to-record uncertainty, (b) modifications for total uncertainty.

Changes in the probability of collapse at the MCE intensity will affect the collapse margin ratio, *CMR*. Figure 7-3 shows collapse fragility curves for two hypothetical seismic-force-resisting systems that have different levels of

collapse uncertainty. In this example, both systems have been designed for the same seismic response coefficient, C_S, and happen to have the same median collapse intensity, $\hat{S}_{CT}$. System No. 1, however, has a larger uncertainty and a "flatter" collapse fragility curve. To achieve the same 10% probability of collapse for MCE ground motions, a larger collapse margin ratio is required for System No. 1 than is required for System No. 2 (i.e., $CMR_1 > CMR_2$). Thus, System No. 1 would have to be designed using a smaller response modification coefficient, R, than System No. 2.

Figure 7-4 shows collapse fragility curves for another set of hypothetical seismic-force-resisting systems with different levels of collapse uncertainty. As in Figure 7-3, both systems are designed for the same seismic response coefficient, C_S, but in this case, the two systems are also designed for the same response modification coefficient, R. The difference in uncertainty, however, requires different collapse margin ratios to achieve the same median probability of collapse. In order to utilize the same response modification coefficient, R, System No. 1, with larger uncertainty and flatter collapse fragility, is required to have a larger collapse margin ratio than System No. 3 (i.e., $CMR_1 > CMR_3$).

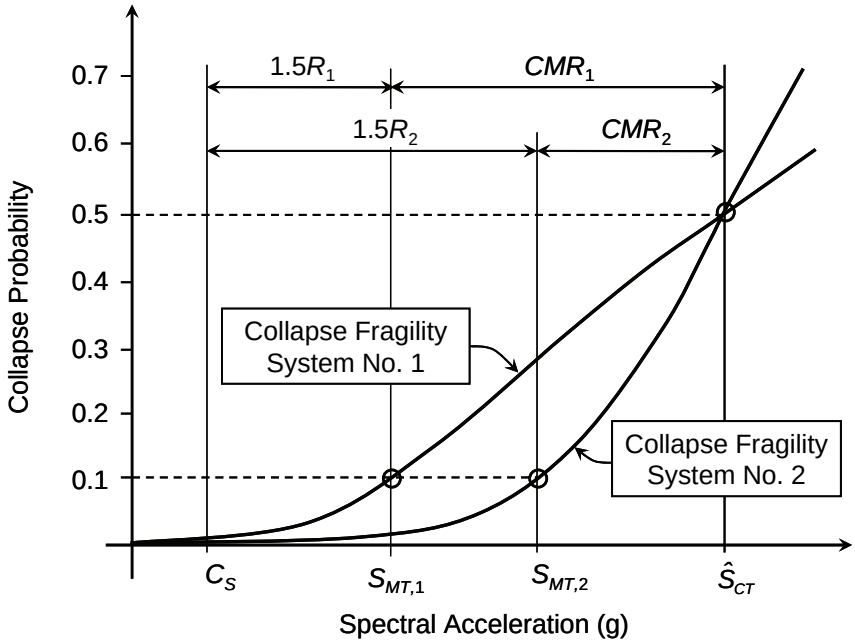

Figure 7-3 Illustration of fragility curves and collapse margin ratios for two hypothetical seismic-force-resisting systems – same median collapse level.

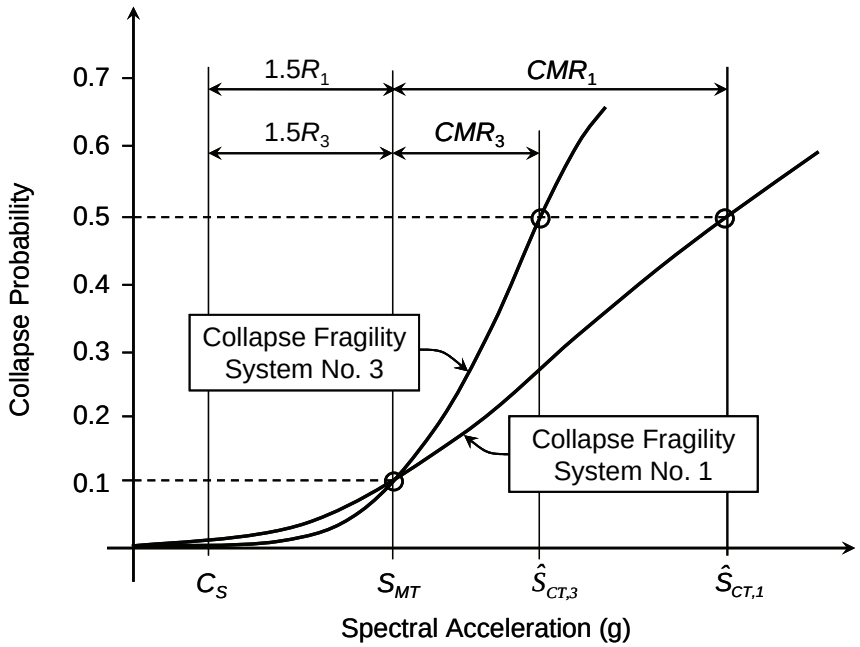

Figure 7-4 Illustration of fragility curves and collapse margin ratios for two hypothetical seismic-force-resisting systems – same *R* factor.

7.3.4 Total System Collapse Uncertainty

Total system collapse uncertainty is calculated based on Equation 7-5, and is a function of record-to-record (*RTR*) uncertainty, design requirements-related (*DR*) uncertainty, test data-related (*TD*) uncertainty, and modeling (*MDL*) uncertainty.

Quality ratings for design requirements, test data, and nonlinear models are translated into quantitative values of uncertainty based on the following scale: (A) Superior, $\beta = 0.10$; (B) Good, $\beta = 0.20$; (C) Fair, $\beta = 0.35$; and (D) Poor, $\beta = 0.50$. A broad range of subjective values of uncertainty are associated with the four quality ratings (Superior, Good, Fair and Poor) to reward "higher quality" systems that have more robust design requirements, more comprehensive test data, and more reliable nonlinear analysis models with lower values of total system collapse uncertainty.

Record-to-record uncertainty and, hence, total system collapse uncertainty, depends on period-based ductility. While subjective in nature, uncertainty values associated with quality ratings, when combined with record-to-record uncertainty, yield reasonable values of total system collapse uncertainty. Resulting values range from $\beta_{TOT} = 0.275$ for the most certain of systems (all Superior quality ratings and $\beta_{RTR} = 0.2$), to $\beta_{TOT} = 0.950$ for the least certain of systems (all Poor quality ratings and $\beta_{RTR} = 0.4$).

Values of total system collapse uncertainty, β_{TOT}, for index archetype models with a period-based ductility, $\mu_T \geq 3$ are provided in Table 7-2a through Table 7-2d, based on record-to-record uncertainty, $\beta_{RTR} = 0.4$. Each of these four tables is specific to a different model quality rating of (A) Superior, (B) Good, (C) Fair, or (D) Poor. Values in each table are based on Equation 7-5 and the applicable combination of quality ratings for test data and design requirements.

Table 7-2a Total System Collapse Uncertainty (β_{TOT}) for Model Quality (A) Superior and Period-Based Ductility, $\mu_T \geq 3$

Quality of Test Data	Quality of Design Requirements

In general, most archetypes are expected to have a period-based ductility of $\mu_T \geq 3$, and Tables 7-2a through 7-2d will be used for collapse performance evaluation of most systems. For index archetype models that have a period-based ductility of $\mu_T < 3$, tables have not been provided. Values of record-to-record uncertainty, β_{RTR}, should be calculated using Equation 7-2, and total collapse system uncertainty, β_{TOT}, should be calculated using Equation 7-5, rounded to the nearest 0.025. Values of design requirements uncertainty, β_{DR}, test data uncertainty, β_{TD}, and model uncertainty, β_{MDL}, should be based on their respective quality ratings.

7.4 Acceptable Values of Adjusted Collapse Margin Ratio

Acceptable values of adjusted collapse margin ratio are based on total system collapse uncertainty, β_{TOT}, and established values of acceptable probabilities of collapse. They are based on the assumption that the distribution of collapse level spectral intensities is lognormal, with a median value, $\hat{S}_{CT}$, and a lognormal standard deviation equal to the total system collapse uncertainty, β_{TOT}.

Table 7-3 provides acceptable values of adjusted collapse margin ratio, $ACMR_{10\%}$ and $ACMR_{20\%}$, based on total system collapse uncertainty and values of acceptable collapse probability, taken as 10% and 20%, respectively. Other values of collapse probability ranging from 5% - 25% are shown for comparison and reference. Lower values of acceptable collapse probability and higher levels of collapse uncertainty result in higher required values of adjusted collapse margin ratio.

Table 7-3 Acceptable Values of Adjusted Collapse Margin Ratio ($ACMR_{10\%}$ and $ACMR_{20\%}$)

Total System Collapse Uncertainty	Collapse Probability				
	5%	10% ($ACMR_{10\%}$)	15%	20% ($ACMR_{20\%}$)	25%
0.275	1.57	**1.42**	1.33	**1.26**	1.20
0.300	1.64	**1.47**	1.36	**1.29**	1.22
0.325	1.71	**1.52**	1.40	**1.31**	1.25
0.350	1.78	**1.57**	1.44	**1.34**	1.27
0.375	1.85	**1.62**	1.48	**1.37**	1.29
0.400	1.93	**1.67**	1.51	**1.40**	1.31
0.425	2.01	**1.72**	1.55	**1.43**	1.33
0.450	2.10	**1.78**	1.59	**1.46**	1.35
0.475	2.18	**1.84**	1.64	**1.49**	1.38
0.500	2.28	**1.90**	1.68	**1.52**	1.40
0.525	2.37	**1.96**	1.72	**1.56**	1.42
0.550	2.47	**2.02**	1.77	**1.59**	1.45
0.575	2.57	**2.09**	1.81	**1.62**	1.47
0.600	2.68	**2.16**	1.86	**1.66**	1.50
0.625	2.80	**2.23**	1.91	**1.69**	1.52
0.650	2.91	**2.30**	1.96	**1.73**	1.55
0.675	3.04	**2.38**	2.01	**1.76**	1.58
0.700	3.16	**2.45**	2.07	**1.80**	1.60
0.725	3.30	**2.53**	2.12	**1.84**	1.63
0.750	3.43	**2.61**	2.18	**1.88**	1.66
0.775	3.58	**2.70**	2.23	**1.92**	1.69
0.800	3.73	**2.79**	2.29	**1.96**	1.72
0.825	3.88	**2.88**	2.35	**2.00**	1.74
0.850	4.05	**2.97**	2.41	**2.04**	1.77
0.875	4.22	**3.07**	2.48	**2.09**	1.80
0.900	4.39	**3.17**	2.54	**2.13**	1.83
0.925	4.58	**3.27**	2.61	**2.18**	1.87
0.950	4.77	**3.38**	2.68	**2.22**	1.90

7.5 Evaluation of the Response Modification Coefficient, *R*

Acceptable performance is defined by the following two basic collapse prevention objectives:

- The probability of collapse for MCE ground motions is approximately 10%, or less, on average across a performance group.
- The probability of collapse for MCE ground motions is approximately 20%, or less, for each index archetype within a performance group.

Acceptable performance is achieved when, for each performance group, adjusted collapse margin ratios, *ACMR*, for each index archetype meet the following two criteria:

- the average value of adjusted collapse margin ratio for each performance group exceeds $ACMR_{10\%}$:

$$\overline{ACMR_i} \geq ACMR10\% \tag{7-6}$$

- individual values of adjusted collapse margin ratio for each index archetype within a performance group exceeds $ACMR_{20\%}$:

$$ACMR_i \geq ACMR20\% \tag{7-7}$$

7.6 Evaluation of the Overstrength Factor, Ω_O

The average value of archetype overstrength, Ω, is calculated for each performance group. The value of the system overstrength factor, Ω_O, for use in design should not be taken as less than the largest average value of calculated archetype overstrength, Ω, from any performance group. The system overstrength factor, Ω_O, should be conservatively increased to account for variation in overstrength results of individual index archetypes, and judgmentally rounded to half unit intervals (e.g., 1.5, 2.0, 2.5, and 3.0).

The system overstrength factor, Ω_O, need not exceed 1.5 times the response modification coefficient, *R*. A practical limit on the value of Ω_O is about 3.0, consistent with the largest value of this factor specified in Table 12.2-1 of ASCE/SEI 7-05 for all current approved seismic-force-resisting systems.

Example applications (Chapter 9) show that values of archetype overstrength, Ω, can be as large as $\Omega = 6.0$ for certain configurations, and are highly variable. Limiting system overstrength to $\Omega_O = 3.0$, as specified in ASCE/SEI 7-05, was considered necessary for practical design considerations.

7.7 Evaluation of the Deflection Amplification Factor, C_d

The deflection amplification factor, C_d, is based on the acceptable value of the response modification factor, R, reduced by the damping factor, B_I, corresponding to the inherent damping of the system of interest:

$$C_d = \frac{R}{B_I} \tag{7-8}$$

where: C_d = deflection amplification factor

R = system response modification factor

B_I = numerical coefficient as set forth in Table 18.6-1 of ASCE/SEI 7-05 for effective damping, β_I, and period, T

β_I = component of effective damping of the structure due to the inherent dissipation of energy by elements of the structure, at or just below the effective yield displacement of the seismic-force-resisting system, Section 18.6.2.1 of ASCE/SEI 7-05.

In general, inherent damping may be assumed to be 5 percent of critical, and a corresponding value of the damping coefficient, $B_I = 1.0$ (Table 18.6-1, ASCE/SEI 7-05). Thus, for most systems the value of C_d will be equal to the value of R.

Equating the deflection amplification factor, C_d, to the R factor is based on the "Newmark rule," which assumes that inelastic displacement is approximately equal to elastic displacement (at the roof). This is consistent with research findings for systems with nominal (5% of critical) damping and fundamental periods greater than the transition period, T_s. It is recognized that for short-period systems ($T < T_s$) inelastic displacement generally exceeds elastic displacement, but it was not considered appropriate to base the deflection amplification factor on response of short-period systems, unless the systems are displacement sensitive. Short-period, displacement sensitive systems should incorporate the consequences of these larger inelastic displacements.

Chapter 8
Documentation and Peer Review

This chapter describes documentation and peer review requirements for a proposed seismic-force-resisting system. It identifies recommended qualifications, expertise, and responsibilities for personnel involved with the development and review of a proposed system. It lists information that should be included in a report documenting the development of a system, and discusses requirements for review at each step of the developmental process.

8.1 Recommended Qualifications, Expertise and Responsibilities for a System Development Team

In order to collect the necessary data and apply the procedures of this Methodology, a system development team will need to have certain qualifications, experience, and expertise. These include the ability to: (1) adequately test materials, components and assemblies; (2) develop comprehensive design and construction requirements; (3) develop archetype designs; and (4) analyze archetype models.

A development team is responsible for following the procedures of this Methodology in determining seismic performance factors for a proposed system, defining the limits under which a system will be applicable, documenting results, and obtaining approval of the peer review panel.

8.1.1 System Sponsor

The system sponsor is a person or organization that has conceived a new seismic-force-resisting system and will benefit from its use. The system sponsor is responsible for assembling a development team, selecting an independent peer review panel, and submitting a proposed system for approval and use.

8.1.2 Testing Qualifications, Expertise and Responsibilities

The testing laboratories engaged in the development of a proposed system must have the capability to perform material, component, connection, assembly, and system tests necessary for quantifying the material and behavioral properties of the system. Testing laboratories used to conduct the

experimental investigation program should comply with national or international accreditation criteria, such as ISO/IEC 17025, *General Requirements for the Competence of Testing and Calibration Laboratories* (ISO/IEC, 2005). Testing laboratories that are not accredited may still be used for an experimental investigation program, subject to the approval of the peer review panel.

Testing facility staff should have the necessary expertise to establish and execute an experimental program, conduct the tests, and mine existing research from other relevant available test data.

8.1.3 Engineering and Construction Qualifications, Expertise and Responsibilities

Member(s) of a development team must have sufficient experience and expertise to develop comprehensive design and construction requirements, and to perform trial system designs. This should include familiarity with seismic design requirements specified in ASCE/SEI 7, and material-specific reference standards for design and detailing requirements for other similar systems. To be viable for use, a proposed system must be feasible to construct. Familiarity with proposed construction techniques, or established construction techniques for other similar systems is needed.

8.1.4 Analytical Qualifications, Expertise and Responsibilities

Member(s) of a development team must have sufficient experience and expertise to interpret test data and develop sophisticated nonlinear models capable of simulating the potential failure modes and collapse behaviors of a proposed system. This should include knowledge and experience in the analytical approaches specified in the Methodology, knowledge of material, component, connection, and overall system performance, and experience with analysis software capable of simulating system response.

8.2 Documentation of System Development and Results

The results of system development efforts must be thoroughly documented at each step of the process for: (1) review and approval by the peer review panel; (2) review and approval by an authority having jurisdiction over its eventual use; and (3) use in design and construction.

Documentation of the development of seismic performance factors for a proposed system should include, but is not necessarily limited to, the following:

- Description of the intended system applications and expected performance
- Limitations on system use
- Typical horizontal and vertical geometric configurations
- Clear and complete design requirements and specifications for the system, providing enough information to quantify strength limit states, proportion and detail components, analyze predicted response, and confirm satisfactory behavior
- Summary of test data and other supporting evidence from an experimental investigation program validating material properties and component behavior, calibrating nonlinear analysis models, and establishing performance acceptance criteria
- Description of index archetype configurations and extent of archetype design space
- Identification of performance groups, applicable Seismic Design Categories, and gravity load intensities
- Idealized model configurations, nonlinear modeling parameters, documentation of analysis software, and information used in model calibration
- Criteria for non-simulated collapse modes
- Summary of nonlinear model results, demand parameters, and response quantities
- Quality ratings for design requirements, test data, and nonlinear models
- Summary of performance evaluation results, derived quantities, and acceptance criteria
- Proposed seismic performance factors (R, Ω_O, and C_d)

8.3 Peer Review Panel

Implementation of this Methodology involves much uncertainty, judgment and potential for variation. Deciding on an appropriate level of detail to adequately characterize performance of a proposed system should be performed at each step in the process in collaboration with an independent peer review panel.

It is recommended that a peer review panel consisting of knowledgeable experts be retained for this purpose. The peer review panel should be familiar with the procedures of this Methodology, should have sufficient

knowledge to render an informed opinion on the developmental process, and should include expertise in each of the following areas:

- Material, component, and assembly testing
- Engineering design and construction
- Nonlinear collapse simulation

Members of the peer review panel must be qualified to critically evaluate the development of the proposed system including testing, design, and analysis. If a unique computer code is developed by the development team, the peer review panel should be capable of performing independent analyses of the proposed system using other analysis platforms.

8.3.1 Peer Review Panel Selection

It is envisioned that the cost of the peer review panel will be borne by the system sponsor. As such, it is expected that members of the peer review panel could be selected by the system sponsor. An alternative arrangement could be made in which the system sponsor submits funding to the authority having jurisdiction, which then uses the funding to implement an independent peer review process. Such an arrangement would be similar to the outside plan check process currently used in some building departments.

It is intended that the peer review panel be an independent set of reviewers who will advise and guide the development team at each step in the process. It is recommended that other stakeholders, including authorities with jurisdiction over the eventual use of the system in design and construction, be consulted in the selection of peer review panel members, and in the deliberation on their findings.

8.3.2 Peer Review Roles and Responsibilities

The peer review panel is responsible for reviewing and commenting on the approach taken by the development team including the extent of the experimental program, testing procedures, design requirements, development of structural system archetypes, analytical approaches, extent of the nonlinear analysis investigation, and the final selection of the proposed seismic performance factors.

The peer review panel is responsible for reporting their opinion on the work performed by the developmental team, their findings, recommendations, and conclusions. All documentation from the peer review panel should be made available for review by the authority having jurisdiction over approval of the proposed system.

If there are any areas where concurrence between the peer review panel and the development team was not reached, or where the peer review panel was not satisfied with the approach or extent of the work performed, this information should be made available as part of the peer review documentation, and reflected in the total uncertainty used in calculating the system acceptance criteria, and in determining the final values of proposed seismic performance factors.

8.4 Submittal

It is expected that a system sponsor will wish to submit a proposed system to an authority for approval and use. For national building codes and standards, one such authority is the National Institute of Building Science's Building Seismic Safety Council (BSSC) Provisions Update Committee (PUC), which has jurisdiction over the FEMA's National Earthquake Hazards Reduction Program *(NEHRP) Recommended Provisions for Seismic Regulations for New Buildings and Other Structures* (*NEHRP Recommended Provisions*). BSSC's PUC, along with its technical subcommittees, is a nationally recognized leader in reviewing and endorsing new seismic force-resisting systems for ultimate inclusion in national building codes and standards.

In some cases, a proposed system could be submitted to the ASCE/SEI 7 standard development committee, but this committee would normally only accept systems similar to systems that are already listed in the standard. Systems can also be submitted directly to model building codes through the code change process.

Another approach is to promote a new system through a relevant material standard organization, such as the American Concrete Institute (ACI), American Institute of Steel Construction (AISC), American Iron and Steel Institute (AISI), or the American Forest & Paper Association (AF&PA). Approval through one of these organizations, however, will still require adoption by national building codes or standards before use.

If a proposed system is intended for a single project application, then documentation should be submitted, along with drawings and calculations for the single application, to the authority having jurisdiction over the site where the system is being proposed for use.

Chapter 9
Example Applications

This chapter presents examples illustrating the application of the Methodology to reinforced concrete special moment frame, reinforced concrete ordinary moment frame, and wood light-frame shear wall seismic-force-resisting systems.

9.1 General

In the following sections three seismic-force-resisting systems are evaluated using the methods outlined Chapters 3 through 7. The examples span different system types, design requirements, test data, archetype models, and analysis software. Models include both simulated and non-simulated collapse modes. Each system is currently contained in Table 12.2-1 of ASCE/SEI 7-05, and the examples utilize design requirements and test data currently available for these approved systems. For new (proposed) systems, design requirements will generally not exist, and would need to be developed.

These examples illustrate the application of the Methodology, and one example illustrates the process of iteratively modifying the system design requirements so that the proposed structural system meets the prescribed collapse performance objectives of the Methodology. These examples also demonstrate consistency between the acceptance criteria of the Methodology and the inherent safety against collapse intended by current seismic codes.

These examples were completed in parallel with the development of the Methodology. As such, they are consistent with the procedures contained herein, but are not necessarily in complete compliance with every requirement. Where they occur, deviations are noted, and explanations are provided as to how the example could be completed in accordance with the Methodology.

In contrast to the process for developing structural system archetypes in Chapter 4, these examples begin with the development of a representative index archetype model, which is used as a basis for generating a set of archetypical configurations that do not attempt to rigorously interrogate the limits of what is permitted within the governing design requirements. As such, they do not necessarily include archetypes that bound the full extent of

the design space. Additionally, the archetype designs used in these examples do not account for potential overstrength caused by wind load requirements.

While representative examples from current code-approved systems have been selected for developmental studies, the results are not intended to propose specific changes to current building code requirements for any currently approved system.

9.2 Example Application - Reinforced Concrete Special Moment Frame System

9.2.1 Introduction

In this example, a reinforced concrete special moment frame system, as defined by ACI 318-05 *Building Code Requirements for Structural Concrete* (ACI, 2005), is considered as if it were a new system proposed for inclusion in ASCE/SEI 7-05.

9.2.2 Overview and Approach

In this example, detailing requirements of ACI 318-05 are assumed to be given. The system design requirements of ASCE/SEI 7-05 are used as the framework, and seismic performance factors (SPFs) are determined by iteration until the acceptance criteria of the Methodology are met. Seismic performance factors under consideration in this example include the R factor, C_d factor, and Ω_0 factor.

All pertinent design requirements of ASCE/SEI 7-05, including drift limits and minimum base shear requirements are assumed to apply initially. In the Methodology, the user has full flexibility to define and modify any aspect of the proposed system design requirements, as long as modifications are tested within the index archetype configurations. This includes the R factor, stiffness requirements, detailing requirements, capacity design requirements, minimum base shear requirements, height limits, drift limits, and any other requirements that control the design of the structural system.

The iterative assessment process begins with initial assumptions of $R = 8$, $C_d = 5.5$[1], story drift limits of 2%, and minimum design base shear requirements consistent with ASCE/SEI 7-05. Overstrength, Ω_0, is not assumed initially, but is determined from the computed lateral overstrength

[1] $C_d = 5.5$ is used in this example, based on the value specified for reinforced concrete special moment frames in ASCE/SEI 7-05. In actual applications of the Methodology, $C_d = R$ should be used unless $C_d < R$ can be substantiated in accordance with the criteria of Section 7.7.

of the archetype designs. A set of structural system archetypes are developed for reinforced concrete special moment frame buildings, nonlinear models are developed to simulate structural collapse, models are analyzed to predict the collapse capacities of each design, and the adjusted collapse margin ratios are evaluated and compared to acceptance criteria.

After completing an assessment using the initial set of SPFs, certain archetypes (taller building configurations) did not meet the acceptance criteria, and were found to have inadequate collapse safety. Aspects of the structural design requirements were modified, and the system was reassessed and found to pass the acceptance criteria.

This example has been adapted from collaborative research on the development of structural archetypes for reinforced concrete special moment frames, calibration of nonlinear element models for collapse simulation, simulation of structural response to collapse, spectral shape considerations, and treatment of uncertainties (Haselton and Deierlein, 2007).

9.2.3 Structural System Information

Design Requirements

This example utilizes ACI 318-05 design requirements in place of the requirements that would be developed for a newly proposed system. For the purpose of assessing uncertainty according to Section 3.4, ACI 318-05 design requirements are categorized as (A) Superior since they represent many years of development and include lessons learned from a number of major earthquakes.

In the process of completing the assessment of the class of reinforced concrete special moment frame buildings, it was found that often seemingly subtle design requirements have important effects on the design and resulting structural performance; the various design requirements often interact and affect the design and performance differently than one might expect. Therefore, for newly proposed systems, it is important that the set of design requirements is well developed and clearly specified, and that the requirements are applied in their totality when designing the archetype structures.

Test Data

This example assessment relies on existing published test data in place of test data that would be developed for a newly proposed system. Specifically, column tests reported in Pacific Earthquake Engineering Research Center's Structural Performance Database developed by Berry, Parrish, and Eberhard

(PEER, 2006b; Berry et al., 2004) are utilized. To develop element models, the data are utilized from cyclic and monotonic tests of 255 rectangular columns failing in flexure and flexure-shear.

The quality of the test data is an important consideration when quantifying the uncertainty in the overall collapse assessment process. The test data used in this example cover a wide range of column design configurations and contain both monotonic and cyclic loading protocols. Even so, many of the loading protocols are not continued to deformations large enough to observe loss of strength, and it is difficult to use such data to calibrate models for structural collapse assessment. These test data also do not include beam elements with attached slabs. Additionally, data include no systematic test series that both (1) subject similar specimens to different loading protocols (e.g., monotonic and cyclic) and (2) continue the loading to deformations large enough for the capping behavior to be observed. Lastly, only column element tests were utilized when used to calibrate the element model, while sub-assemblage tests and full-scale tests were not used. Based on the guidelines of Section 3.6 and considering the above observations, this test data set is categorized as (B) Good.

9.2.4 Identification of Reinforced Concrete Special Moment Frame Archetype Configurations

Figure 9-1 shows the two-dimensional three-bay multi-story frame that is considered an appropriate index archetype model for reinforced concrete frame buildings. This archetype model includes joint panel elements, beam and column elements, elastic foundation springs, and a leaning column to account for the P-delta effect from loads on the gravity system. This two-dimensional model, not accounting for torsional effects, is considered acceptable because most reinforced concrete special moment frame buildings that are regular in plan will not be highly sensitive to torsional effects, and the goal is to verify the performance of a full class of buildings, rather than one specific building with a unique torsional issue. This index archetype model was used as a basis for postulating the index archetype configurations covering the archetype design space for reinforced concrete special moment frame buildings. Appendix C provides more background on the development of this archetype configuration and model.

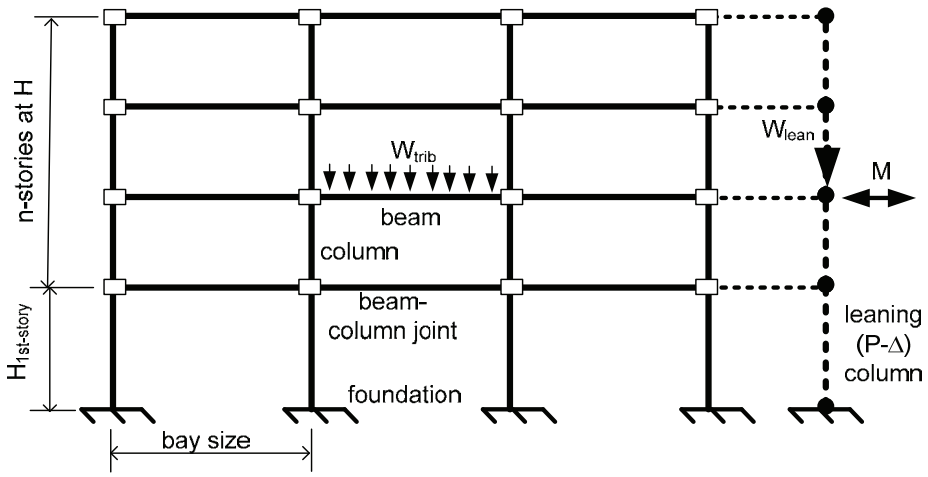

Figure 9-1 Index archetype model for moment frame buildings (after Haselton and Deierlein, 2007, Chapter 6).

Using the above index archetype model, a set of structural archetype designs are developed to represent the archetype design space, following the design configuration and performance group requirements of Chapter 4. Chapter 4 specifies consideration of up to 16 archetype performance groups for a structural system whose performance can be adequately evaluated using two basic configurations, as shown in Table 9-1. Two basic configurations are considered in the example evaluation of the reinforced concrete special moment frame system, archetypes with 20-foot and 30-foot bay widths, respectively. While two configurations are sufficient to illustrate the Methodology, additional configurations would likely be required to fully investigate performance of the reinforced concrete special moment frame system.

High and low gravity load intensities are represented by space frame and perimeter frame systems, respectively. For the archetypes used in this example, the ratio of gravity load tributary area to lateral load tributary area is typically six times larger for space frame systems.

Table 9-1 Performance Groups for Evaluation of Reinforced Concrete Special Moment Frame Archetypes

Performance Group Summary					
Group No.	Grouping Criteria				Number of Archetypes
	Basic Config.	Design Load Level		Period Domain	
		Gravity	Seismic		
PG-1	20-foot Bay Width	High (Space Frame)	SDC D_{max}	Short	2+1[1]
PG-2				Long	4
PG-3			SDC D_{min}	Short	0
PG-4				Long	1[2]
PG-5		Low (Perimeter Frame)	SDC D_{max}	Short	2+1[1]
PG-6				Long	4
PG-7			SDC D_{min}	Short	0
PG-8				Long	3[2]
PG-9	30-foot Bay Width	High (Space Frame)	SDC D_{max}	Short	0
PG-10				Long	1[3]
PG-11			SDC D_{min}	Short	0
PG-12				Long	
PG-13		Low (Perimeter Frame)	SDC D_{max}	Short	0
PG-14				Long	1[3]
PG-15			SDC D_{min}	Short	0
PG-16				Long	

1. Example includes only two archetypes for each short-period performance group (PG-1 and PG-5); full implementation of the Methodology requires a total of 3 (2+1) archetypes in each performance group.
2. Example evaluates a selected number of low seismic (SDC D_{min}) archetypes to determine that high seismic (SDC D_{max}) archetypes control the *R* factor.
3. Example evaluates two 30-foot bay width archetypes to determine that 30-foot bay width archetypes do not control performance.

Archetypes are designed within a range of building heights (six heights between 1-story and 20-stories, as expected for reinforced concrete frame buildings with no walls), and then separated into the short-period and long-period performance groups. At a minimum, three buildings are needed for each performance group, so if 16 complete performance groups were evaluated, then at least 48 archetypes would need to be designed and assessed. Instead of designing and assessing all 48 buildings, initial pilot studies were used to find the more critical design cases: in this case, high-seismic (SDC D) designs with 20-foot bay spacing. By utilizing these pilot studies and then focusing on the critical design cases, it was possible to reduce the number of required archetypes from 48 to 18 (for a complete

exercise of the Methodology, a few additional archetypes would be needed, as described below). Appendix C provides a more detailed discussion on the development of structural system archetypes for the reinforced concrete special moment frame system.

Table 9-1 shows archetypes used in assessing the reinforced concrete special moment frame structural system, and provides the rationale for why each archetype was chosen. As indicated in the table, full implementation of the Methodology would require two additional three-story buildings to be added to PG-1 and PG-5 to meet the required minimum three archetypes per group.

The approach utilized here, focusing on the critical design cases, is not required in the Methodology. The benefit of this approach is that it can significantly reduce the number of required archetype designs (this example needed only 20, instead of 48 archetypes) and allow a wider range of design conditions to be considered in the assessment. When this approach is utilized, the peer review panel should closely review choice of critical design cases.

Table 9-2 shows the properties for each of the archetype designs used in this evaluation. Seismic demands are represented by the maximum and minimum seismic criteria of Seismic Design Category (SDC) D, in accordance with Section 5.2.1: S_{DS} = 1.0 g and S_{D1} = 0.60 g for SDC D_{max} and S_{DS} = 0.50 g and S_{D1} = 0.20 g for SDC D_{min}[2]. The space frame buildings are denoted by "S" and the perimeter frame buildings are denoted by "P." The computed value of the fundamental period, *T*, in Table 9-2, is based on Equation 5-5.

Each archetype was fully designed in accordance with the governing design requirements. Additional information on index archetype designs is provided in Appendix C. Figure 9-2 shows example design documentation for the four-story, SDC D_{max} design with 30-foot bay width of Archetype ID 1010. This archetype will be used throughout this illustrative assessment, to clearly show how the Methodology should be applied in assessing each archetype design.

[2] In this example, archetypes designed for low seismic (SDC D_{min}) loads, assumed S_{D1} = 0.167 g based on interim criteria, which differs slightly from the S_{D1} = 0.20 g required by the Methodology.

Table 9-2 Reinforced Concrete Special Moment Frame Archetype Structural Design Properties

Archetype ID	No. of Stories	Key Archetype Design Parameters

Figure 9-2 Design documentation for a four-story space frame archetype with 30-foot bay spacing (Archetype ID 1010) (after Haselton and Deierlein 2007, Chapter 6). The notation used in this figure is defined in the list of symbols at the end of the document.

9.2.5 Nonlinear Model Development

This section summarizes explicit modeling of structural collapse. A more complete discussion on nonlinear modeling of reinforced concrete special moment frame systems is provided in Appendices D and E.

Index Archetype Models

System-level modeling uses the three-bay multi-story frame configuration shown in Figure 9-1. This model consists of elastic joint elements, plastic hinge reinforced concrete beam and column elements, a leaning column to account for P-delta effects, and elastic foundation springs to account for foundation and soil flexibility.

Nonlinear Beam-Column Element Models

Even though many reinforced concrete element models exist, most cannot be used to simulate structural collapse. Recent research by Ibarra, Medina, and Krawinkler (2005) has resulted in an element model that is capable of capturing the severe deterioration that precipitates sideway collapse (Appendix E). Figure 9-3 shows the tri-linear monotonic backbone curve and associated hysteretic behavior of this model. This model includes important aspects, such as the "capping point," where monotonic strength loss begins, and the post-capping negative stiffness. These features enable modeling of the strain-softening behavior associated with concrete crushing, rebar buckling and fracture, or bond failure. In general, accurate simulation of sidesway structural collapse requires modeling this post-capping behavior.

Researchers have also used a variety of other methods to simulate cyclic response of reinforced concrete beam-columns, including creating fiber models that can capture cracking behavior and the spread of plasticity throughout the element (e.g., Filippou, 1999). The decision to use a lumped-plasticity approach was based on the observation that currently available fiber element models are not capable of simulating the strain-softening associated with rebar buckling, and thus cannot reliably simulate collapse of flexurally dominated reinforced concrete frames. Research is ongoing, and this modeling limitation may be overcome in the near future. In future applications of this Methodology, the choice of element model should be carefully evaluated for any given structural system, with consideration of available simulation technologies and their capabilities for simulating structural collapse.

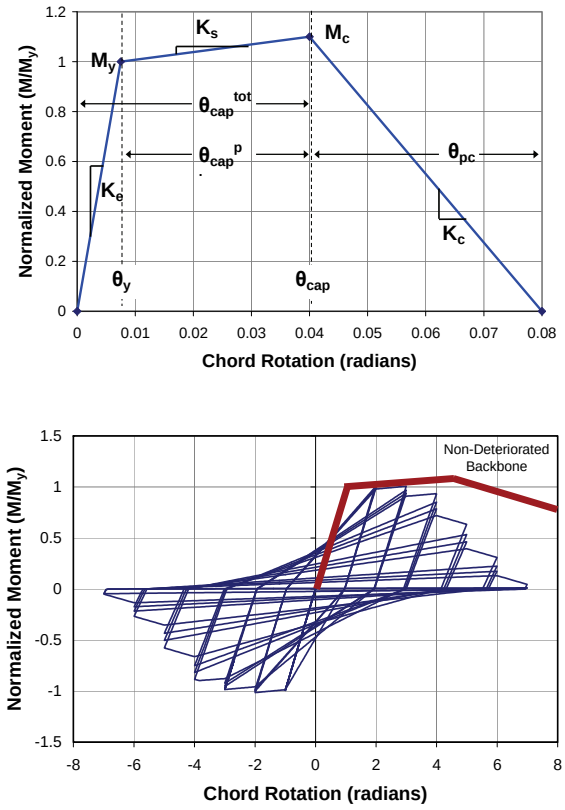

Figure 9-3 Monotonic and cyclic behavior of component model used in this study (after Haselton and Deierlein 2007, Chapter 4).

Figure 9-4 shows an example of the experimental and calibrated response of a reinforced concrete column specimen. Appendix E presents a detailed discussion of how this element model was calibrated using cyclic and monotonic tests of 255 rectangular reinforced concrete elements. Such calibration needs to be completed carefully, in order to avoid errors in the collapse capacity prediction. Often various deterioration modes are improperly mixed together in the calibration process, such as cyclic strength deterioration versus in-cycle strength loss, and this can lead to substantial errors in collapse predictions.

The calibration results for the 255 tests (Appendix E) were subsequently used to create empirical equations to predict the element model parameters (as shown in Figure 9-3), based on the element design information such as axial load ratio and confinement ratio. These equations were used to predict the modeling parameters for the archetype designs used in this example. For illustration, Figure 9-5 shows the predicted modeling parameters for each element of Archetype ID 1010 which is a four-story SDC D_{max} design with 30-foot bay width.

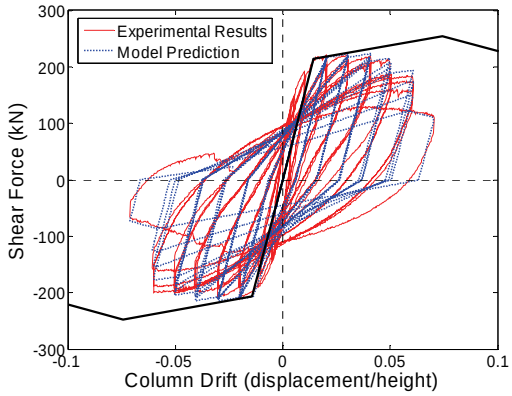

Figure 9-4 Illustration of experimental and calibrated element response (Saatciolgu and Grira, specimen BG-6) (after Haselton et al., 2007). The solid black line shows the calibrated monotonic backbone. The notation is defined in the list of symbols at the end of this document.

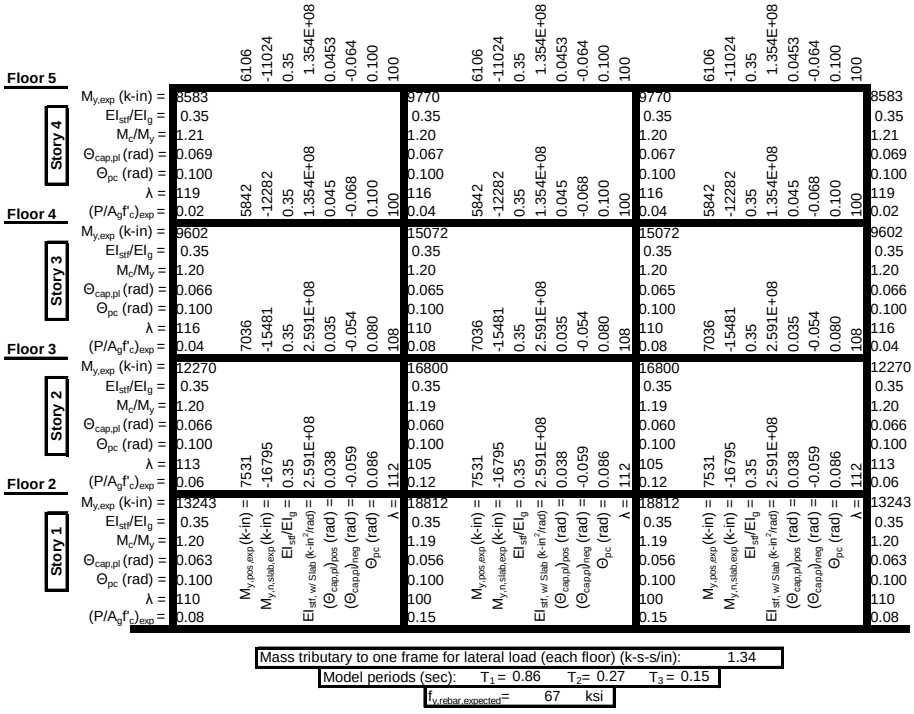

Figure 9-5 Structural modeling documentation for a four-story space frame archetype with 30-foot bay spacing (Archetype ID 1010) (after Haselton and Deierlein, 2007, Chapter 6).

Uncertainty due to Model Quality

For the purpose of assessing uncertainty, this modeling is rated as (B) Good, according to the guidelines of Section 5.7. Reinforced concrete special moment frame buildings are controlled by many detailing and capacity

design requirements, which limit possible failure modes. The primary expected failure mode is flexural hinging leading to sidesway collapse, which the modeling approach can simulate reasonably well by capturing post-peak degrading response under both monotonic and cyclic loading. The modeling approach is able to directly simulate structural response up to collapse by simulating all expected modes of damage that could lead to collapse, and is well calibrated to large amounts of data. Even so, this model is not given the (A) Superior rating because there is still room for improvement in the model: the model was calibrated using column data and is not well-calibrated to beam-slabs, and the model does not capture axial-flexural interaction in columns. Additionally, for a complete assessment, the archetype design space would likely need to be expanded to include a wider range of basic configurations beyond 20-foot and 30-foot bay spacings.

9.2.6 Nonlinear Structural Analysis

The structural analysis software selected for completing this example is the Open Systems for Earthquake Engineering Simulation (OpenSees, 2006), which was developed by the Pacific Earthquake Engineering Research (PEER) Center. This software includes the modeling aspects required for collapse simulation of reinforced concrete special moment frame buildings, such as the Ibarra et al. element model, joint models, a large deformation geometric transformation, and several numerical algorithms for solving the systems of equations associated with nonlinear dynamic and static analyses.

Nonlinear static (pushover) analysis is performed in accordance with Section 6.3[3], in order to compute the system overstrength factor, Ω_0, and period-based ductility, μ_T, and to help verify the structural model. Figure 9-6 shows an example of the pushover curve and story drift distributions for Archetype ID 1010.

For the reinforced concrete special moment frame archetype, yielding occurs at story drift ratio 0.005 and the effective yield roof displacement, $\delta_{y,eff}$, is computed according to Equation 6-7 as $0.0042h_r$. A maximum strength, V_{max}, of 635 kips is reached and followed by the onset of negative stiffness which occurs at a story drift ratio of 0.040 and a roof displacement of $0.035h_r$. This is then followed with 20% strength loss at $\delta_u = 0.056h_r$. Using these values, the overstrength factor of Archetype ID 1010 can be computed as Ω = 635k/193k = 3.3, and the period-based ductility, which will be used

[3] In this example, pushover analysis is based on the lateral load pattern prescribed by Equation 12.8-13 of ASCE/SEI 7-05.

later to adjust the *CMR* according to Section 7.2, can be computed as $\mu_T = \delta_u / \delta_{y,eff} = 0.056h_r/0.0042h_r = 13.2$.

To compute the collapse capacity for each archetype design, the incremental dynamic analysis (IDA) approach is used (Section 6.4), with the Far-Field ground motion set and ground motion scaling method presented in Section 6.2.3 (and Appendix A). Note that Section 6.4 does not require a full IDA (as is shown in Figure 9-7) but only a simplified version, which has the goal of quantifying the median collapse capacity of each archetype model.

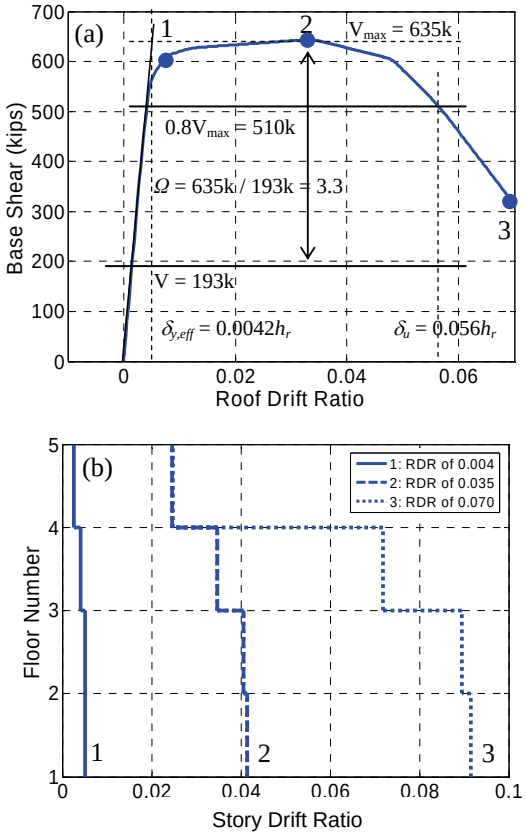

Figure 9-6 (a) Monotonic static pushover, and (b) peak story drift ratios at three deformation levels during pushover for Archetype ID 1010. The pushover is based on the building code specified lateral load distribution (ASCE, 2005) (after Haselton and Deierlein, 2007, Chapter 6).

Figure 9-7 illustrates how the IDA method is used to compute the collapse capacity of Archetype ID 1010. For each of the 44 ground motions of the Far-Field Set the spectral acceleration at collapse (S_{CT}) is computed. Next the median collapse level ($\hat{S}_{CT}$) is computed to be 2.58 g. The collapse margin ratio (*CMR*), defined as the ratio of $\hat{S}_{CT}$ to the Maximum Considered Earthquake (MCE) ground motion demand (S_{MT}), is 2.50 for Archetype ID

1010. Although a full IDA was utilized in this example, it is not required to quantify *CMR*, as discussed in Section 6.4.2.

In this example, it is assumed that reinforced concrete special moment frame buildings collapse in a sideway mechanism, which can be directly simulated using the structural analysis model. This assertion is made due to the many detailing, continuity, and capacity design provisions preventing other collapse modes (Appendix D). For structural systems where some collapse modes are not simulated by the structural model, these additional modes must be accounted for using component limit state checks for non-simulated collapse modes (Section 5.5).

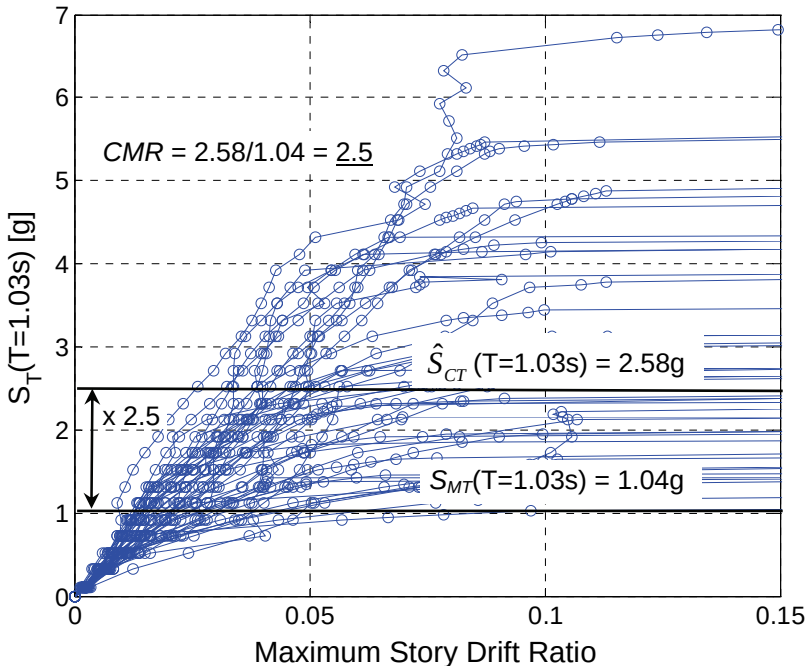

Figure 9-7 Incremental dynamic analysis to collapse, showing the Maximum Considered Earthquake ground motion intensity (S_{MT}), median collapse capacity intensity ($\hat{S}_{CT}$), and collapse margin ratio (*CMR*) for Archetype ID 1010.

Table 9-3 summarizes the results of pushover and IDA analyses. These IDA results show that the average *CMR* is 1.34 and 1.26 for perimeter frame performance groups and is 2.01 and 1.56 for the space frame performance groups. These values have not yet been adjusted for the beneficial effects of spectral shape (Section 7.2). Allowable *CMR* values and acceptance criteria are discussed later.

In addition, these results verify that the buildings designed in low-seismic regions have higher *CMR*s (i.e., lower collapse risk) than those designed in

high-seismic regions. Compared to a building with 20-foot bay width, buildings with 30-foot bay width tend to have slightly higher *CMR*, due to gravity load effects causing some increases in overstrength, and due to joint shear provisions making columns slightly larger and more ductile. Therefore, the remaining assessment focuses on 12 more critical archetype buildings which are designed for high-seismic sites (SDC D_{max}) and with 20-foot bay width. This approach substantially reduces the number of required structural designs and analyses.

Table 9-3 Summary of Collapse Results for Reinforced Concrete Special Moment Frame Archetype Designs

Archetype ID	Design Configuration			Pushover and IDA Results

9.2.7 Performance Evaluation

The previous section discussed how to simulate structural collapse, compute median collapse level, $\hat{S}_{CT}$, and compute the collapse margin ratio, *CMR*. However, *CMR* does not account for the unique spectral shape of rare ground motions. Chapter 7 discusses spectral shape and how it affects the predicted collapse capacity, and provides simplified spectral shape factors, *SSF*s, that are used to adjust the median collapse level , $\hat{S}_{CT}$, to account for spectral shape effects. Table 9-4 and Table 9-5 (taken from Chapter 7) show these factors for Seismic Design Categories B, C, and D_{min} and SDC D_{max}, respectively. The values in these tables depend on the fundamental period, *T*, period-based ductility, μ_T, and the seismic design category. The tables show that the *SSF* values range from 1.0 to 1.37 for Seismic Design Categories B, C, and D_{min} and from 1.00 to 1.61 for SDC D_{max}.

The adjusted collapse margin ratio, *ACMR*, is computed by multiplying *SSF* (from Table 9-4 or Table 9-5) and *CMR* (from Table 9-3). Later, Table 9-8 will show this margin adjustment for the reinforced concrete special moment frame archetypes, and the resulting *ACMR* values.

Table 9-4 Spectral Shape Factor (*SSF*) for Archetypes Designed for Seismic Design Categories B, C, or D_{min} Seismic Criteria (from Table 7-1a)

1.2	1.00	1.07	1.15	1.2	1.28	1.34	1.44	1.52
1.3	1.00	1.08	1.16	1.21	1.29	1.36	1.46	1.55
1.4	1.00	1.08	1.16	1.22	1.31	1.38	1.49	1.58
≥ 1.5	1.00	1.08	1.17	1.23	1.32	1.4	1.51	1.61

In addition to quantifying the *ACMR* by Equation 7-1, the composite uncertainty, β_{TOT}, in collapse capacity is also needed. Table 9-6 (from Table 7-2b) shows composite uncertainties, which account for the variability between ground motion records of a given intensity (defined as a constant $\beta_{RTR} = 0.40$ for systems with $\mu_T \geq 3$), the uncertainty in the nonlinear structural modeling ((B) Good), the quality of data used to calibrate the element models ((B) Good), and the quality of the structural system design requirements ((A) Superior). For this example assessment, the composite uncertainty is $\beta_{TOT} = 0.500$ and is shown in bold.

Table 9-6 Total System Collapse Uncertainty (β_{TOT}) for Model Quality (B) Good and Period-Based Ductility, $\mu_T \geq 3$ (from Table 7-2b)

Quality of Test Data	Quality of Design Requirements			
	(A) Superior	(B) Good	(C) Fair	(D) Poor
(A) Superior	0.475	0.500	0.575	0.675
(B) Good	**0.500**	0.525	0.600	0.700
(C) Fair	0.575	0.600	0.675	0.750
(D) Poor	0.675	0.700	0.750	0.825

The acceptable collapse margin ratio is determined from the composite uncertainty and the acceptable conditional probability of collapse under the MCE ground motions. Chapter 7 defines the collapse performance objectives as: (1) a conditional collapse probability of 20% for each archetype building, and (2) a conditional collapse probability of 10% for each performance group. Table 9-7 (from Table 7-3) shows values of acceptable *ACMR* computed assuming a lognormal distribution of collapse capacity. Based on $\beta_{TOT} = 0.500$, the acceptable $ACMR_{20\%}$ value is 1.52 for

each individual archetype and the acceptable $ACMR_{10\%}$ value is 1.90 for the average of each performance group.

Table 9-7 Acceptable Values of Adjusted Collapse Margin Ratio ($ACMR_{10\%}$ and $ACMR_{20\%}$) (from Table 7-3)

Total System Collapse Uncertainty	Collapse Probability				
	5%	10% ($ACMR_{10\%}$)	15%	20% ($ACMR_{20\%}$)	25%
0.400	1.93	**1.67**	1.51	**1.40**	1.31
0.425	2.01	**1.72**	1.55	**1.43**	1.33
0.450	2.10	**1.78**	1.59	**1.46**	1.35
0.475	2.18	**1.84**	1.64	**1.49**	1.38
0.500	2.28	**1.90**	1.68	**1.52**	1.40
0.525	2.37	**1.96**	1.72	**1.56**	1.42
0.550	2.47	**2.02**	1.77	**1.59**	1.45
0.575	2.57	**2.09**	1.81	**1.62**	1.47
0.600	2.68	**2.16**	1.86	**1.66**	1.50

Table 9-8 presents the final results and acceptance criteria for each of the 18 archetype designs. This shows the collapse margin ratio (*CMR*) computed directly from IDA, the *SSF*, and the final adjusted collapse margin ratio (*ACMR*). The acceptable margins are then shown, and each archetype is shown to either pass or fail the acceptance criteria.

The results in Table 9-8 show that high-seismic archetypes (SDC D_{max} designs) have lower *ACMR* values (as compared to SDC D_{min} designs) and control the collapse performance. Additionally, the 20-foot bay width designs have slightly lower *ACMR* values. Therefore, this example focuses on the performance groups containing archetypes designed for high seismic (SDC D_{max}) with 20-foot bay widths (PG-1, PG-3, PG-5, and PG-6). Based on the results shown in Table 9-8, the perimeter frame performance groups are more critical than the space frame performance groups, so PG-5 or PG-6 will govern the response modification factor, *R*.

Table 9-8 Summary of Final Collapse Margins and Comparison to Acceptance Criteria for Reinforced Concrete Special Moment Frame Archetypes

1. For completeness, the reinforced concrete special moment frame example assumes values of static overstrength and *ACMR* of missing 3-story archetypes (based on the average of respective 2-and 4-story values).

The overstrength factor, Ω_O, will likely not be governed by the same performance group that governs the response modification factor, *R*. Table 9-8 shows that the space frame performance groups have higher overstrength,

Ω, values than perimeter frame groups, short-period space frames have higher overstrength values than long-period space frames, and the four-story 30-foot bay width design has a higher overstrength than 20-foot bay width designs (e.g., Archetype ID 1010 versus 1008). This suggests that either PG-9 or PG-11 (defined in Table 9-1) would govern the overstrength factor, Ω_O., but the archetypes in these performance groups were not designed and assessed in this example application.

The results for the two performance groups that may govern the response modification factor (PG-5 or PG-6), show that the majority of archetype buildings have acceptable *ACMR*, but a trend is evident: for space and perimeter frame buildings taller than four-stories, the *ACMR* decreases substantially with increased building height. This causes the 20-story perimeter frame archetype to have an unacceptable *ACMR* and causes the average *ACMR* of the long period perimeter frame performance group (PG-6) to also be unacceptable.

As currently defined' the "newly proposed" reinforced concrete special moment frame system does not meet the collapse performance objectives of this Methodology, and needs adjusted design requirements in order to meet the acceptance criteria. One simple alternative would be to limit the proposed system to a maximum height of 12-stories (or 160 feet), or to require a space frame system for buildings taller than 160 feet. This solution is not ideal, so the next section looks more closely at other possible solutions.

9.2.8 *Iteration: Adjustment of Design Requirements to Meet Performance Goals*

The reinforced concrete special moment frame system did not meet the performance criteria with the initial set of design requirements. For the initially assessed designs, the *ACI 318-05* design requirements were used along with $R = 8$, $C_d = 5.5$, a story drift limit of 2%, and minimum design base shear requirements of ASCE/SEI 7-05. These requirements must now be modified in some way that will improve the reinforced concrete special moment frame collapse performance and cause the system to meet the performance criteria of Section 7.4.

According to Table 9-8, the adjusted collapse margin ratio (*ACMR*) decreases with increasing height. Haselton and Deierlein (2007) showed that this type of poor performance is caused by the damage localizing more for taller moment frames since damage localization is driven primarily by higher P-delta effects as the building height increases. In order to ensure better collapse performance in taller reinforced concrete frame buildings, this issue could be addressed in various ways. More conservative strong-column-

weak-beam ratios, i.e., larger than 1.2, could be developed for taller buildings, to spread more uniformly over the height of the building. Instead, strength requirements could also be increased for taller buildings, by using a period-dependent *R* factor. Krawinkler and Zareian (2007) illustrate how the *R* factor would need to change, as a function of building period, in order to create uniform collapse probabilities for moment frame buildings of varying height (more strength required for longer period frame buildings).

In this example, another simple approach is attempted and the minimum design base shear is increased to solve this problem. This solution is not the most direct way to solve the specifically identified problems of damage localization and P-delta for taller moment-resisting frame buildings, but it is a simple solution that works. Specifically, the ASCE/SEI 7-05 minimum base shear requirement, $C_s = 0.01$ (ASCE, 2006a, Equation 12.8-5) is replaced by Equation 9.5.5.2.1-3 of ASCE 7-02 (ASCE, 2002). The ASCE 7-02 equation is shown here as Equation 9-1.

$$C_s \geq 0.044 S_{DS} I \tag{9-1}$$

This change to the design requirements impacts only the design of the 12- and 20-story archetypes in SDC D_{max} and the design of the 8-, 12-, and 20-story archetypes in SDC D_{min}.

Table 9-9 shows the design information for the redesigned buildings. A comparison to Table 9-2 shows that the design base shear coefficient (V/W) increased from 0.022 to 0.044 for the 20-story archetype in SDC D_{max} and increased from 0.010 to 0.017 for the 20-story archetype in SDC D_{min}. The base shear coefficient also increased, to a lesser extent, for the other buildings shown in Table 9-9. The minimum base shear requirement is governing the design of the taller frames.

The building designs were revised and the collapse assessments were completed for the revised designs. Table 9-10 shows the updated collapse performance results, with the italic lines showing the designs that were affected by the change to the minimum base shear requirement. This shows that each archetype building meets the performance requirement of $ACMR \geq 1.52$ (i.e., 20% conditional collapse probability) and the average $ACMR \geq 1.90$ for each performance group (i.e., 10% conditional collapse probability). This shows that after modifying the minimum design base shear requirement, the "newly proposed" reinforced concrete special moment frame system attains the required collapse performance and could be added as a "new system" in the building code provisions.

Table 9-9 Structural Design Properties for Reinforced Concrete Special Moment Frame Archetypes Redesigned Considering a Minimum Base Shear Requirement

4021	20	S	D_{min}	8.0	3.6	4.03	0.017	0.065

1. Effective value of R due to limits on the seismic coefficient, C_s.

Notice that the short-period perimeter frame high-seismic performance group (PG-5) is now the governing group that controls the value of the response modification factor, R. It is common that short-period structures have higher strength demands than moderate period structures, and therefore can control the collapse performance assessment; this has been documented in many research publications, starting with Newmark and Hall (1973).

Table 9-10 shows that building archetypes were only assessed up to a height of 20 stories. Taller buildings were not assessed because of the limitations of the ground motion record set, which is applicable only to buildings with elastic fundamental periods below 4.0 seconds (Chapter 6). Even so, Table 9-10 shows a trend that the collapse safety increases with building height. As long as this trend is observed for buildings with fundamental periods below 4.0 seconds, and the peer review committee believes that the trend is stable and defensible, then a height limit would not need to be imposed for this reinforced concrete special moment frame system.

Table 9-10 Summary of Final Collapse Margins and Comparison to Acceptance Criteria for Archetypes Redesigned with an Updated Minimum Base Shear Requirement

1. For completeness, the reinforced concrete special moment frame example assumes values of static overstrength and *ACMR* of missing 3-story archetypes (based on the average of respective 2- and 4-story values).

9.2.9 Evaluation of Ω_0 Using Final Set of Archetype Designs

At this point, the overstrength, Ω_0, value can be established for use in the proposed design provisions. Chapter 7 specifies that the Ω_o value should not be taken as less than the largest average value of overstrength, Ω, from any performance group, and should be conservatively increased to account for variations in individual Ω values. The final Ω_o value should be rounded to the nearest 0.5, and limited to a maximum value of 3.0.

Section 9.2.7 explained that the governing performance group for the overstrength factor, Ω_O, will either be PG-9 or PG-11 (as defined in Table 9-1). This portion of this example is not entirely complete, because the archetypes in these performance groups were not designed and assessed. Even so, the results from other performance groups are used to determine the appropriate overstrength factor, Ω_O.

The average Ω values for the high-seismic 20-foot bay width performance groups are 1.7 and 1.6 for the perimeter frame performance groups (PG-5 and PG-6) and 3.8 and 2.3 for the space frame performance groups (PG-1 and PG-3). Even though all performance groups were not completed, these results are enough to show that the upper-bound value of Ω_o = 3.0 is warranted, due to the average Ω value of 3.8 observed for PG-1.

9.2.10 Summary Observations

This example shows that current seismic provisions for reinforced concrete special moment frame systems in ACI 318-05 and ASCE/SEI 7-05 provide an acceptable level of collapse safety in SDC D, with an important modification of imposing the minimum base shear requirement from the ASCE 7-02 provisions. In addition, it demonstrates that the Methodology is reasonably well calibrated because recent building code design provisions lead to acceptable collapse safety, as defined by the Methodology (Section 7.4). This example also illustrates how the Methodology could be used as a tool for testing possible changes to building code requirements and evaluating code change proposals.

9.3 Example Application - Reinforced Concrete Ordinary Moment Frame System

9.3.1 Introduction

In this example, a reinforced concrete ordinary moment frame system, as defined by ACI 318-05 and ASCE/SEI 7-05, is evaluated as if it were a new system proposed for inclusion in ASCE/SEI 7-05.

This example illustrates the Methodology for limited ductility systems, which are only permitted in lower seismic design categories, are typical of construction in the Central and Eastern United States, and are designed for a much lower ratio of lateral to gravity loads. Since these systems lack the capacity design and ductile detailing provisions of special moment frames, reinforced concrete ordinary moment frame systems are susceptible to additional modes of damage, such as shear failure in columns, leading to rapid strength and stiffness deterioration. Because there are many possible failure modes in reinforced concrete ordinary moment frame systems, this example incorporates limit state checks for collapse modes that are not simulated directly in nonlinear analysis.

9.3.2 Overview and Approach

The structural system for this example is defined by the design and detailing provisions of ASCE/SEI 7-05 and ACI 318-05, and is evaluated using the methods of Chapters 3 through 7. A set of structural system archetypes are developed for reinforced concrete ordinary moment frame buildings, nonlinear models are developed to simulate structural collapse, models are analyzed to predict the collapse capacities of each archetype, and adjusted collapse margin ratios are evaluated and compared to acceptance criteria.

This example has been adapted from collaborative research on the development of structural archetypes for reinforced concrete ordinary moment frames, calibration of nonlinear element models for collapse simulation, simulation of structural response to collapse, and treatment of uncertainties (Liel and Deierlein, 2008).

9.3.3 Structural System Information

Design Requirements

This example utilizes ACI 318-05 design requirements, which are extremely detailed and represent years of accumulated research and building code development. For the purpose of assessing composite uncertainty, the design requirements are categorized as (A) Superior to reflect the high degree of confidence in the design equations for reinforced concrete ordinary moment frames. This rating is in agreement with the reinforced concrete special moment frame example.

Test Data

The element models used in this study are the same as those in the reinforced concrete special moment frame study and based on published test data from the Pacific Earthquake Engineering Research Center's Structural

Performance Database (PEER, 2006b, Berry et al., 2004). Although extensive data is available for reinforced concrete elements, there are still limitations as discussed in Section 9.2.3. Accordingly, for the purpose of assessing the total uncertainty, the test data is categorized as (B) Good, in agreement with the reinforced concrete special moment frame example.

Seismic Design Criteria

Reinforced concrete ordinary moment frames are permitted only in Seismic Design Categories B and below. Following the requirements of Section 4.2.1, the highest allowable SDC is the focus of the performance evaluation. Accordingly, reinforced concrete ordinary moment frames are evaluated at the lower limit of SDC B, where S_{D1} = 0.067 g and S_{DS} = 0.167 g (B_{min}), and the upper limit of SDC B, where S_{D1} = 0.133 g and S_{DS} = 0.33g (B_{max}). A subset of archetype models is also evaluated at the limits of SDC C, where reinforced concrete ordinary moment frames are not permitted, to illustrate how the Methodology can be used to evaluate current code limits.

9.3.4 Identification of Reinforced Concrete Ordinary Moment Frame Archetype Configurations

Figure 9-8 shows the two-dimensional three-bay multi-story frame that is considered an appropriate index archetype model for reinforced concrete ordinary moment frame buildings. This is the same general archetype model that was used to evaluate the reinforced concrete special moment frame system, and includes joint panel elements, beam and column elements, elastic foundation springs, and a leaning column to account for P-delta effects due to the seismic mass on the gravity system.

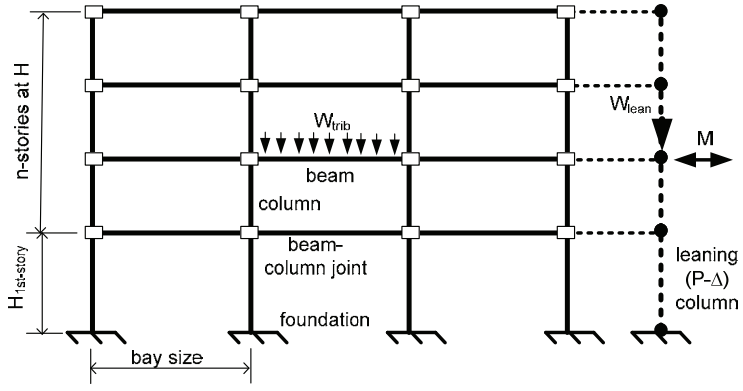

Figure 9-8 Index archetype model for reinforced concrete ordinary moment frames.

Using the above index archetype model, a set of structural archetype designs are developed to represent the archetype design space, following the design configuration and performance group requirements of Chapter 4. Since this

example is intended primarily to demonstrate that the Methodology is applicable to reinforced concrete ordinary moment frame systems, a partial group of archetypes is considered and it is recognized that this partial group does not interrogate all basic design configurations that would be permitted by the code. Therefore, a complete FEMA P695 assessment of the reinforced concrete ordinary moment frame system would include a wider range of design configurations, in addition to the subset of archetypes evaluated here.

Table 9-11 shows how archetypes are organized into performance groups, according to the requirements of Section 4.3. These groups represent the two basic configurations considered in this example, the range of allowable gravity loads and design ground motion intensities, and the building period range (short- and long-period systems).

Table 9-11 Performance Groups for Evaluation of Reinforced Concrete Ordinary Moment Frames

Performance Group Summary					
Group No.	Grouping Criteria				Number of Archetypes
	Basic Config.	Design Load Level		Period Domain	
		Gravity	Seismic		
PG-1	20-foot Bay Width	High (Space Frame)	SDC B_{max}	Short	0[1]
PG-2				Long	
PG-3			SDC B_{min}	Short	
PG-4				Long	
PG-5		Low (Perimeter Frame)	SDC B_{max}	Short	
PG-6				Long	
PG-7			SDC B_{min}	Short	
PG-8				Long	
PG-9	30-foot Bay Width	High (Space Frame)	SDC B_{max}	Short	0[2]
PG-10				Long	4
PG-11			SDC B_{min}	Short	0[2]
PG-12				Long	4
PG-13		Low (Perimeter Frame)	SDC B_{max}	Short	0[2]
PG-14				Long	4
PG-15			SDC B_{min}	Short	0[2]
PG-16				Long	4

1. Performance of reinforced concrete ordinary moment frame archetypes with 20-foot beam span not evaluated, because 30-foot spans judged to be representative for reinforced concrete ordinary moment frames.

2. No short-period reinforced concrete ordinary moment frame archetypes are considered in this example; for a complete reinforced concrete ordinary moment frame assessment, a 1-story would need to be investigated.

Table 9-11 shows that only four performance groups are utilized in this example, accounting for the variations in seismic design level and gravity load level. For reinforced concrete ordinary moment frame buildings, the bay width is not varied, and the rationale for this is explained below. Since reinforced concrete ordinary moment frames tend to be flexible systems, all designs fall into the long-period performance groups. For a full application of the Methodology, at least one one-story building would need to be evaluated in each of the short-period performance groups (PG-9, PG-11, PG-13, and PG-15).

Space frames, which are typical for OMF designs are "high gravity" systems. "Low gravity" systems could represent either perimeter frames of a flat plate system, or the perimeter framing of a one-way joist system. Figure 9-9 and Figure 9-10 show the layout of the archetype space and perimeter frame systems. Buildings have a bay spacing of 30-feet and cover a range of building heights (2-, 4-, 8-, or 12-stories). The bay spacing is different from the default of 20-feet used in the special moment frame example, to better reflect the typical configurations of gravity-dominated reinforced concrete ordinary moment frame designs. For space-frames, a transverse span of 35 feet was used to maximize the gravity load contribution, whereas a smaller transverse span of 30 feet was used for the lightly loaded perimeter-frames.

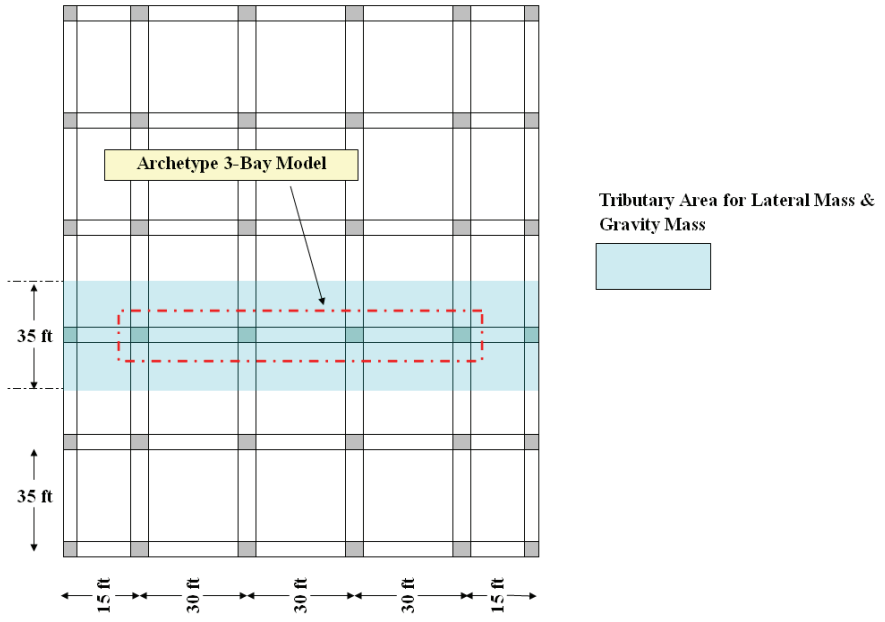

Figure 9-9 High gravity (space frame) layout.

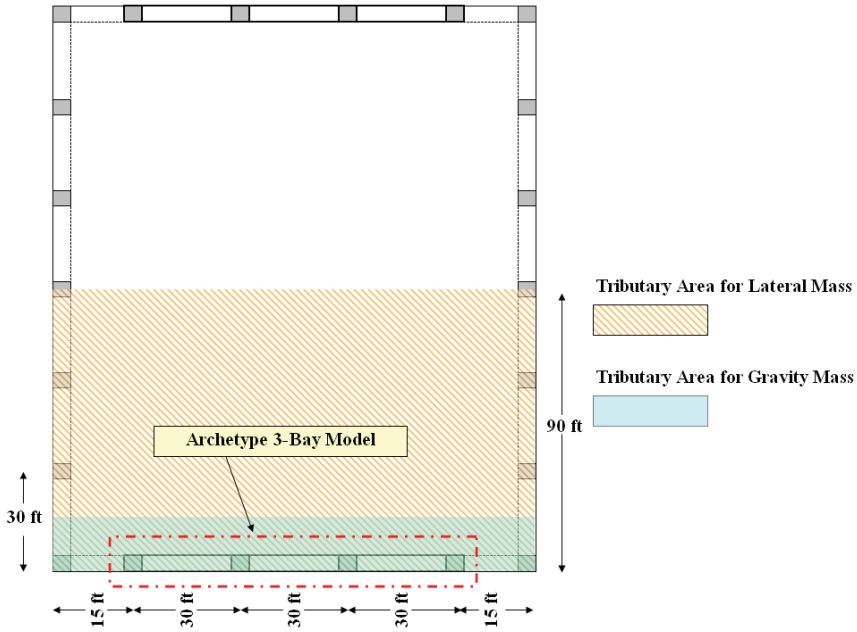

Figure 9-10 Low gravity (perimeter frame) layout. Interior (gravity) columns are not shown for clarity.

Table 9-12 summarizes the design properties of the reinforced concrete ordinary moment frame archetype designs needed to evaluate SDC B, including the design base shear and code-calculated structural period. Each of the archetypes was fully designed in accordance with the governing design requirements (ASCE/SEI 7-05 and ACI 318-05). Additional information on archetype designs is provided in Appendix C.

The design documentation provided is consistent with that provided for the special moment frame models and an example for Archetype ID 9203 is shown in Figure 9-11. Similar documentation has been maintained for all other archetype designs.

9.3.5 Nonlinear Model Development

The nonlinear models of reinforced concrete ordinary moment frames are similar to those developed in the reinforced concrete special moment frame system example; model development was discussed in Section 9.2.5 and is also discussed in more exhaustive detail in Appendix E. For illustration, Figure 9-12 shows the predicted modeling parameters for each element of Archetype ID 9203. As expected, reinforced concrete beams and columns in these structures have substantially less ductility than their special moment frame counterparts, as reflected in the deformation capacity ($\theta_{cap,pl}$ and θ_{pc}) and cyclic deterioration parameters (λ). As with the special moment frame example, these models were implemented in the OpenSees software platform, developed by the Pacific Earthquake Engineering Research Center (OpenSees, 2006).

Shear failure and subsequent loss of gravity-load bearing capacity in columns is not explicitly included in the analysis models, but according to requirements of Section 5.5, it is incorporated through post-processing as a non-simulated failure mode. Shear-induced axial failure of columns is difficult to simulate using available technologies and test data, and is accounted for in post-processing for this reason; however, if possible, it would be better to incorporate this failure mode directly into the nonlinear structural simulation.

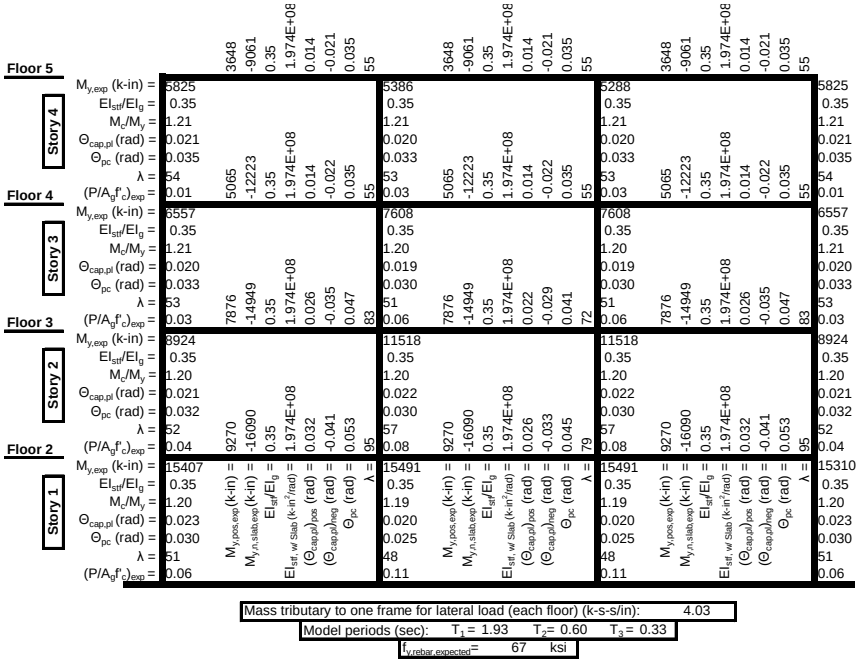

Figure 9-12 Structural modeling documentation for a 4-story reinforced concrete ordinary moment frame archetype (Archetype ID 9203).

9.3.6 *Nonlinear Structural Analysis*

Static Pushover Analysis

To compute the system overstrength, Ω, of each archetype design, a monotonic static pushover analysis is utilized with the lateral load pattern prescribed in ASCE/SEI 7-05. Figure 9-13 illustrates results of static pushover analysis for Archetype ID 9203. For this reinforced concrete ordinary moment frame archetype, the effective yield roof displacement, $\delta_{y,eff}$, is computed according to Equation 6-7 as $0.0047h_r$. The capping displacement (the onset of negative stiffness) occurs at roof displacement of about $0.0125h_r$ and the displacement at 20% strength loss is $\delta_u = 0.018h_r$. The period-based ductility (which will later be used to adjust the *CMR* according to Section 7.2), can be computed as $\mu_T = \delta_u / \delta_{y,eff} = 3.8$. These structures have substantially less ductility than their reinforced concrete special moment frame counterparts (e.g., Figure 9-13 compared to Figure 9-6).

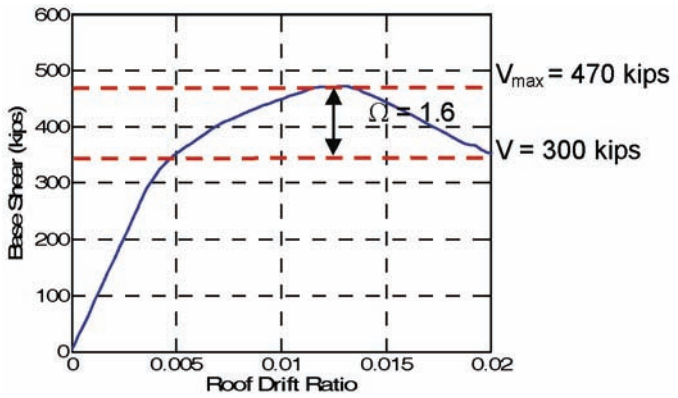

Figure 9-13 Monotonic static pushover for reinforced concrete ordinary moment frame archetype (Archetype ID 9203).

Results from pushover analysis are tabulated below in Table 9-13 for all performance groups in SDC B. Pertinent results include computed static overstrength (Ω) and period-based ductility ($\mu_T = \delta_u / \delta_{y,eff}$). When non-simulated collapse modes are considered in the collapse assessment, δ_u should account for the occurrence of the non-simulated collapse mode.

Nonlinear Dynamic Analysis and Simulation

The collapse capacity for each archetype design is computed according to Section 6.4, using the incremental dynamic analysis (IDA) approach. Ground motions (the Far-Field record set) and scaling procedures are based on requirements of Sections 6.2.2 and 6.2.3, respectively. Figure 9-14 illustrates how the IDA method is used to compute the sidesway collapse

margin ratio of Archetype ID 9203. It should be noted that a full IDA is not required to quantify *CMR*, as discussed in Section 6.4.2.

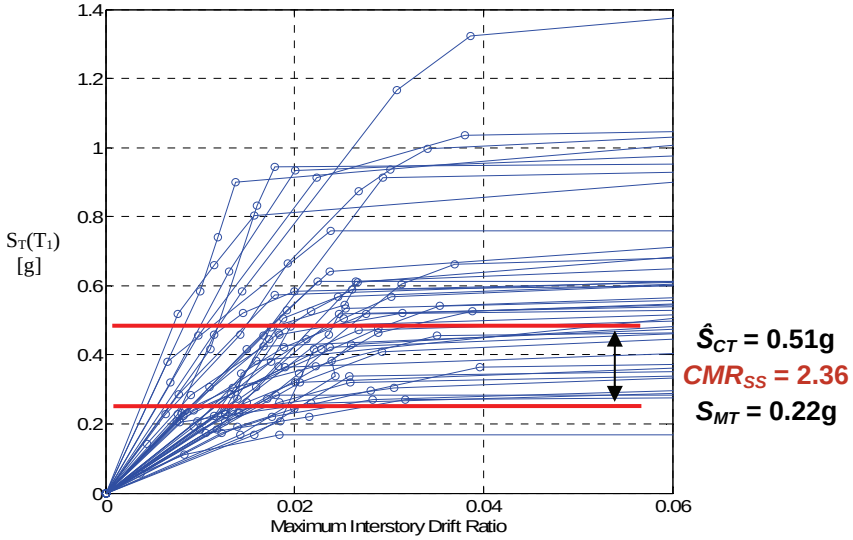

Figure 9-14 Incremental dynamic analysis to collapse showing the Maximum Considered Earthquake ground motion intensity (S_{MT}), median collapse capacity intensity ($\hat{S}_{CT}$), and sidesway collapse margin ratio (CMR_{SS}) for Archetype ID 9203.

Table 9-13 summarizes the IDA results for the selected 16 archetype designs. These results reflect only the sidesway collapse mechanism, which is directly simulated in the structural analysis model. The subscript "SS" denotes consideration of sidesway collapse only and not the non-simulated collapse modes. As such, CMR_{SS} is *not used for system evaluation*, but is presented here for illustrative purposes only.

Non-Simulated Collapse Modes

In this example, only sidesway collapse mechanisms based on strength and stiffness degradation due to flexure and flexure-shear are simulated directly in the analysis. Nonlinear models do not predict the occurrence of column shear failure and subsequent rapid deterioration and loss of gravity-load bearing capacity, which may occur because reinforced concrete ordinary moment frame columns have light transverse reinforcement and are not subject to capacity design requirements. A detailed discussion of possible failure modes in reinforced concrete moment frames is included in Appendix D.

To account for failure modes not directly included in analysis modes, according to Section 5.5, further post-processing of the nonlinear dynamic results is required. Results of static pushover analysis also require post-processing so that the computed period-based ductility, μ_T, (which is used to compute the *SSF*) accounts for non-simulated failure modes. The ultimate

roof displacement, δ_u, should be based on the roof displacement corresponding to a 20% loss of base shear or the occurrence of the non-simulated collapse mode, whichever occurs at a smaller displacement.

Table 9-13 Summary of Pushover Analysis and IDA Sidesway Collapse Results for Reinforced Concrete Ordinary Moment Frame Archetype Designs, SDC B

1. Due to time constraints, μ_T values do not account for non-simulated collapse modes, Even so, these must be included when computing period-based ductility.

Fragility functions (adopted from Aslani, 2005) are introduced to determine the drift at which the column loses its ability to carry gravity loads following shear failure. To determine if the shear-induced axial failure mode has occurred, the column drift level (demand) is extracted from the analysis data and compared to the median drift level associated with column axial failure from the fragility functions (capacity). If the median drift level has been exceeded in any column, the non-simulated collapse mode is assumed to have occurred. This approach is likely conservative because is assumes that

when the non-simulated collapse limit is exceeded in *one* element, it triggers collapse of the entire building. In many cases, gravity loads can be redistributed to nearby elements, and the axial failure of a single column will not cause complete collapse of an entire structure. However, because the structural simulation model cannot represent system behavior and redistribution after the vertical collapse of a column, this is taken as the non-simulated collapse state.

Using the approach to non-simulated collapse modes in Section 5.5, the collapse fragility is adjusted, increasing the probability of collapse to include both the simulated and non-simulated failure modes. This change reduces the collapse margin ratio. This reduction is more significant in space frame structures that have higher column axial loads. The effect of non-simulated failure modes on the computed collapse margin ratios for the 16 archetype structures is shown in Table 9-14.

Table 9-14 Effect of Non-Simulated Collapse Modes on Computed Collapse Margin Ratios for Reinforced Concrete Ordinary Moment Frame Archetypes, SDC B

9.3.7 Performance Evaluation for SDC B

The collapse margin ratio is adjusted according to Section 7.2 to account for the proper spectral shape of rare ground motions through the spectral shape factor, *SSF*. According to Table 9-4 (from Section 7.2.2), the spectral shape factor is computed based on the SDC, the period-based ductility, μ_T, and the structural periods, T and T_1; these parameter values are documented in Table 9-12 and later in Table 9-15. These structures have an average period-based ductility, μ_T, of 3.2, resulting in an average *SSF* of 1.17, as shown below in Table 9-15. Since the ordinary moment frame archetypes are designed for SDC B, where the benefit of spectral shape is more limited, and they have limited deformation capacity, the *SSF* values are smaller than for the special moment frame example.

To assess the ordinary moment frame system, the composite uncertainty, β_{TOT}, in collapse capacity is needed. As described above, the quality of test data is rated (B) Good and the quality of structural system design requirements is rated (A) Superior. According to Section 5.7, the uncertainty in the archetype model is based on (1) the completeness of the set of index archetypes and (2) how well the structural collapse behavior is captured either by direct simulation or use of non-simulated component checks. Regarding the completeness of the set of archetypes, it has already been stated that this example is a partial example, and the archetype set is not complete; however, for the purpose of quantifying model uncertainty in this example, it is assumed that the set of archetypes is complete. Regarding the collapse modeling, although the component model is calibrated to columns that fail in flexure-shear, the structural simulation model may lose some fidelity after the occurrence of shear failure, because shear failure is not directly predicted. Based on this rationale, the archetype model quality is rated as (C) Fair. Based on these individual values for the ordinary moment frame example, the composite uncertainty determined to be $\beta_{TOT} = 0.575$, according to Section 7.3.4.

The acceptable collapse margin ratio is determined from the composite uncertainty and the acceptable conditional probability of collapse under the MCE ground motions. Chapter 7 defines the collapse performance objectives as: (1) a conditional collapse probability of 20% for each archetype building, and (2) a conditional collapse probability of 10% for each performance group. For the reinforced concrete ordinary moment frame systems with a composite uncertainty of 0.575, this corresponds to a required $ACMR_{20\%}$ of 1.62 for each archetype building, with a required average $ACMR_{10\%}$ of 2.09 for each performance group. These values are taken from Table 7-3 (also shown in Table 9-7).

Table 9-15 presents the final results and acceptance criteria for the 16 reinforced concrete ordinary moment frame archetypes in SDC B. As shown in Table 9-15, the reinforced concrete ordinary moment frame structural system passes for each of the two performance groups in both B_{max} and B_{min}. Although the average *ACMR* is close to the limit for PG-14, in some cases the *ACMR*s are considerably above the required values. The large *ACMR*s tend to occur for structures with substantial overstrength, which resulted from the dominance of gravity loading in the design, especially where seismic design forces are low compared to gravity loading (e.g., spaceframes in SDC B_{min}).

1. Due to time constraints, μ_T values do not account for non-simulated collapse modes. Even so, these must be included when computing period-based ductility.

9.3.8 Performance Evaluation for SDC C

A smaller subset of archetypes was utilized to assess whether reinforced concrete ordinary moment frame buildings designed in SDC C would meet the collapse safety criteria of Section 7.4. The archetype designs and results for B_{max} are used in this assessment, since B_{max} is identical to C_{min}. In addition, we consider four additional archetype reinforced concrete ordinary moment frames, designed for C_{max}, as shown in Table 9-16. These four designs compose two partial performance groups for SDC C_{max}; complete performance groups would include at least three designs in each group.

Seismic performance is assessed using the same procedure as described for the evaluation of reinforced concrete ordinary moment frames in SDC B. Table 9-17 shows the computed overstrength, Ω, and period-based ductility, μ_T, factors from static pushover analysis. The computed collapse margin ratios, showing only the results that include non-simulated failure modes, are also reported in Table 9-17. This table also compares the adjusted collapse margin ratios to the acceptance criteria.

Table 9-16 Reinforced Concrete Ordinary Moment Frame Archetype Design Properties for SDC C Seismic Criteria

1. Due to time constraints, μ_T values do not account for non-simulated collapse modes. Even so, these must be included when computing period-based ductility.

As shown in Table 9-17, archetype structures with a perimeter configuration fail the acceptance criteria for C_{max} seismic criteria for both the average *ACMR* of the long-period performance group, as well as individual Archetype ID 9307 (i.e., taller archetype). These results indicate that the Methodology would not allow the use of reinforced concrete ordinary moment frames from SDC C, consistent with current Code restrictions. In order to be permitted in SDC C a lower *R* factor or other changes in design requirements would be necessary.

9.3.9 Evaluation of Ω_o Using Set of Archetype Designs

Development of the overstrength factor, Ω_o, is based on SDC B archetype designs, since this is the highest SDC that is currently allowed for this

system. If the system were being approved for use in SDC C, then the SDC C archetypes would instead be used for establishing Ω_o.

The first step is to compute the overstrength values (Ω) for each individual archetype building. There is a relatively wide range of overstrength observed for the set of archetype designs (Ω ranges from 1.5 to 6.6, as reported in Table 9-17). The PG-14 archetypes (SDC B_{max}, perimeter frame) that govern the R factor have computed Ω values ranging from 1.5 to 1.7, with an average of 1.6. The PG-10 archetypes (SDC B_{max}, space frame) have higher computed overstrength values, between 2.9 and 3.8, with an average of 3.2. The PG-12 archetypes (SDC B_{min}, space frame) have the largest overstrength values, ranging up to 6.6, with an average of 6.0. Due to the average values being greater than 3.0 for one or more of the performance groups, the upper-bound value of Ω_o = 3.0 is recommended for reinforced concrete ordinary moment frames, based on the requirements of Section 7.6.

9.3.10 Summary Observations

This example shows that current seismic provisions for reinforced concrete ordinary moment frame systems provide an acceptable level of collapse safety for SDC B, but not for SDC C. These results are consistent with the provisions for use of reinforced concrete ordinary moment frame in ASCE/SEI 7-05. Levels of collapse safety observed for reinforced concrete ordinary moment frames in SDC B_{max} are comparable to those for reinforced concrete special moment frames in SDC D_{max}, and in B_{min} these systems have a large margin against collapse. Note that in some cases the collapse safety of actual reinforced concrete ordinary moment frame buildings may be higher than calculated in this example, particularly when there are a large number of gravity-designed columns which increase structural strength and stiffness. Even so, for the purpose of establishing seismic design requirements according to this Methodology, Chapter 4 requires that only elements that are designed as part of the seismic-force-resisting system, and are accordingly governed by seismic design requirements, be included in this assessment.

To account for non-simulated failure modes as described in Section 5.5, component limit state checks are incorporated through post-processing of dynamic analysis results. In some cases, incorporation of the non-simulated failure modes significantly affects the collapse margin ratio, demonstrating the importance of carefully considering and including all critical failure modes either explicitly in the simulation models or in non-simulated limit state checks. Use of non-simulated failure modes to account for collapse due

to column loss of gravity-load bearing capacity may be conservative, because it does not allow for load redistribution.

9.4 Example Application - Wood Light-Frame System

9.4.1 Introduction

In this example, a wood light-frame system with structural panel sheathing is considered as if it were a new system proposed for inclusion in ASCE/SEI 7-05.

9.4.2 Overview and Approach

Wood light-frame system design requirements of ASCE/SEI 7-05 are used as the framework. A set of structural archetypes are developed for wood light-frame buildings, nonlinear models are developed to simulate structural collapse, models are analyzed to predict the collapse capacities of each design, and the adjusted collapse margin ratio, *ACMR*, is evaluated and compared to acceptance criteria.

Seismic performance factors (SPFs) are determined by iteration until the acceptance criteria of the Methodology are met. This example begins with an initial value of $R = 6$ and checks if such designs pass the acceptance criteria of Section 7.4. This value is different from the current value of $R = 6.5$ for wood light-frame shear wall systems with wood structural panel sheathing in ASCE/SEI 7-05. It has been rounded to the nearest whole number for simplicity, and because developmental studies have shown that there is no discernable difference in collapse performance of structures design for fractional R factors (e.g., $R = 6$ versus $R = 6.5$). The Ω_0 factor is not assumed initially, but is determined from the actual overstrength factors, Ω, calculated for the archetype designs.

9.4.3 Structural System Information

Design Requirements

This example utilizes design requirements for engineered wood light-frame buildings included in ASCE/SEI 7-05, in place of the requirements that would need to be developed for a newly proposed system. For the purpose of assessing uncertainty, the ASCE/SEI 7-05 design requirements are categorized as (A) Superior since they represent many years of development, include lessons learned from a number of major earthquakes, and consider recent results obtained from large research programs on wood light-frame systems, such as the FEMA-funded CUREE-Caltech Woodframe Project and the NSF/NEES-funded NEESWood Project.

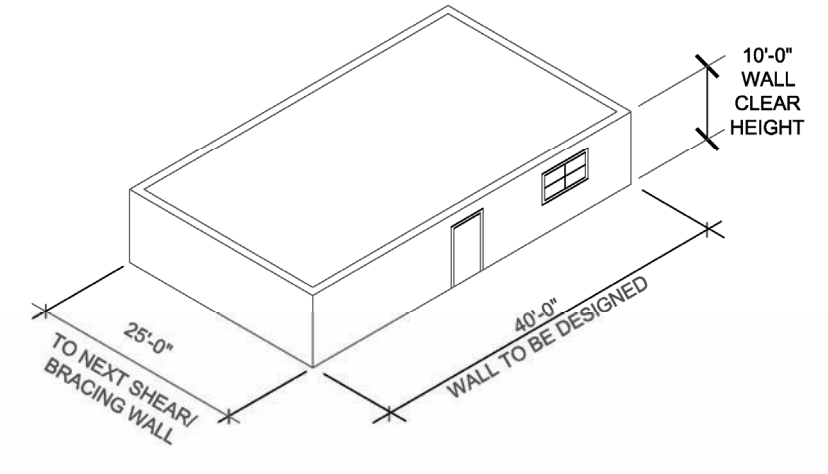
Test Data

This example relies on existing published sheathing-to-framing connection test data and wood shear wall assembly test data. Specifically, this example relies on information developed during the CUREE-Caltech Woodframe Project (Fonseca et al., 2002; Folz and Filiatrault, 2001), the NEESWood Project (Ekiert and Hong, 2006), the CoLA wood shear wall test program (CoLA, 2001), and data provided directly by the wood industry (Line et al., 2008).

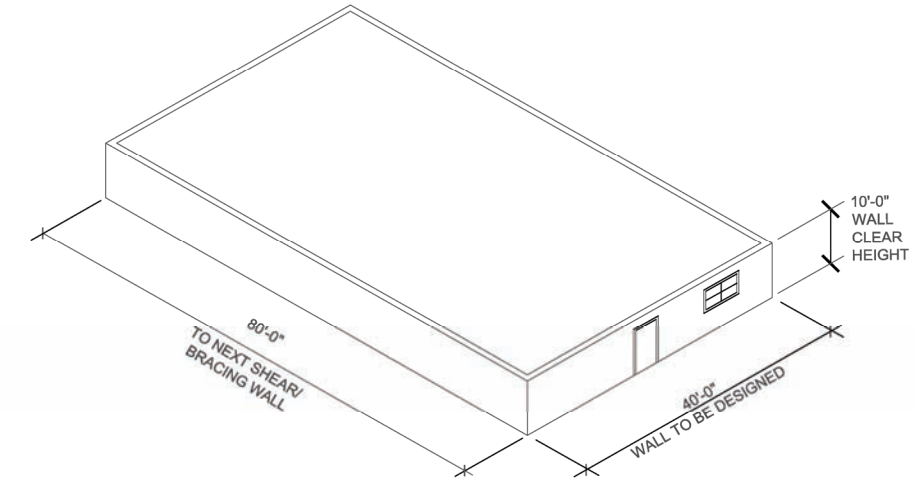
The quality of the test data is an important consideration when quantifying the uncertainty in the overall collapse assessment process. Cyclic test data were provided by the wood industry for each of the archetypes used later in this example. In addition, more data were used by the authors to calibrate and validate the numerical model; these include monotonic and cyclic tests which cover a wide range of wood sheathing types and thicknesses (e.g., oriented strand board and plywood), framing grades, species, and connector types (e.g., common vs. box nails). All loading protocols were continued to deformations large enough for the capping strength to be observed, which allows better calibration of models for structural collapse assessment. Nevertheless, some uncertainties still exist with these test data sets including: (1) premature failures in some of the CUREE data set caused by specimens with smaller connector edge distances than specified; (2) the use of the Sequential Phased Displacement, SPD, loading protocol in the CoLA tests that tends to cause premature specimen failure by connectors fatigue, which is seldom observed after real earthquakes; (3) the inherent large variability associated with the material properties of wood; and (4) a lack of duplicate tests of the same specimen. Therefore, for the purpose of assessing uncertainty, this test data set is categorized as (B) Good.

9.4.4 Identification of Wood Light-Frame Archetype Configurations

The archetypes are established according to the requirements of Chapter 4, and separated into performance groups according to Section 7.4. The first step in archetype development is to establish the possible building design configurations. Figure 9-15 shows the two different building configurations that are assumed to be representative for the purpose of defining the two-dimensional archetypes for wood light-frame shear wall systems with wood structural panel sheathing. The first configuration is representative of residential buildings, while the second configuration is associated with office, retail, educational, and warehouse/light-manufacturing buildings.



Residential building dimensions



Commercial/educational building dimensions

Figure 9-15 Building configurations considered for the definitions of wood light-frame archetype buildings.

Table 9-18 lists the range of design parameters considered for the development of the two-dimensional archetype wall models. According to Section 5.3, two-dimensional archetype wall models, not accounting for torsional effects, are considered acceptable because the intended use of the Methodology is to verify the performance of a full class of buildings, rather than one specific building with a unique torsional issue. According to the requirements of Section 4.2.3, nonstructural wall finishes, such as stucco and gypsum wallboard, were not considered in the modeling of the archetypes. These finishes are excluded because they are not defined as part of the lateral structural system, and therefore are not governed by the seismic design

provisions. Depending on their type, wall finishes may greatly influence the seismic response of wood buildings. The Methodology would allow such elements to be included in the structural model, if one defines them as part of the lateral structural system, and design provisions are included to govern their design.

Table 9-18 Range of Variables Considered for the Definition of Wood Light-Frame Archetype Buildings

Variable	Range
Number of stories	1 to 5
Seismic Design Categories (SDC)	D_{max} and D_{min}
Story height	10 ft
Interior and exterior nonstructural wall finishes	Not considered
Wood shear wall pier aspect ratios	High/Low

Following the guidelines of Section 4.3, low aspect ratio (1:1 to 1.43:1) and high aspect ratio (2.70:1 to 3.33:1) walls were used as the two basic configurations in the archetype designs. This was done to evaluate the influence of the aspect ratio strength adjustment factor contained in ASCE/SEI 7-05, which effectively increases the strength of high aspect ratio wood shear walls.

Table 9-19 shows the performance groups (PG) used to evaluate the wood light-frame buildings, consistent with the requirements of Section 4.3.1. To represent these ranges of design parameters, 48 archetypes could have been used to evaluate the system (three designs for each of the 16 performance groups shown in Table 9-19). However, Table 9-19 shows that 16 archetypes were found to be sufficient. The notes in the table explain why these specific archetypes were selected, including the rationale for why these 16 can be used in place of the full set of 48. These 16 wood archetypes were divided among five performance groups: (1) three low aspect ratio wall short-period archetypes designed for SDC D_{max} (PG-1); (2) five SDC D_{max} - high aspect ratio wall short-period archetypes in SDC D_{max} (PG-9); (3) one low aspect ratio shear wall long-period archetype designed for SDC D_{min} (PG-4); and (4) seven SDC D_{min} - high aspect ratio shear wall systems, which are divided into four short-period buildings (PG-11) and three long-period buildings (PG-12). It is believed that this ensemble of 16 archetypes covers the current design space for wood light-frame buildings fairly well, but additional configurations would be required for a complete application of the Methodology. Appendix C provides detailed descriptions of the 16 archetype models developed for wood light-frame buildings.

Table 9-19 Performance Groups Used in the Evaluation of Wood Light-Frame Buildings

Performance Group Summary					
Group No.	Grouping Criteria				Number of Archetypes
	Basic Config.	Design Load Level		Period Domain	
		Gravity	Seismic		
PG-1	Low Wall Aspect Ratio	High (Nominal)	SDC D_{max}	Short	3
PG-2				Long	0[1]
PG-3			SDC D_{min}	Short	0
PG-4				Long	1[2]
PG-5		Low (NA)	SDC D_{max}	Short	0[3]
PG-6				Long	
PG-7			SDC D_{min}	Short	
PG-8				Long	
PG-9	High Wall Aspect Ratio	High (Nominal)	SDC D_{max}	Short	5
PG-10				Long	0[1]
PG-11			SDC D_{min}	Short	4
PG-12				Long	3
PG-13		Low (NA)	SDC D_{max}	Short	0[3]
PG-14				Long	
PG-15			SDC D_{min}	Short	
PG-16				Long	

1. No long-period SDC D_{max} wood-frame archetypes, because representative designs never exceed $T = 0.6$ s.
2. Only one archetype in low-aspect/SDC D_{min}/long-period performance group, because only one representative design exceeds $T = 0.4$ s.
3. No archetypes because light wood-frame archetype design and performance not influenced significantly by gravity loads (i.e., nominal gravity loads used for all designs).

Table 9-20 reports the properties of each of these 16 archetypes. Seismic demands are based on the ground motion intensities of Seismic Design Category D. The archetypes are designed for maximum and minimum seismic criteria of Section 5.2.1: S_{DS} = 1.0 g and S_{D1} = 0.6 g for SDC D_{max}, and S_{DS} = 0.50 g and S_{D1} = 0.20 g for SDC D_{min}[4]. The MCE ground motion spectral response accelerations, S_{MT}, shown in Table 9-20 are based on Table 6-1. In accordance with Section 5.2.4, the periods reported in Table 9-20 are the fundamental period of the archetypes based on Section 12.8.2 of ASCE/SEI 7-05 ($T = C_u T_a$) with a lower bound limit of 0.25 sec.

[4] In this example, archetypes designed for low seismic (SDC D_{min}) loads, are based on S_{DS} = 0.38 g and S_{D1} = 0.167 g, based on interim criteria which differ slightly from the final values required by the Methodology.

Table 9-20 Wood Light-Frame Archetype Structural Design Properties

Arch. ID	No. of Stories	Key Archetype Design Parameters						
		Building Configuration	Wall Aspect Ratio	Seismic Design Criteria				$S_{MT}(T)$ [g]
				SDC	*T* [sec]	T_1 [sec]	*V/W* [g]	
Performance Group No. PG-1 (Short Period, Low Aspect Ratio)								
1	1	Commercial	Low	D_{max}	0.25	0.40	0.167	1.50
5	2	Commercial	Low	D_{max}	0.26	0.46	0.167	1.50
9	3	Commercial	Low	D_{max}	0.36	0.58	0.167	1.50
Performance Group No. PG-9 (Short Period, High Aspect Ratio)								
2	1	1&2 Family	High	D_{max}	0.25	0.29	0.167	1.50
6	2	1&2 Family	High	D_{max}	0.26	0.37	0.167	1.50
10	3	Multi-Family	High	D_{max}	0.36	0.44	0.167	1.50
13	4	Multi-Family	High	D_{max}	0.45	0.53	0.167	1.50
15	5	Multi-Family	High	D_{max}	0.53	0.62	0.167	1.50
Partial Performance Group No. PG-4 (Long Period, Low Aspect Ratio)

14	4	Multi-Family	High	D_{min}	0.51	0.81	0.063	0.75
16	5	Multi-Family	High	D_{min}	0.60	0.91	0.063	0.75

9.4.5 Nonlinear Model Development

Structural modeling of the wood light-frame archetypes is based on a "pancake" approach (Isoda et al., 2001). This system-level modeling approach is capable of simulating the three-dimensional seismic response of a wood light-frame building through a degenerated two-dimensional planar analysis. The computer program SAWS: Seismic Analysis of Woodframe Structures, developed within the CUREE-Caltech Woodframe Project (Folz and Filiatrault, 2004a, b), was used to analyze the wood light-frame archetype models. Because this example does not involve any buildings with torsional irregularities, only a two-dimensional model is utilized by fixing the rotational degree-of-freedom in the SAWS model.

In the SAWS model, the building structure is composed of rigid horizontal diaphragms and nonlinear lateral load resisting shear wall elements. The pinched, strength and stiffness degrading hysteretic behavior of each wood shear wall in the building is characterized using an associated numerical

model (Folz and Filiatrault, 2001) that predicts the load-displacement response of the full wall assemblies under general quasi-static cyclic loading, based on sheathing-to-framing connection cyclic test data. Alternatively, cyclic test results from full-scale walls can also be used directly to characterize their hysteretic response. In the SAWS model, the hysteretic behavior of each wall panel is represented by an equivalent nonlinear shear spring element. As shown in Figure 9-16, the hysteretic behavior of this shear spring includes pinching, as well as stiffness and strength degradation, and is governed by 10 different physically identifiable parameters (Folz and Filiatrault 2004a, b). The predictive capabilities of the SAWS program have been demonstrated by comparing its predictions with the results of shake table tests performed on full-scale wood light-frame buildings (Folz and Filiatrault, 2004b; White and Ventura, 2007).

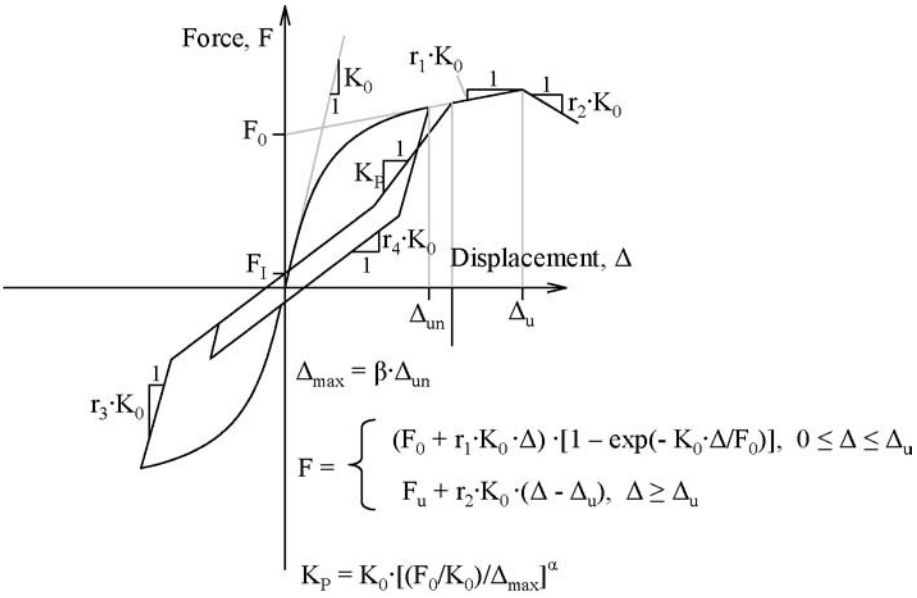

Figure 9-16 Hysteretic model of shear spring element included in SAWS program (after Folz and Filiatrault, 2004a, b).

Table 9-21 shows the sheathing-to-framing connector hysteretic parameters used to construct the equivalent nonlinear shear spring elements of each of the walls contained in the archetype models. The hysteretic model used for these sheathing-to-framing connectors is the same model used for the entire wall panel assemblies, which is shown in Figure 9-16. Figure 9-17 shows the monotonic backbone curves of 8' x 8' shear wall specimens generated using the hysteretic parameters for 8d common nail on 7/16" OSB sheathing shown in Table 9-21, compared with average test data provided by the wood industry (Line et al., 2008). This wood industry data is based on the cyclic envelope averaged from two identical test specimens. Very good agreement is observed between the numerical predictions and the test data shown here,

which typically continues up to displacements near the onset of strength loss. The capping displacement and the post-capping behavior of the analytical model are based on additional cyclic test data that is not shown here, which was continued to larger displacements to exhibit strength deterioration.

Table 9-21 Sheathing-to-Framing Connector Hysteretic Parameters Used to Construct Shear Elements for Wood Light-Frame Archetype Models

Connector Type	K_0 (lbs/in)	r_1	r_2	r_3	r_4	F_o (lbs)	F_I (lbs)	Δ_u (in)	α	β
7/16" OSB - 8d common nails	6,643	0.026	-0.039	1.0	0.008	228	32	0.51	0.7	1.2
19/32" Plywood - 10d common nails	7,777	0.031	-0.056	1.1	0.007	235	39	0.49	0.6	1.2

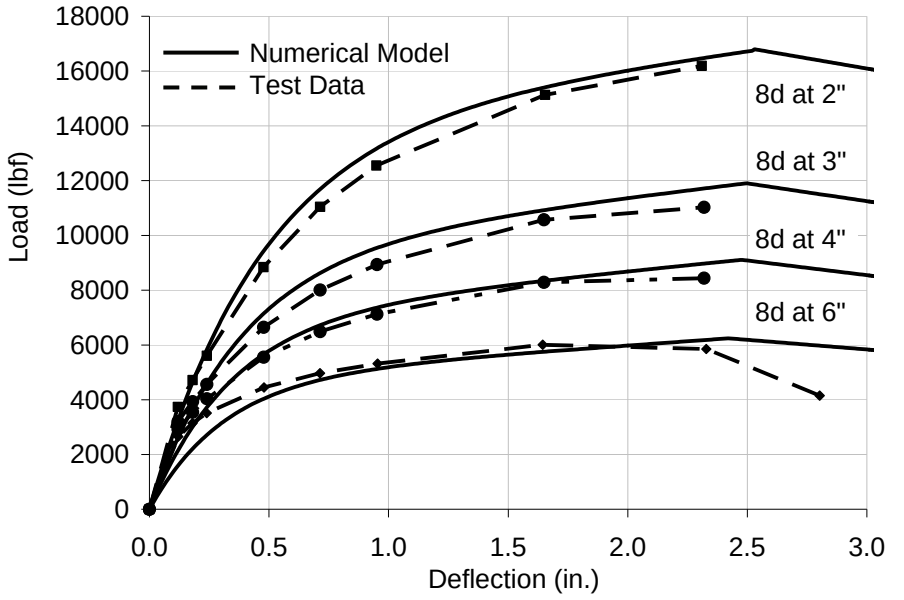

Figure 9-17 Comparison of monotonic backbone curves of 8′ x 8′ shear wall specimens generated using the hysteretic parameters for 8d common nail on 7/16″ OSB sheathing shown in Table 9-21 with average cyclic envelope test data provided by the wood industry (Line et al.,2008).

Uncertainty due to Model Quality

For the purpose of assessing model uncertainty, according to Section 5.7, the archetype designs are assumed to be well representative of the archetype design space, even though a complete assessment may include more basic structural configurations. The structural modeling approach for the wood light-frame archetypes captures the primary shear deterioration modes of the shear walls that precipitate sidesway collapse. However, not all behavioral aspects are captured by this system-level modeling, such as axial-flexural

interaction effects of the wall elements, the uplift of narrow wall ends, and the slippage of sill and top plates. These effects are secondary for walls with low aspect ratios, which deform mainly in a shear mode, but are important for archetypes incorporating walls with high aspect ratios. Therefore, the structural model for the archetypes incorporating low-aspect ratio walls is rated as (B) Good, while the same structural model for the archetypes incorporating high-aspect ratio walls is rated as (D) Poor.

9.4.6 Nonlinear Structural Analyses

To compute the system overstrength, Ω, and to help verify the structural model, monotonic static pushover analysis is used with an inverted-triangular lateral load pattern; this approach differs slightly from the final requirements of Section 6.3. Figure 9-18 shows an example of the pushover curve for the two-story Archetype ID 5. For the wood light-frame archetype, the design LRFD seismic coefficient is $V/W = 0.167$. Capping (the onset of negative stiffness) occurs for a seismic coefficient of 0.417 and at a roof drift ratio of 0.0229. Therefore, Ω is calculated to be 2.49 for this archetype model

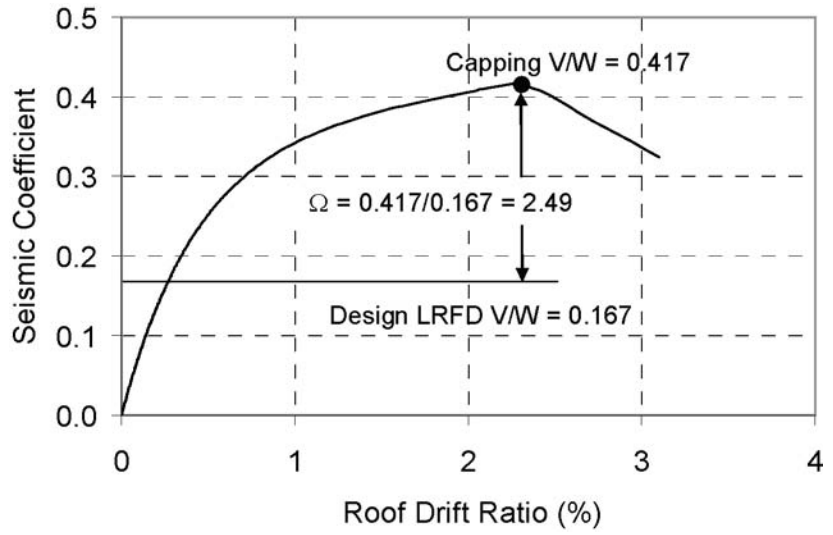

Figure 9-18 Monotonic static pushover curve and computation of Ω for two-story wood light-frame archetype (Archetype ID 5).

Following Section 6.4, to compute the collapse capacity of each wood light-frame archetype design, the incremental dynamic analysis (IDA) approach is used with the Far-Field record set and ground motion scaling method specified in Section 6.2. The intensity of the ground motion causing collapse of the wood light-frame archetype models is defined as the point on the intensity-drift IDA plot having a nearly horizontal slope but without exceeding a peak story drift of 7% in any wall of a model. This collapse story drift limit was selected based on recent collapse shake table testing

conducted on full-scale two-story wood buildings in Japan (Isoda et al., 2007). The resulting collapse capacities should not be highly sensitive to this choice of 7% drift, since the IDA curves are relatively flat at such large drifts (see Figure 9-19 below).

Figure 9-19 and Figure 9-20 illustrate how the IDA method is used to compute the collapse margin ratio, *CMR*, for the two-story Archetype ID 5. The spectral acceleration at collapse is computed for each of the 44 ground motions of the Far-Field Set, as shown in Figure 9-19. The collapse fragility curve can then be constructed from the IDA plots, as shown in Figure 9-20. The collapse level earthquake spectral acceleration (spectral acceleration causing collapse in 50% of the analyses) is $S_{CT}(T = 0.26 \text{ sec}) = 2.23$ g for this example. The collapse margin ratio, *CMR*, of 1.49 is then computed as the ratio of S_{CT} and the MCE spectral acceleration value at $T = 0.26$ sec, which is $S_{MT} = 1.50$ g for this building and SDC.

It should be noted that a full IDA is not required to quantify *CMR*, as discussed in Section 6.4.2.

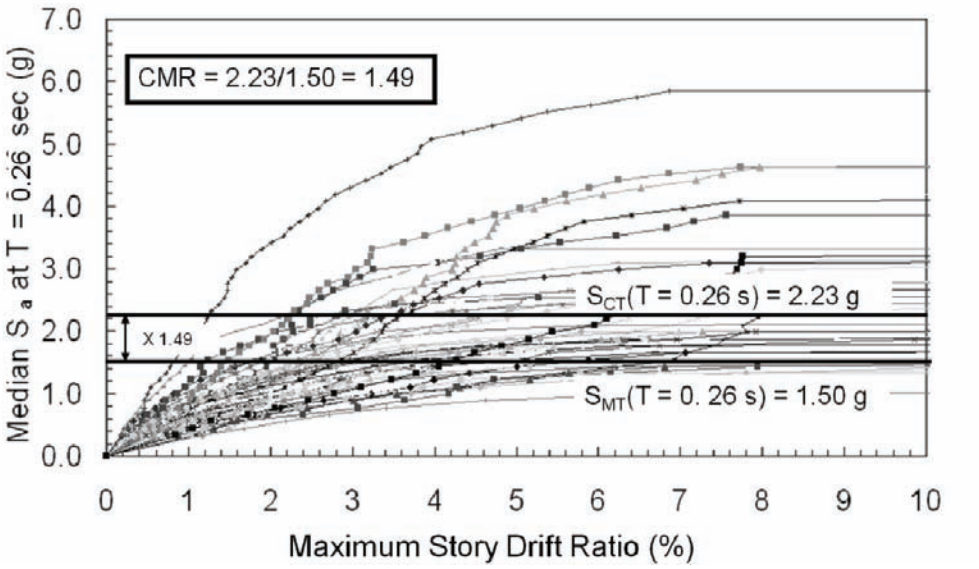

Figure 9-19 Results of incremental dynamic analysis to collapse for the two-story wood light-frame archetype (Archetype ID 5).

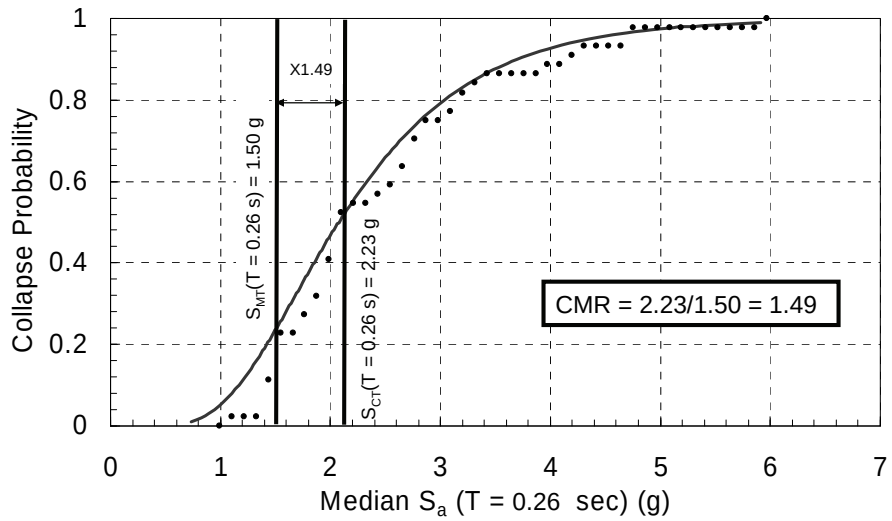

Figure 9-20 Collapse fragility curve for the two-story wood light-frame archetype (Archetype ID 5).

Static pushover analyses were conducted and the IDA method was applied to each of the 16 wood light-frame archetype designs, and Table 9-22 summarizes the results of these analyses. These IDA results indicate that the average collapse margin ratio is 1.43 for the SDC D_{max}, short period – low aspect ratio archetypes (PG-1), 1.90 for the SDC D_{max}, short period – high aspect ratio archetypes (PG-9), 2.64 for the SDC D_{min}, long period – low aspect ratio archetypes (partial PG-4), 2.57 for the SDC D_{min}, short period – high aspect ratio archetypes (PG-11) and 2.82 for the SDC D_{min}, long period – high aspect ratio archetypes (PG-12). These margin values, however, have not yet been adjusted for the beneficial effects of spectral shape (according to Section 7.2). Allowable collapse margins and acceptance criteria are discussed later.

The results shown in Table 9-22 show that the wood light-frame archetypes designed for minimum seismic criteria (SDC D_{min}) have higher collapse margin ratios (lower collapse risk) compared with the archetypes designed for maximum seismic criteria (SDC D_{max}). It is believed that this result originates from the longer vibration periods of archetypes designed for lower levels of seismic load, since the longer periods reduce seismic demands. Also, archetypes incorporating walls with high aspect ratios have higher collapse margin ratios than archetypes with low aspect ratio walls. This is the result of the ASCE/SEI 7-05 strength reduction factor applied to walls with high aspect ratios, which cause an increase in required number of nails to reach a given design strength. This increased nailing density causes an increase in the shear capacity of the walls with high aspect ratios, but the model does not account for the associated increase in flexural deformations.

Table 9-22 Summary of Collapse Results for Wood Light-Frame Archetype Designs

Archetype ID	Design Configuration			Pushover and IDA Results			
	No. of Stories	Building Configuration	Wall Aspect Ratio	Static Ω	$S_{MT}[T]$ (g)	$S_{CT}\,T]$ (g)	*CMR*

Mean of Performance Group:				**3.6**	**NA**	**NA**	**2.82**

9.4.7 Performance Evaluation

Collapse margin ratios computed above do not account for the unique spectral shape of rare ground motions. According to Section 7.2, spectral shape adjustment factors, *SSF*, must be applied to the *CMR* results to account for spectral shape effects. In accordance with Section 7.2.2, the *SSF* can be computed for each archetype based on the SDC and the archetypes' period-based ductility, μ_T, obtained from the pushover curve. Figure 9-21 shows an example of calculating μ_T from the pushover curve for the two-story Archetype ID 5. The period-based ductility, μ_T, of 7.1 is then computed as the ratio of the ultimate roof displacement (defined as the displacement at

80% of the capping strength in the descending branch of the pushover curve) of $\delta_u = 0.0303h_r$, to the equivalent yield roof displacement of $\delta_{y,eff} = 0.0043h_r$.

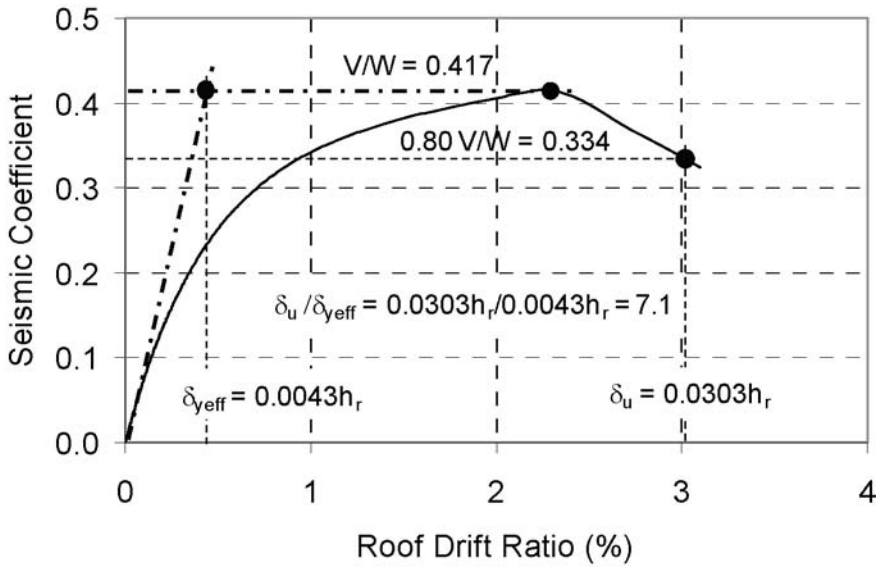

Figure 9-21 Monotonic static pushover curve and computation of $\delta_u/\delta_{y,eff}$ for the two-story wood light-frame Archetype ID 5.

The adjusted collapse margin ratio, *ACMR*, is then computed for each wood light-frame archetype as the multiple of the *SSF* (from Table 7-1b for SDC D) and *CMR* (from Table 9-22). Table 9-23 shows the resulting adjusted collapse margin ratios for the wood light-frame archetypes.

To calculate acceptable values of the adjusted collapse margin ratio, the total system uncertainty is needed. Section 7.3.4 provides guidance for this calculation. Table 7-2 shows these composite uncertainties, which account for the variability between ground motion records of a given intensity (defined as a constant $\beta_{RTR} = 0.40$), the uncertainty in the nonlinear structural modeling, the quality of the test data used to calibrate the element models, and the quality of the structural system design requirements. For this example assessment, the composite uncertainty was based on a (B) Good model quality for archetypes with low aspect ratio walls and a (D) Poor for archetypes with high aspect ratio walls, (A) Superior quality of design requirements and (B) Good quality of test data. Thus, $\beta_{TOT} = 0.500$ for archetype buildings incorporating low aspect ratio walls (Table 7-2b) and $\beta_{TOT} = 0.675$ for archetype buildings incorporating high aspect ratio walls (Table 7-2d).

An acceptable collapse margin ratio must now be selected based on a composite uncertainty, β_{TOT}, and a target collapse probability. Section 7.1.2 defines the collapse performance objectives as: (1) a conditional collapse

probability of 20% for all individual wood light-frame archetypes, and (2) a conditional collapse probability of 10% for the average of each of the performance groups of wood light-frame archetypes. . Table 7-3 presents acceptable values of adjusted collapse margin ratio computed assuming a lognormal distribution of collapse capacity. For archetypes incorporating low aspect ratio walls, this corresponds to an acceptable collapse margin ratio $ACMR_{20\%}$ of 1.52 for every wood light-frame archetype and an $ACMR_{10\%}$ of 1.90 for each performance group. For archetype buildings incorporating high aspect ratio walls, this corresponds to an acceptable collapse margin ratio $ACMR_{20\%}$ of 1.76 for every wood light-frame archetype and an $ACMR_{10\%}$ of 2.38 for each performance group.

Table 9-23 Adjusted Collapse Margin Ratios and Acceptable Collapse Margin Ratios for Wood Light-Frame Archetype Designs

Arch. ID	Design Configuration			Computed Overstrength and Collapse Margin Parameters					Acceptance Check

Table 9-23 summarizes the final results and acceptance criteria for each of the 16 wood light-frame archetypes. The table presents the collapse margin ratios computed directly from the collapse fragility curves, *CMR*, the period-based ductility, μ_T, the Spectral Shape Factor, *SSF*, and the adjusted collapse margin ratio, *ACMR*. The acceptable *ACMR*s are shown and each archetype is shown to either pass or fail the acceptance criteria. Average *ACMR*s are also shown for the four complete performance groups of archetypes.

The results shown in Table 9-23 show that all individual archetypes pass the $ACMR_{20\%}$ criteria and the averages of each performance group pass the $ACMR_{10\%}$ criteria. Therefore, if wood light-frame buildings were a "newly proposed" seismic-force-resisting system with $R = 6$, it would meet the collapse performance objectives of the Methodology, and would be approved as a new system.

The results in Table 9-23 also show that performance groups of archetypes designed for maximum seismic loads (PG-1 and PG-9) have lower adjusted collapse margins ratios than other groups and govern determination of the *R* factor. Another observation is that archetypes incorporating high-aspect ratio walls have higher collapse margin ratios than those with low-aspect ratio walls. Even so, acceptable *ACMR* values are also higher for the high-aspect ratio wall archetypes, due to higher composite uncertainty.

9.4.8 Calculation of Ω_0 using Set of Archetype Designs

This section determines the value of the overstrength factor, Ω_0, which would be used in the design provisions for the "newly-proposed" wood light-frame system. Table 9-23 shows the calculated Ω values for each of the archetypes, with a range of values from 2.0 to 5.4. The average values for each performance group are 2.2, 3.4, 4.1, and 3.6, with the largest value of 4.1 being for the high aspect ratio walls in short-period buildings designed for low-seismic demands (PG-11).

According to Section 7.6, the largest possible $\Omega_o = 3.0$ is warranted, due the average values being greater than 3.0 for three of the performance groups.

9.4.9 Summary Observations

This example shows that current seismic provisions for engineered wood light-frame construction included in ASCE/SEI 7-05 (with use of $R = 6$ rather than $R = 6.5$) to provide an acceptable level of collapse safety. Note that the collapse safety of actual engineering wood light-frame construction is most likely higher than calculated in this example because of the beneficial effects of interior and exterior wall finishes. In accordance with Section

4.2.3, wall finishes were not included in this example because they are not currently defined as part of the lateral structural system, and therefore are not governed by the seismic design provisions.

9.5 Example Applications - Summary Observations and Conclusions

9.5.1 Short-Period Structures

For both reinforced concrete special moment frame and wood light-frame systems, the short-period archetypes (e.g., $T < 0.6$ s for SDC D_{max} designs) were those that had the lowest level of collapse performance. For both of these systems, the short-period performance groups just meet acceptance criteria, and would fail if the Methodology acceptance criteria were made stricter. Thus, it is observed that short-period systems need additional strength (or some other modification that improves the performance) to achieve a level of collapse performance equivalent to systems with longer fundamental periods. This finding is not new, but rather has been reported in research, beginning with Newmark and Hall in 1973. Similar findings have since been reported by a large number of researchers based on analysis of single degree of freedom systems (e.g., Lai and Biggs, 1980; Elghadamsi and Mohraz, 1987; Riddell et al., 1989; Nassar and Krawinkler, 1991; Vidic et al., 1992; Miranda and Bertero, 1994), and for simple multiple degree of freedom systems (Takeda et al., 1998; Krawinkler and Zareian, 2007).

The example applications of this Chapter have verified that strength requirements should be higher for short-period systems, if consistent collapse performance is desired for all systems regardless of fundamental period. These strength requirements suggest the use of a period-dependent *R* factor as is proposed in many of the referenced papers and reports on this topic. Currently, the ASCE/SEI 7-05 document utilizes period-independent *R* factors. Future work should look more closely at the question of period-dependent *R* factors and whether or not they should be considered for use in future versions of ASCE/SEI 7-05.

9.5.2 Tall Moment Frame Structures

The reinforced concrete special moment frame system example in Section 9.2 found that perimeter frame buildings taller than 12-stories high designed on the basis of ASCE/SEI 7-05 do not meet the collapse performance objectives of this Methodology, with the collapse safety worsening with increasing building height. Tall buildings have more damage localization and higher P-delta effects, causing this observed trend in performance.

The issue of worsening collapse safety with increasing building height could be addressed in various ways. Larger column to beam strength ratios could be developed for taller buildings, more restrictive drift limits could be imposed, a period-dependent *R* factor could be used, or other approaches could be taken. In the example, minimum base shear requirement of ASCE 7-02 was reintroduced into the design requirements, successfully reversing the trends and creating increasing collapse safety with increasing building height.

This information was made available to the ASCE 7 Seismic Committee and a special code change proposal was passed in 2007 (Supplement No. 2), amending the minimum base shear requirements of ASCE/SEI 7-05 to correct this potential deficiency.

9.5.3 Collapse Performance for Different Seismic Design Categories

Example applications generally found lower collapse safety for buildings designed in seismic design categories with stronger ground motion intensity. For example, the *ACMR* is typically lower for a building designed for SDC D_{max}, as compared to a building design for SDC D_{min}. This trend is primarily caused by the increasing effects of gravity loads for lower levels of seismic demand, which increases the overstrength of the structural system, and in turn increases the collapse capacity of the system.

This finding suggests that the *R* factor will be governed by the SDC with the strongest ground motion for which the system is proposed. Based on this observation, the Methodology requires that this SDC with the strongest ground motion be used when verifying the *R* factor. It is expected that such *R* factors will be conservative for other Seismic Design Categories, but this trend should be confirmed in the archetype investigation.

Chapter 10
Supporting Studies

This chapter describes additional studies performed in support of the development of the Methodology. These studies supplement the illustrative examples presented in Chapter 9, and serve to examine selected aspects of the Methodology as applied to different seismic-force-resisting systems.

10.1 General

Two supporting studies are presented. One study evaluates a 4-story steel special moment frame system. This study illustrates the use of component limit state checks to evaluate failure modes that are not explicitly simulated in the nonlinear dynamic analysis. It also demonstrates the application of the Methodology to steel moment frame systems.

A second study assesses the collapse performance of seismically-isolated systems. This study illustrates application of the Methodology to isolated structural systems, which have fundamentally different dynamic response characteristics, design requirements and collapse failure modes than those of conventional, fixed-base structures. This study also demonstrates the potential use of the Methodology as a tool for validating and improving current design requirements, in this case requirements for isolated structures.

10.2 Assessment of Non-Simulated Failure Modes in a Steel Special Moment Frame System

10.2.1 Overview and Approach

The purpose of this study is to illustrate how component limit state checks can be used to evaluate failure modes that are not explicitly simulated in the nonlinear dynamic analysis. This study follows the approach for non-simulated collapse modes described in Chapter 5.

The procedure for evaluating non-simulated collapse modes is illustrated through the evaluation of a steel special moment frame structure, designed using pre-qualified Reduced Beam Section (RBS) connection details in accordance with current design standards, ASCE/SEI 7-05 and ANSI/AISC 341-05 *Seismic Provisions for Structural Steel Buildings* (AISC, 2005). This study focuses on assessment of a single steel special moment frame building,

which in concept could be one of many index archetype configurations serving to describe the archetype design space. In order to evaluate the entire class of steel special moment frames, the procedures applied to this individual building would be extended to the full set of index archetype models.

The primary collapse mechanism of this steel special moment frame occurs through hinging in the RBS regions of the beams and the columns, which can lead to sidesway collapse under large deformations. While gradual deterioration of the inelastic hinges associated with yielding and local buckling is simulated in the analyses, sudden strength and stiffness degradation associated with ductile fractures are not explicitly modeled. In this study, ductile fracture is not simulated because of software limitations.

The use of separate non-simulated limit state checks is supported by a number of related factors. First, through the use of pre-qualified RBS connections, the initiation of ductile fracture is unlikely to occur until large inelastic rotations have been reached and sidesway collapse has occurred or nearly occurred. Hence, the simplified limit state check for fracture is not expected to dominate the results. Second, available test data suggests that the location where ductile fracture may occur and the deformations at which ductile fracture may occur are highly variable, and simulation models would need to define correlations relating fracture probabilities at multiple connections. In this particular structure, the large columns tend to enforce equal rotations across a story. Therefore, even if ductile fracture were modeled, fractures would tend to form simultaneously across a given story and the collapse results obtained would be similar to those obtained using non-simulated limit state checks, unless correlations were explicitly incorporated in the analysis. There is limited data to support estimation of correlations.

In order to ensure that the collapse assessment process represents the behavior of the structural system of interest, the choice to incorporate a particular failure mode using a limit state check, in lieu of direct simulation, should be based on careful consideration of factors like those described above. Where non-simulated failure modes dominate the results, or where their exclusion jeopardizes simulation accuracy before the non-simulated limit state is reached, the appropriateness of the nonlinear model should be re-examined.

10.2.2 Structural System Information

The steel special moment frame archetype analyzed in this study is one of four perimeter moment frames that comprise the seismic-force-resisting system of a four-story building illustrated in Figure 10-1. The four-bay four-story frame provides lateral support to a floor area of 10,800 sq. ft. per floor and gravity support to a tributary area of 1,800 sq. ft. The seismic weight (mass) is equal to 940 kips on the second, third and fourth floors and 1,045 kips on the roof, for a total of 3,865 kips per frame.

The building is designed for a high seismic site located in Seismic Design Category (SDC) D, based on $T = 0.94$ seconds and a Maximum Considered Earthquake (MCE) spectral demand, S_{MT}, of 0.96 g (corresponding to SDC D_{max}). The structure has a design base shear, $V = 0.08W$. Designed in accordance with ASCE/SEI 7-05 and ANSI/AISC 341-05, beam sizes range from W24 to W30, and are governed by minimum stiffness requirements (drift limits). The RBS sections have 45% flange reduction. W24 columns are sized to satisfy the connection panel zone strength requirements without the use of web doubler plates. As such, they automatically satisfy other requirements, including the strong-column weak-beam (SCWB) requirement. As a result, the actual SCWB ratio is about 2.5 times larger than the required minimum. This large column overstrength reflects a possible design decision that is representative of current practice in California; however, it implies that this study will not necessarily demonstrate the lower-bound performance of code-conforming steel special moment frames.

Design requirements for this system are well-established, based on experience in past earthquakes, reflecting a high degree of confidence and completeness. For the purpose of assessing system uncertainty, the design requirements are rated (A) Superior.

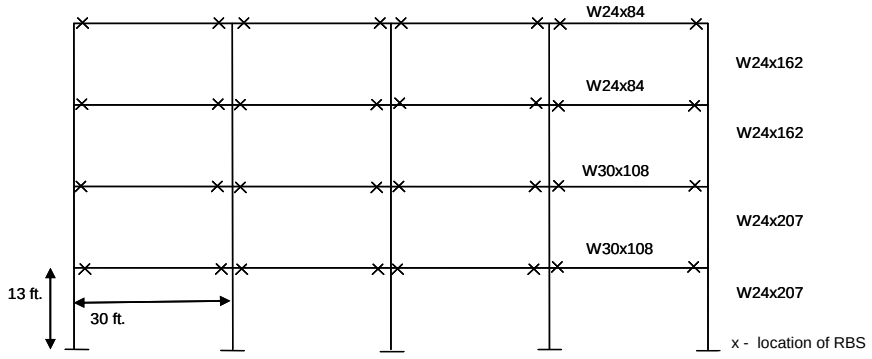

Figure 10-1 Index archetype model of 4-story steel special moment frame seismic-force-resisting system

10.2.3 Nonlinear Analysis Model

This structure is judged to have primarily two collapse modes: (1) sidesway collapse associated with beam and column hinging; and (2) collapse triggered by ductile fracture in one or more RBS connections. Nonlinear dynamic analyses were conducted using the OpenSees (OpenSees, 2006) software, employing elements with concentrated inelastic springs to capture flexural hinging in beams and columns and an inelastic (finite size) joint model for the beam-column panel zone.

Inelastic springs in beams and columns were modeled using the peak-oriented Ibarra element model (Ibarra et al., 2005), which can capture cyclic deterioration and in-cycle negative stiffness in elements as the structure collapses. The monotonic backbone used to model the W24x162 columns is illustrated in Figure 10-2.

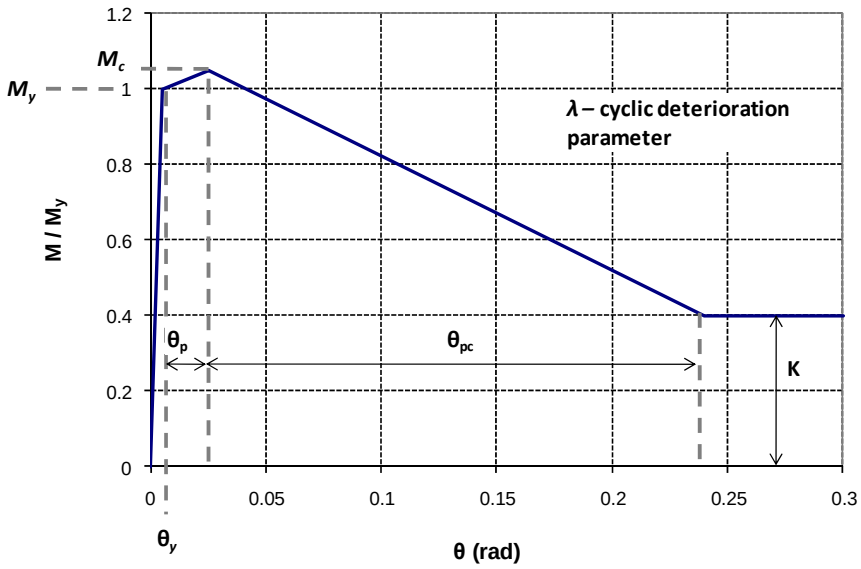

Figure 10-2 Monotonic backbone showing calibrated concentrated plasticity model for a typical column (W24x162).1

Model parameters for beams and columns (e.g., plastic rotation capacity, cyclic deterioration parameters) were calibrated to experimental test data (Lignos and Krawinkler, 2007) and reported in Table 10-1. For each beam and column, the model yield point is defined by the plastic moment capacity of the section, M_p, calculated with expected values for the steel yield strength, i.e., 1.1 x F_y. Column initial rotational stiffness is based on Young's modulus for steel and the cross-sectional stiffness. Calculation of beam stiffness includes the contribution of the composite floor slab, and the

[1]For more information, model parameters are defined in Appendix E. The discussion in Appendix E deals with the same Ibarra model, but as applied to modeling of reinforced concrete beams and columns.

additional flexibility in beams due to the RBS section is neglected. RBS sections are modeled as adjacent to the panel zone, neglecting offsets from the column face. Beam properties are modeled as asymmetric, depending on the loading direction.

Table 10-1 Model Parameters for Column and Beam Plastic Hinges in 4-Story Steel Special Moment Frame

Section	My (kip-in)	Mc/My +(-)	θp +(-)	θpc +(-)	λ	K
W24x162	2.5 x104	1.05	0.025	0.35	330	0.4
W24x207	3.3 x104	1.05	0.03	0.30	440	0.4
W24x84	8.2 x103	1.1(1.05)	0.025(0.020)	0.17	380	0.4
W30x108	1.3 x104	1.1(1.05)	0.022(0.016)	0.15	260	0.5

As described previously, these backbones do not predict ductile fracture of RBS sections, so that failure mode is evaluated through a non-simulated limit state check. The joint panel zone yield point and hardening parameters are based on Equation 9-1 in ANSI/AISC 341-05 and Krawinkler (1971, 1978). The panel zone spring is modeled as non-deteriorating with a bilinear kinematic hardening model.

Other modeling assumptions are consistent with the requirements of Chapter 5 and Chapter 6. Expected dead and live loads ($1.05D + 0.25L$) are applied to the structure and used in the computation of the seismic mass. The contribution of the gravity frame is not included in the analysis model, though the leaning P-delta column accounts for gravity loads not tributary to the seismic-force-resisting system. Foundation flexibility is neglected and the foundation is modeled as a fixed-base.

The model is rated (B) Good in accordance with Table 5-3. The model is rated as to how well it captures the behavior of the system up to the point at which the non-simulated collapse mode (ductile fracture) occurs. This rating is the same as that given to the reinforced concrete special moment frame models of Chapter 9, using much of the same rationale. The model is judged to have a high degree of accuracy and robustness, but does not account for effects of overturning on column behavior.

The available test data is also rated (B) Good in accordance with Table 3-2. There is significant test data for steel columns, which has been conducted by a number of different researchers. However, as with the reinforced concrete component test data certain critical configurations are missing, such as tests of steel beams with reinforced concrete slabs.

10.2.4 Procedure for Collapse Performance Assessment, Incorporating Non-Simulated Failure Modes

Accounting for non-simulated failure modes in assessment of collapse margin ratio first requires the identification and calibration of appropriate limit-state models. These limit state models are used to evaluate analysis results to see if the non-simulated limit state was exceeded. The *CMR* is then computed to account for both simulated and non-simulated failure modes, and adjusted for spectral shape effects with the *SSF*. The resulting *ACMR* is compared to the acceptance criteria in Chapter 7.

Identify Non-Simulated Collapse Modes

Properties of beam-column plastic hinges in the analysis model for steel special moment frames are calibrated to predict hinging and gradual deterioration associated with yielding and local buckling. However, experimental data (e.g., Engelhardt et al., 1998; Ricles et al., 2004; Lignos and Krawinkler, 2007) suggest that the steel frame may also experience ductile fracture in RBS sections, or possibly at the joint between the beam and column. For example, in testing done as part of the SAC Steel Project, Engelhardt et al. (1998) reported fractures in qualifying connections at inelastic rotations between 0.05 and 0.07 radians. It should be emphasized that the fracture being considered here is triggered by ductile crack initiation, and occurs after significant inelastic yielding has occurred, in contrast to the connection fractures observed in steel frame structures during the 1994 Northridge earthquake.

Ductile-fracture-induced collapse is conservatively assumed to take place if ductile fracture occurs in any RBS. This collapse limit state is chosen because the steel special moment frame model is able to capture critical aspects of system behavior until the point at which ductile fracture occurs in the first RBS. If the analysis was continued after a ductile fracture is experienced, the fidelity of the results would be in doubt. Since the strong column sidesway mechanism in this frame imposes similar peak rotations in all the RBS hinges, the assumption of equating the first instance of a fractured connection with fracture-induced collapse may not be too unreasonable (overly conservative) for this particular example.

Generally, it would be desirable to incorporate fracture deterioration directly in the nonlinear model. Since it is not directly incorporated in this analysis, a conservative judgment is made about what constitutes collapse for the fracture limit state. A typical representation of the deformations at fracture is shown in Figure 10-3.

Develop Component Fragility

Calculation of the non-simulated collapse mode requires the definition of a fracture fragility function. In this case, the fragility function relates the probability of ductile fracture in the RBS hinge to a response parameter such as the maximum plastic hinge rotation that has occurred in the plastic hinge. Figure 10-4 shows the resulting fragility function, P[Fracture|θ_p], which is based on available data (Lignos and Krawinkler, 2007) and engineering judgment.

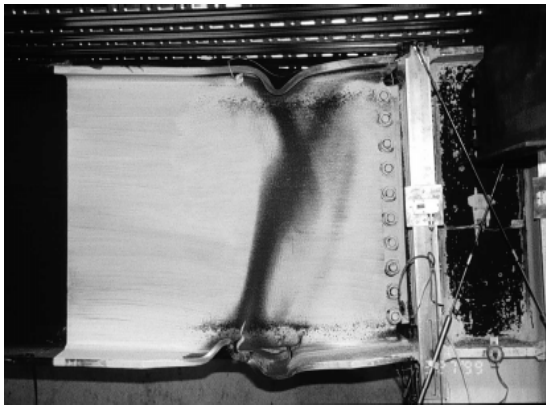

Figure 10-3 Illustration of fracture behavior (Engelhardt et al., 1998).

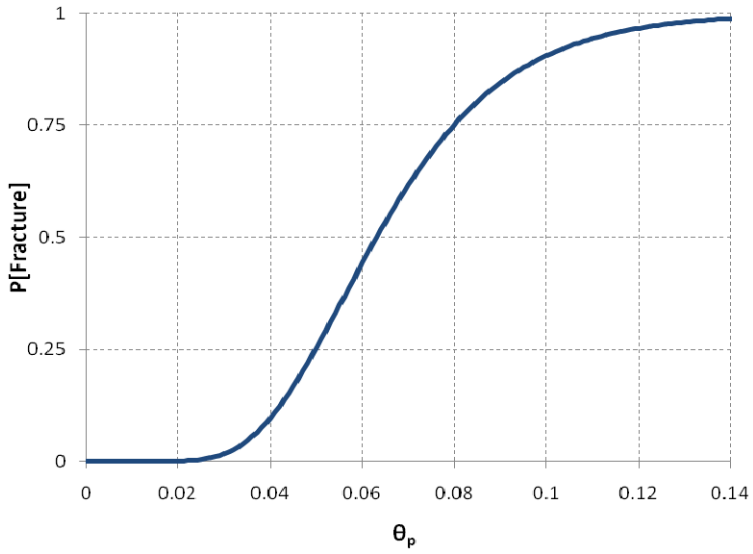

Figure 10-4 Component fragility function, describing probability of ductile fracture occurring as a function of the plastic rotation, θ_p.

The fragility function for fracture is assumed to follow a lognormal distribution, and has a median capacity of $\hat{\theta}_p$ = 0.063 radians and a logarithmic standard deviation of β_F = 0.35. The dispersion, β_F, reflects both test data statistics (from 10 tests) and judgment as to the additional variability that may be encountered in actual buildings. Assuming that the parameters

associated with fracture are the same throughout the building, the fragility function is applicable to every RBS in the building.

Identify Collapse Limit based on Component Fragility

The collapse limit point for the non-simulated collapse mode is defined by the median value of the fragility function associated with component failure. Therefore, if the plastic rotation in a RBS exceeds the median of 0.063 radians, that component is assumed to be fractured and the non-simulated limit state is triggered.

Note that the collapse limit state in this formulation ignores the effect of dispersion, β_F, in the collapse fragility. The magnitude of the impact of β_F on the total collapse uncertainty, β_{TOT}, depends on the relative dominance of simulated (sidesway) and non-simulated failure modes. However, the other sources of uncertainty considered in the Methodology (e.g., β_{RTR}, β_{DR}, β_{TD}, β_{MDL}) dominate the uncertainty in the collapse fragility. For explanation of a rigorous approach accounting for the effects of β_F, see Aslani (2005).

Nonlinear Static (Pushover) Analysis

The static pushover analysis results for the steel special moment frame are illustrated in Figure 10-5. The maximum base shear, V_{max}, is 1170 kips, compared to a design base shear of approximately 345 kips, for an overstrength, Ω = 3.4. This large overstrength relative to the design lateral forces is due to the very strong columns sized to avoid doubler plates.

The period-based ductility, given by $\mu_T = \delta_u/\delta_{y,eff}$, is obtained from the pushover analysis as described in Section 6.3. The ultimate roof displacement, δ_u, is taken as either the roof displacement corresponding to a 20% loss in base shear, or the roof displacement at which the non-simulated (ductile fracture) failure mode occurs. Since the strong columns in this structure impose approximately uniform distribution of story drift, the roof displacement at which the non-simulated (fracture) failure mode occurs is approximately $0.063h_r$, corresponding to a roof displacement of 39.3 inches. For comparison, δ_u associated with a 20% loss in base shear from pushover analysis, is approximately $0.075h_r$, corresponding to a roof displacement of approximately 46.8 inches. The effective yield displacement, $\delta_{y,eff}$, is computed from Equation 6-7 as $0.009h_r$, or 5.6 inches, for this structure. Therefore, μ_T is 7.0.

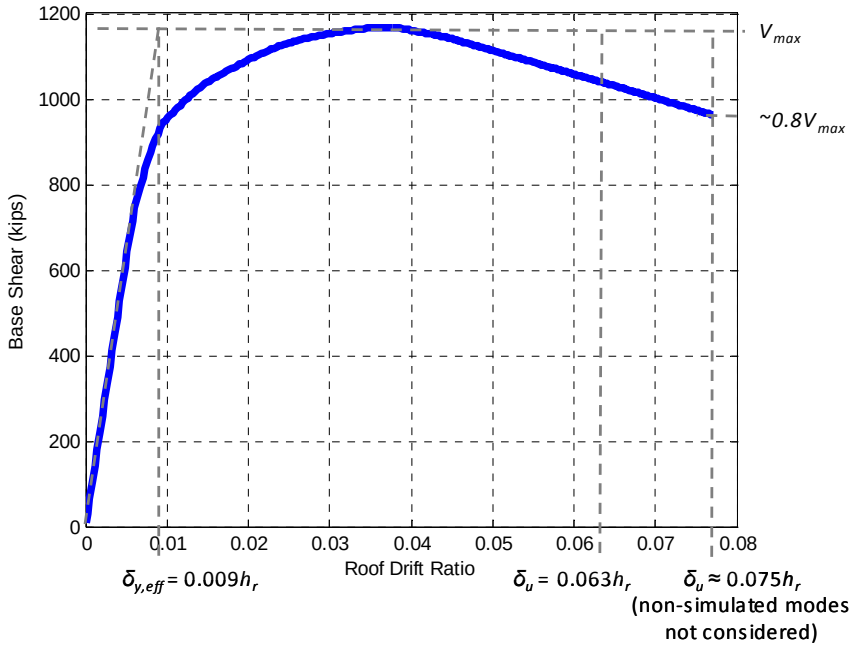

Figure 10-5 Results of nonlinear static (pushover) analysis of a steel special moment frame, illustrating computation of period-based ductility from non-simulated collapse modes.

Assess Collapse Performance

To assess collapse performance, response of the 4-story steel special moment frame is calculated using the Far-Field record set and nonlinear dynamic analysis, as described in Chapters 5 through 7. If only simulated collapse modes are considered, a median collapse capacity, $\hat{S}_{CT}$, of 2.36 g is obtained. Due to the strength of the columns relative to the beams, the sidesway collapse mode is a full four-story mechanism with hinges at all RBS regions and at the fixed column bases for all ground motions.

The collapse fragility is computed based on both simulated and non-simulated collapse modes. This procedure is illustrated graphically in Figure 10-6, using representative curves from incremental dynamic analysis for this structure (each curve contains the dynamic analysis results for one ground motion, scaled until collapse). The non-simulated fracture mode occurs if the plastic rotations at any RBS in the building exceed the median capacity defined by the component fragility function. In the figure, sidesway collapse points based on results from simulation, $S_{CT(SC)}$, are shown with short bold pointers. Non-simulated (fracture-induced) collapse points, $S_{CT(NSC)}$, are shown with pointers from hatched circles corresponding to maximum story drift at fracture ($\hat{\theta}_p$ = 0.063 radians).

For the purposes of this figure, the component collapse limit of $\hat{\theta}_p$ = 0.063 is shown as approximately equal to the story drift ratio. This assumption is

made for illustration purposes only, and is not actually used in computing the occurrence of non-simulated failure modes. Of the three curves shown in Figure 10-6, the lowest reaches simulated sidesway collapse and the non-simulated collapse limit state at approximately the same level of ground motion intensity. The other curves reach the non-simulated collapse point under less intense ground motions than suggested by sidesway collapse. Investigation of the occurrence of simulated and non-simulated failure modes is repeated for all ground motions. In computing the collapse fragility, the more critical of these two limit states is taken as the governing collapse point for each ground motion record.

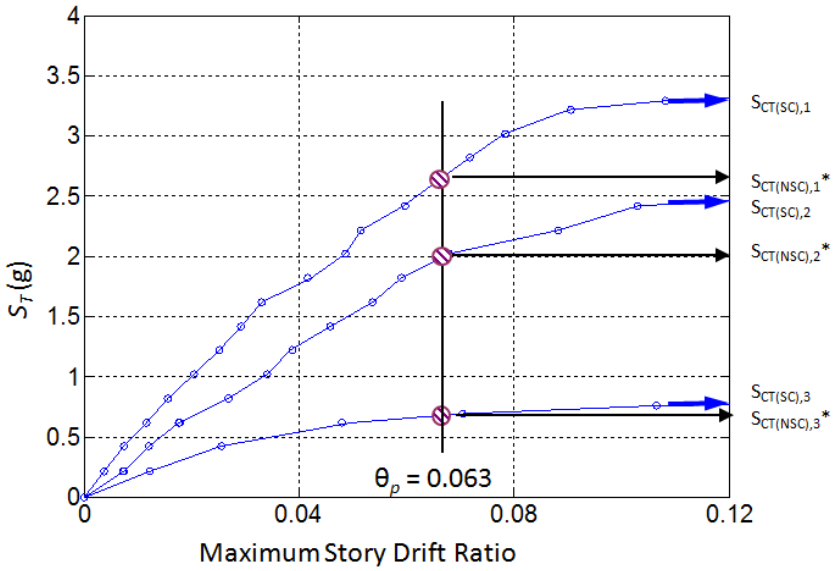

Figure 10-6 Selected simulation results for the steel special moment frame illustrating the identification of non-simulated collapse modes. The governing collapse point for each ground motion record is identified with an asterisk (*).

Given ratings of (B) Good for modeling, (A) Superior for design requirements, and (B) Good for test data, the total system collapse uncertainty is $\beta_{TOT} = 0.500$. Since $\mu_T \geq 3$ for this building, this value includes record-to-record uncertainty, $\beta_{RTR} = 0.40$, in accordance with Section 7.3.4. It is noted that for systems driven by very brittle non-simulated collapse modes, β_{RTR} can potentially be reduced in accordance with Equation 7-2. This reduction should be exercised with caution. The approach to non-simulated failure modes is based only on the median component limit state, neglecting the underlying uncertainty associated with the occurrence of the component failure mode, β_F. If record-to-record variability is significantly reduced with Equation 7-2, the total uncertainty in the collapse fragility could be too low, and non-conservative.

The combined collapse fragility is illustrated in Figure 10-7. In this figure, the horizontal axis fragility parameter, S_{CT}, is normalized by MCE demand, S_{MT} to permit direct comparison of the collapse margin ratio, *CMR*, for the structure with and without consideration of non-simulated fracture-induced failure modes. For this structure, the net result of including the fracture-induced collapse is a 32% reduction in the collapse margin ratio, *CMR*, from 2.5 for the simulated sidesway-only case, to 1.9. The conditional probability of collapse at the MCE increases from 8% to 14%. (Note: these margins and the collapse probabilities do not include the spectral shape factor, which is considered in the evaluation of acceptance criteria.)

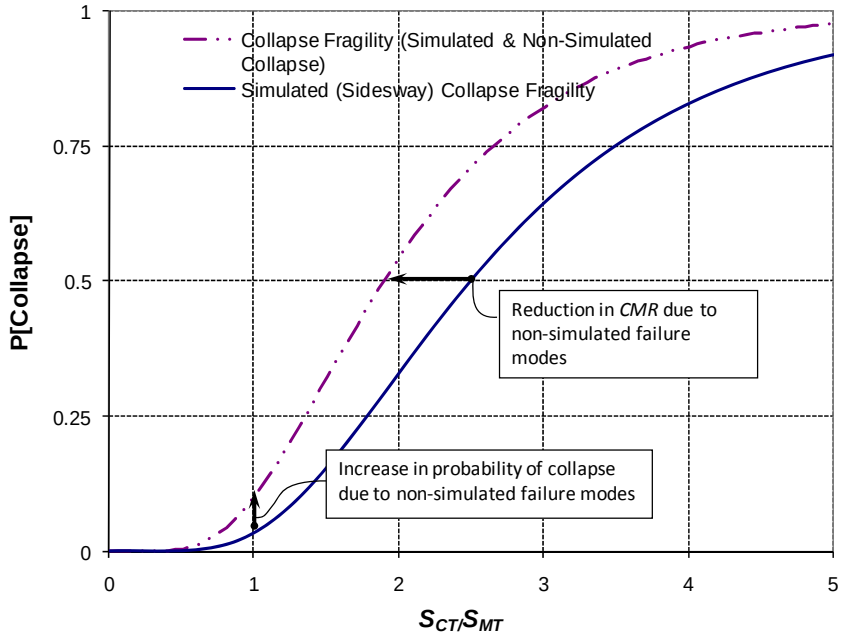

Figure 10-7 Comparison of steel special moment frame collapse fragilities for sidesway-only and combined simulated and non-simulated (sidesway and fracture-induced) collapse (not adjusted for spectral shape).

Compare to Acceptance Criteria

Finally, the combined fragility data, reflecting the likelihood of both simulated and non-simulated collapse, should be compared to the acceptance criteria in Chapter 7. For this structure, the spectral shape factor, *SSF*, of 1.41 is determined from Table 7-1b with T = 0.94 seconds and $\delta_u/\delta_{y,eff}$ = 7.0, which gives an *ACMR* of 2.7. The acceptable *ACMR* is obtained from Table 7-3, with β_{TOT} = 0.500. The *ACMR* is compared to an acceptable collapse margin ratio, $ACMR_{10\%}$, of 1.90 (based on the 10% probability of collapse limit), and easily satisfies the acceptance criteria.

If the Methodology were applied to a complete set of steel special moment frames, including different performance groups for high and low gravity loads, maximum and minimum seismic criteria and short-period and long period systems, each individual archetype would be compared to $ACMR_{20\%}$, and the average of each performance group would be compared to $ACMR_{10\%}$ from Table 7-3.

10.3 Collapse Evaluation of Seismically Isolated Structures

10.3.1 Introduction

Seismic isolation (commonly known as base isolation) is a technology that is intended to protect facility function and provide substantially greater damage control than conventional, fixed-base, structures for moderate and strong earthquake ground motions. For extreme ground motions, seismically isolated structures are expected to be at least as safe against collapse as their conventional counterparts. To ensure adequate performance, ASCE/SEI 7-05 requires explicit evaluation of the design of every isolated structure under Maximum Considered Earthquake (MCE) ground motions and comprehensive testing of prototype isolator units to verify design properties and demonstrate stability under MCE loads.

The provisions of ASCE/SEI 7-05 require the seismic force-resisting system of the structure above the isolation system (superstructure) to be designed for response modification factors, R_I, that are smaller than the R factors permitted for conventional structures. Reduced values of the response modification factor are intended to keep the superstructure "essentially elastic" for design earthquake ground motions. To protect against potential brittle failure for extreme ground motions, ASCE/SEI 7-05 requires the superstructure to have the same ductile capacity as that required for a conventional structure of the same type in the seismic design category of interest. The provisions of ASCE/SEI 7-05 are generally considered to be conservative with respect to design of the superstructure, although the degree of conservatism, if any, is not known.

Objectives

This study is intended to demonstrate the application of the Methodology to isolated structures, which have fundamentally different dynamic response characteristics, performance properties and collapse failure modes than those of conventional, fixed-base structures. Special issues include the following:

Period Definition. The fundamental-mode "effective" period of an isolated structure is based on secant stiffness at the response

amplitude of interest, rather than "elastic" stiffness used to define the period, *T*, of conventional structures.

Record-to-Record (RTR) Variability. Record-to-record variability may be smaller than 0.4 because base isolated structures typically do not undergo large period elongation before collapse. Are the recommendations for reduced record-to-record (RTR) variability in Chapter 7 suitable for isolated structures?

Test Data and Modeling Uncertainty. Can the collapse margin ratio (*CMR*) of isolated structures be evaluated using the same uncertainty associated with test data and modeling of the superstructure as considered for a conventional structure with the same type of seismic-force-resisting system?

Spectral Shape Factor (SSF). Can the spectral shape factor (*SSF*) used to adjust the *CMR* of isolated structures be calculated using the same methods as those specified for conventional structures (Appendix B)?

This study is also intended to illustrate how the Methodology can be used as a tool for assessing the validity of current design requirements, in this case Chapter 17 of ASCE/SEI 7-05, and to develop improved code provisions. In order to evaluate the design requirements for isolated structures, this study specifically explores the sensitivity of collapse performance to the following key design properties of isolated structures:

Superstructure Strength. How does collapse performance vary for superstructures that have different design strength levels (e.g., superstructures designed for different effective values of the R_I factor)? Effective R_I values yielding higher and lower design base shears than the code-specified values are considered.

Superstructure Ductility. How does superstructure ductility influence collapse performance (e.g., performance of special moment frame superstructures as compared to that of ordinary moment frame superstructures)?

Moat Wall Clearance. How does collapse performance vary for isolated structures that have different amounts of clearance between the isolated structure and the moat wall?

Scope and Approach

The scope of this study is necessarily limited and relies on archetypical models available from other examples developed in this project to represent the superstructures of isolated archetypes. Specifically, superstructures are based on the 2-dimensional, archetypical models of 4-story reinforced concrete special moment frame and ordinary moment frame systems, from the example applications included in Chapter 9. Design of isolator systems in this study varies from typical isolator design in that isolator properties are designed to satisfy ASCE/SEI 7-05 design requirements between the isolation system and the superstructure, given the reinforced concrete frame superstructures developed in the Chapter 9 examples.

The archetypical models of isolated structures incorporate force-deflection properties of isolation systems typical of actual projects that use either (1) elastomeric, rubber bearings (RB), or (2) sliding, friction-pendulum (FP) bearings. These two isolation system types are designed and archetypical models of the isolated structure evaluated for maximum and minimum SDC D ground motions (SDC D_{max} and SDC D_{min}). SDC D_{max} ground motions are typical of those used for most seismic isolation projects (e.g., projects in high seismic regions of coastal California).

This study includes discussion of background information necessary for proper application of the Methodology to isolated structures and related development of isolated archetypes. Archetype configurations, nonlinear analysis techniques, and collapse performance methods are described with reference to specific differences in applying the methodology to isolated structures. Collapse evaluation results are reported for archetypes that comply with the design requirements of ASCE/SEI 7-05 (referred to herein as Code-Conforming archetypes) and for archetypes that deviate from current requirements (Non-Code-Conforming archetypes). The Non-Code-Conforming archetypes demonstrate potential use of the Methodology as a tool for code development, by evaluating collapse performance for archetype models that have weaker (or stronger) superstructures, less ductility, or different moat clearances than those specified in ASCE/SEI 7-05.

10.3.2 Isolator and Structural System Information

Archetypes of isolated structures must be designed using established design requirements, and modeling of isolated archetypes must be supported by appropriate test data (Chapter 3). Further, the quality of the design requirements and test data must be rated for establishing system collapse uncertainty (Chapter 7).

Design Requirements

Archetypes of isolated structures are designed according to the provisions of ASCE/SEI 7-05 and related superstructure design codes, including ACI 318-05, except as some specific provisions are modified, or ignored, to evaluate the effects of reduced superstructure strength, or limited ductility, or moat clearance in the Non-Code-Conforming archetypes. Chapter 17 of ASCE/SEI 7-05 requires thorough and rigorous design of the isolated structure, including explicit evaluation of the isolation system for MCE ground motions, and peer review.

For the purpose of assessing the composite uncertainty in the Methodology, the isolation system and superstructure design requirements are rated as (A) Superior, as they are thorough, detailed and vetted through the building code process.

Test Data

The requirements for test data relate both to testing of superstructure components (i.e., reinforced concrete beams, columns and connections), and testing of prototype isolator units. The test data related to reinforced concrete elements is rated (B) Good, as discussed in the Chapter 9 examples. While there is a large amount of test data on reinforced concrete components, there are still several areas where test data are not complete (i.e. tests of beams with slabs, tests to very large deformations).

Test data related to isolation units is both qualitatively and quantitatively different. For the purposes of modeling conventional structures, test data is taken from a variety of different researchers regarding components which are similar, but not identical, to the components being modeled in the structure. In contrast, the provisions ASCE/SEI 7-05 require prototype testing of isolator units for the purpose of establishing and validating the design properties of the isolation system and verifying stability for MCE response. These tests are specific to the isolation system installed in a particular building, and follow detailed requirements for force-deflection response outlined in the design requirements. As a result, there is substantially smaller uncertainty related to the test data in an isolated system than the superstructure.

A rating of (B) Good is assigned to the uncertainty assessment for test data for these systems. This rating is associated with uncertainty in test data related to superstructure modeling and potential isolator failure modes at loads and displacements greater than those required for isolator prototype testing by Section 17.8 of ASCE/SEI 7-05.

10.3.3 Modeling Isolated Structure Archetypes

This section identifies the basic configuration, systems and elements of the isolated structures of this study and provides a general overview of the index archetype models used to evaluate collapse performance of these systems. Section 10.3.4 describes specific design properties for the isolation system, moat wall clearance, and the superstructure of each model.

The seismic-force-resisting system of an isolated structure includes: (1) the isolation system; and (2) the seismic-force-resisting system of the superstructure above the isolation system. The isolation system includes individual isolator units (e.g., elastomeric or sliding bearings), structural elements that transfer seismic force between elements of the isolation system (e.g., beams just above isolators) and connections to other structural elements. Energy dissipation devices (dampers) are sometimes used to supplement damping of isolator units, but such devices are not considered in this study.

Isolated structures are typically low-rise or mid-rise buildings that have relatively stiff superstructures. This study assumes that the seismic-force-resisting system of the superstructure is a reinforced-concrete moment frame system, in order to make use of already developed models for Chapter 9 that explicitly capture sidesway collapse. A relatively short height (4 stories) is used to assure adequate stiffness of the superstructure.

Isolated structures typically have a "moat" around all or part of the perimeter of the building at the ground floor level. The moat is usually covered by architectural components (e.g., cover plates) that permit access to the building, but do not inhibit lateral earthquake displacement of the isolated structure.

Impact with the moat wall can cause collapse. Accordingly, Section 17.2.5.2 of ASCE/SEI 7-05 requires a minimum building separation to "retaining walls and other fixed obstructions" not less than the total maximum (MCE) displacement of the isolation system. The intent of this provision is to limit the likelihood of such impacts, even for strong ground motions. However, Section 17.2.4.5 of ASCE/SEI 7-05 recognizes that providing clearance for MCE ground motions may not be practical for some systems and permits isolation system design to incorporate a "displacement restraint" that would limit MCE displacement, provided certain criteria are met. These criteria include the requirement that "the structure above the isolation system is checked for stability and ductility demand of the maximum considered earthquake." This study shows how the Methodology can be used to perform this check.

Index Archetype Models

Models of isolated systems consist of a superstructure model, an isolator model, and a moat wall model. Each of these components must be capable of capturing the inelastic effects in the structure up until the point at which the structure collapses. Analysis models are two-dimensional, and neglect possible torsional effects. A schematic diagram of the index archetype model for isolated systems is illustrated in Figure 10-8.

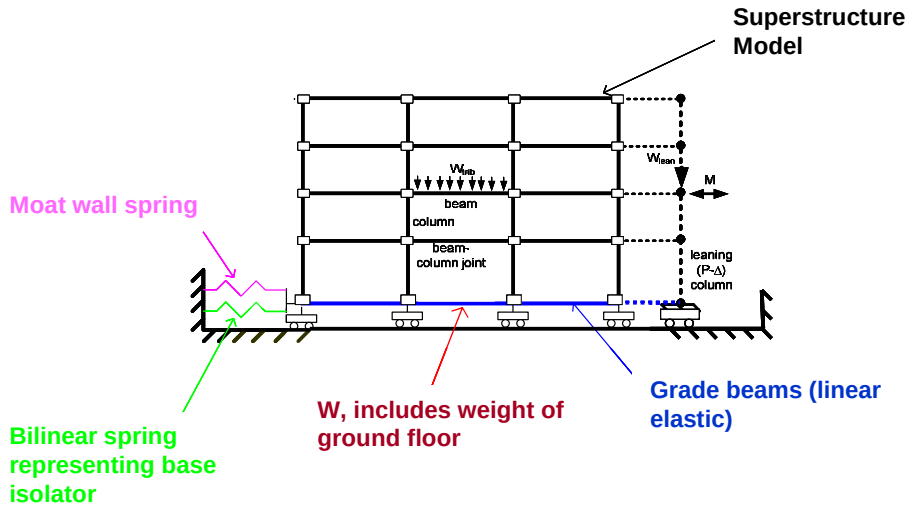

Figure 10-8 Index archetype model for isolated systems.

The superstructure is modeled using the same assumptions as described in the Chapter 9 examples. The model incorporates material nonlinearities in beams, columns and beam-column joints, as well as deterioration of strength and stiffness as the structure becomes damaged. As before, the superstructure model includes a leaning (P-delta) column to account for the effect of the seismic mass on the gravity system.

Isolator Modeling

The isolation system bearings (isolators) are modeled using a bilinear spring between the foundation and the ground-floor of the superstructure, as shown in Figure 10-8. The bilinear spring is assumed to be a non-degrading, fully hysteretic element. Some isolators exhibit significant changes in properties with repeated cycles of loading as a result of heating, but explicit modeling of such behavior is currently in its infancy and is beyond the scope of this study. Bilinear springs are commonly used in practice and provide sufficiently accurate estimates of nonlinear response when their stiffness and damping properties are selected to match those of the isolators (Kircher, 2006).

Figure 10-9 illustrates the modeled force-displacement response of nominal, upper-bound and lower-bound bilinear springs used to represent isolators in this study. In general, isolators are modeled with nominal spring properties. However, in certain cases, isolators are modeled with upper-bound and lower-bound spring properties to evaluate the effects of these properties on collapse. Upper-bound and lower-bound properties are also needed for isolation system design. Section 17.5 of ASCE/SEI 7-05 requires lower-bound properties for calculation of isolation system displacements, and upper-bound properties for calculation of design forces. The range of upper-bound and lower-bound bilinear spring properties used to model isolators is based on the prototype testing acceptance criteria of Section 17.8.4 of ASCE/SEI 7-05.

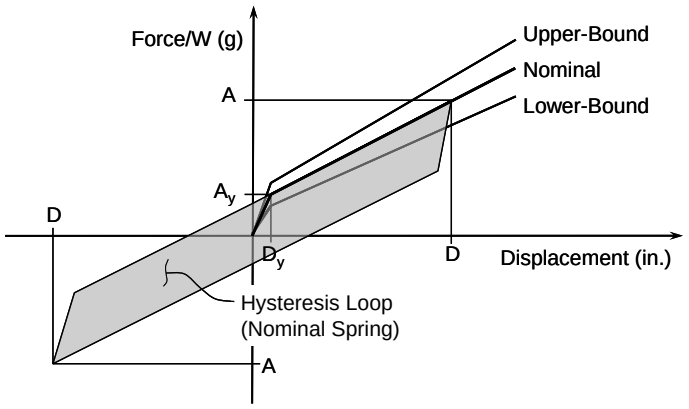

Figure 10-9 Example nominal, upper-bound and lower-bound bilinear springs and hysteretic properties used to model the isolation system.

Design of the isolation system is defined by the two control points, the "yield" point (D_y, A_y) and the post-yield point (D, A), located somewhere on the yielded portion of the curve. The resulting bilinear response is illustrated in Figure 10-9. The yield point represents the dynamic friction level of sliding bearings (e.g., FP bearings) and is closely related to the (normalized) characteristic strength of elastomeric bearings (e.g., lead-rubber or high-damping rubber bearings). The post-yield point is used simply to define the slope of yielded system (and the isolation system is assumed capable of displacing without failure beyond this point). The properties are assumed to be symmetric for positive and negative displacements.

Amplitude-dependent values of effective stiffness, k_{eff}, effective period, T_{eff} (in seconds), and effective damping, β_{eff}, of the isolation system may be calculated by the following equations:

$$k_{eff} = \frac{AW}{D} \tag{10-1}$$

$$T_{eff} = 2\pi \sqrt{\frac{D}{gA}} \tag{10-2}$$

$$\beta_{eff} = \frac{2}{\pi} \sqrt{\frac{A_y D - D_y A}{D A}} \tag{10-3}$$

Equations 10-1, 10-2, and 10-3 are consistent with the definitions of effective stiffness, k_{eff}, and effective damping, β_{eff}, of Section 17.8.5 of ASCE/SEI 7-05. In Section 17.8.5, these equations are used to determine the force-deflection characteristics of the isolation system from the tests of prototype isolators.

ASCE/SEI 7-05 defines two amplitude-dependent fundamental-mode periods for isolated structures based on secant stiffness, T_D, (effective period at the design displacement), and T_M, (effective period at the MCE displacement). Values of T_D and T_M are typically close together. Isolated systems are initially stiff (see Figure 10-9), but yield early and become very flexible, so this representation of period is different from conventional fixed-base structures, which use an estimation of initial stiffness for an "elastic" period.

The MCE fundamental-mode period, T_M, as defined by ASCE/SEI 7-05, is used for evaluation of seismic collapse performance of isolated structures in this study:

$$T_M = 2\pi \sqrt{\frac{W}{k_{Mmin}\, g}} \tag{10-4}$$

where:

T_M = effective period, in seconds, of the seismically isolated structure at the maximum displacement in the direction under consideration, as prescribed by Equation 17.5-4 of ASCE/SEI 7-05,

W = effective seismic weight of the structure above the isolation interface, as defined in Section 17.5.3.4 of ASCE/SEI 7-05, and

k_{Mmin} = minimum effective stiffness, in kips/in, of the isolation system at the maximum displacement in the horizontal direction under consideration, as prescribed by Equation 17.8-6 of ASCE/SEI 7-05.

Moat Wall Modeling

Nonlinear springs are used to represent the effects of impact with the moat wall when the seismic demand on the isolated system exceeds the clearance provided. The moat wall is represented by 5 symmetrical gap springs implemented in parallel as illustrated in Figure 10-10.

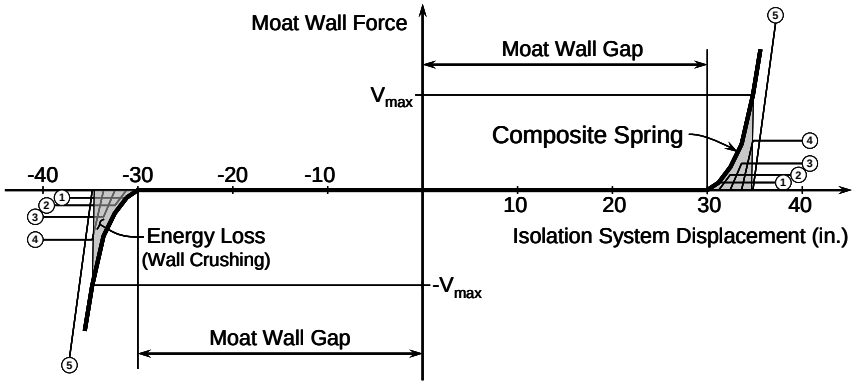

Figure 10-10 Five individual springs and effective composite spring used to model moat wall resistance for an example 30-inch moat wall gap.

Gap springs have zero force until the isolated structure reaches the moat wall, and then begin to resist further displacement of the isolated structure. The five springs engage sequentially to effect increasing stiffness and nonlinear resistance as the structure pushes into the moat wall. Gap springs are modeled as inelastic elements to account for energy loss due to localized crushing at the structure-wall interface. Gap spring properties are defined relative to the strength of the superstructure such that moat wall force is equal to the strength of the superstructure, V_{max}, at approximately 4 inches of moat wall displacement. (Note. A similar result could have been obtained using a more complicated force-displacement relationship and a single gap spring, depending on available models in software.)

Model Limitations

It should be noted that the models used in this study, and illustrated in Figure 10-9 and Figure 10-10, are relatively simplistic representations of isolated systems and neglect many complex aspects of isolator performance. Bilinear properties of the isolator neglect stiffening that may occur at large displacements, and reduction in characteristic strength that can occur for repeated cycles of loading. The isolation system model also neglects potential uplift at isolators (when overturning loads exceed gravity loads and isolator tension capacity). Local uplift of isolators is a potential failure mode, but permitted by Section 17.2.4.7 of ASCE/SEI 7-05 provided that "resulting deflections do not cause overstress or instability of isolator units or

other structure elements." Softening and damping loss due to heat effects in elastomeric bearings are not considered. Despite these limitations, the models represented in Figures 10-8, 10-9, and 10-10 are expected to give reasonable predictions of dynamic response and collapse performance, as well as relative differences in performance associated with variability in design parameters.

Uncertainty due to Model Quality

Model quality is rated as (B) Good for the purpose of assessing the composite uncertainty in the performance predictions of index archetype models with a reinforced concrete special moment frame superstructure, and (C) Fair for index archetype models with a reinforced concrete ordinary moment frame superstructure. These model quality ratings are the same as those assigned to the reinforced concrete frame examples in Chapter 9.

Since design of isolated structures require a nonlinear, building-specific model of the superstructure, the model of an isolated structure represents an individual building rather than one archetype within a performance group, as in the Chapter 9 examples. In addition, the isolation system filters out some higher-mode effects that contribute to collapse variability in fixed-base structures. Therefore, it may be possible for an isolated system to earn a better model rating than the constituent superstructure. However, in this study, the simplified modeling of isolators, such as neglecting cyclic changes to bearing properties, does not warrant better model quality ratings.

10.3.4 Design Properties of Isolated Structure Archetypes

Specific design properties of index archetype models in this study include isolation system properties, moat wall clearance and superstructure properties. The archetypes are selected to probe the effects of the critical design parameters on collapse performance. The goal of considering a wide variety of archetype configurations is to assess the validity of current code provisions. As such, archetypes are developed for both "Code-Conforming" systems that comply with ASCE/SEI 7-05 requirements, and "Non-Code-Conforming" systems that deviate from ASCE/SEI 7-05 requirements in terms of superstructure strength or ductility.

Isolation System Design Properties

Design properties of the isolation system are developed using the equations and design requirements of the Equivalent Lateral Force Procedure, Section 17.5 of ASCE/SEI 7-05. These equations provide a convenient basis for design and are commonly used for preliminary design and review of isolated structures.

This study considers archetype isolation systems that are representative of systems with either elastomeric rubber bearings (RB) or sliding friction pendulum (FP) bearings. Isolation systems are designed for either SDC D_{max} or SDC D_{min} seismic criteria (Site Class D). The response characteristics of isolation systems with either RB or FP bearings are sufficiently similar for strong (SDC D_{max}) ground motions to permit modeling both systems with the same set of bilinear springs properties (i.e., a single set of "generic" properties is used to represent both systems). Such is not the case for moderate (SDC D_{min}) ground motions, and different spring properties are used to model isolation systems with RB and FP bearings.

Nominal isolation system design properties for SDC D_{max} are given in Table 10-2 for the generic (GEN) system, and the RB system and FP system for SDC D_{min}. Upper and lower-bound spring properties are also given for the generic system. Only nominal properties are shown for the RB and FP systems in SDC D_{min} (although MCE design parameters still utilize upper-bound and lower-bound properties, as required by Section 17.5 of ASCE/SEI 7-05).

Table 10-2 also provides design values of the effective period, T_M, effective damping, β_M, and total maximum displacement, D_{TM}, for each system. For each archetype isolation system, design values of the yield and the post-yield control points are selected such that the corresponding values of maximum (MCE) displacement, D_M, effective period, T_M, effective stiffness, and effective damping, β_M, meet the following criteria:

- Values of D_M, T_M and β_M comply fully with the equations and requirements of Section 17.5 of ASCE/SEI 7-05.
- Values of effective stiffness and damping are consistent with actual isolation system properties (i.e. for isolations systems with either elastomeric or sliding bearings)[2].
- Values of effective stiffness and damping in the isolator reduce response such that forces required for design of the superstructure are approximately the same as the design base shear required for a conventional fixed-base system of the same type and configuration, so that models of code-compliant systems from Chapter 9 can be used for the superstructure (without re-design).

[2] The effective stiffness properties of rubber bearings represent a "low modulus" rubber compound and are assumed to be the same as those of friction pendulum bearings to limit the number of models. The corresponding effective period, T_M, is somewhat atypical of rubber bearing systems which generally have an effective period less than or equal to 3 seconds.

Calculation of D_{TM} was based on the Equivalent Lateral Procedure of Section 17.5 of ASCE/SEI 7-05. Total maximum displacement includes an additional 15 percent of torsional displacement, consistent with Equation 17.5-6 of ASCE/SEI 7-05 (assuming a square configuration of the building in plan):

$$D_{TM} = 1.15 D_M \tag{10-5}$$

Table 10-2 Isolation System Design Properties

Isolator Properties		Force-Deflection Curve				MCE Design Parameters		
		Yield Point		Post-Yield		T_M (sec)	β_M (% crit.)	D_{TM} (in.)
Type	Range	D_y (in)	A_y (g)	D (in)	A (g)			
Generic Elastomeric or Sliding Systems - D_{max} Designs								
GEN	Nominal	0.5	0.05	23.3	0.225	3.47	10.5%	29.3
GEN-UB	Upper-Bound	0.5	0.06	21.1	0.23			
GEN-LB	Lower-Bound	0.5	0.04	25.5	0.22			
Rubber (RB) or Friction Pendulum (FP) Systems - D_{min} Designs								
RB	Nominal	1.5	0.04	6.5	0.081	3.18	12.5%	8.5
FP	Nominal	0.1	0.04	4.2	0.072	2.78	28%	5.7

Isolation System Clearance

The performance of isolated structures may also be dependent on the clearance of the isolated system and Table 10-3 summarizes the moat wall clearance (gap) distances used in the archetype isolation systems. For the generic (GEN) isolation system (SDC D_{max} design), five different moat wall distances are used to investigate the effects of this parameter on collapse performance.

Moat wall clearance is based on a fraction of the total maximum displacement, D_{TM}, plus a little extra displacement for fit-up tolerance. Unless dynamic analysis can justify a smaller value, $1.0D_{TM}$ is the minimum clearance permitted by Section 17.5 of ASCE/SEI 7-05. For the generic system, moat wall gap displacements of $0.6D_{TM}$ and $0.8D_{TM}$ test the consequences of restricting isolation system displacement, and clearances of $1.2D_{TM}$ and $1.4D_{TM}$ evaluate the benefits of having extra clearance.

Moat wall clearance is influenced by site conditions (e.g., sloping site), building configuration and architectural features, but economic

considerations usually dictate design at or near the minimum required displacement, so that moat wall clearances between approximately $0.8D_{TM}$ and $1.0D_{TM}$ are typical (when the configuration has a moat wall). A moat wall clearance of $1.4D_{TM}$, or greater (42 inches in this study), is not common. ASCE/SEI 7-05 does not permit moat wall clearance less than $0.8D_{TM}$ unless the superstructure is explicitly evaluated for stability at MCE demand (which is not typically done).

Table 10-3 Summary of Moat Wall Clearance (Gap) Distances

Isolation System Properties			Moat Wall Gap Distance (inches)				
Type	Displacement (in.)		Approximate Fraction of Code Minimum				
	D_{TM}	Fit-up	0.6 D_{TM}	0.8 D_{TM}	1.0 D_{TM}	1.2 D_{TM}	1.4 D_{TM}
Generic Elastomeric or Sliding Systems - D_{max} Designs							
GEN	29.3	0.7	18	24	30	36	42
GEN-UB	29.3	0.7			30		
GEN-LB	29.3	0.7			30		
Rubber (RB) or Friction Pendulum (FP) Systems - D_{min} Designs							
RB	8.5	0.5			9		
FP	5.7	0.3			6		

Superstructure Design Properties

Isolated structure archetypes are grouped as Code-Conforming and Non-Code-Conforming archetypes on the basis of whether the superstructure meets code requirements for strength, ductility, and detailing. Code-Conforming archetypes include systems with reinforced concrete special moment frame superstructures that conform to all the design requirements of Chapter 17 of ASCE/SEI 7-05. Non-Code-Conforming archetypes include systems with superstructures that do not conform, either in terms of design strength, such as reinforced concrete special moment frame superstructures designed for less than the minimum required base shear, or in terms of ductility, such as reinforced-concrete ordinary moment frame superstructures not permitted for use as a SDC D system. In a few cases, the Non-Code-Conforming superstructures exceed code requirements.

Table 10-4 summarizes design properties for the 3 superstructures of Code-Conforming archetypes used in this study:

(C1) – A reinforced concrete special moment frame (perimeter frame) system, designed for base shear, $V_s = 0.092W$ ($R_I = 2.0$).

(C2) – A reinforced concrete special moment frame (space frame) system, designed for base shear, $V_s = 0.092W$ ($R_I = 2.0$).

(C3) – A reinforced concrete special moment frame (space frame) system, designed for base shear, $V_s = 0.077W$.

The first two systems (C1, C2) are superstructures of isolated archetypes designed for SDC D_{max} seismic criteria, and the last system (C3) is the superstructure of isolated archetypes designed for SDC D_{min} seismic criteria. The base shear of the last system is governed by the limit of Section 17.5.4.3 of ASCE/SEI 7-05, which requires the base shear, V_s, not be less than 1.5 times either the "yield level" of an elastomeric system or the "breakaway" friction level of a sliding system. In this case, the base shear ($V_s = 0.077W$) is approximately equal to 1.5 times 0.05, the upper-bound yield level of systems designed for SDC D_{min} seismic criteria with either RB or FP bearings.

Table 10-4 Isolated Structure Design Properties for Code-Conforming Archetypes

Arch. ID	Isolated Structure Archetype Design Properties						
	Superstructure			Isolation System		Isolated Structure	
	V_s/W	Ω	V_{max}/W	Type	Gap (in.)	T_M (sec.)	S_{MT} (g)
Reinforced Concrete Special Moment Frame Perimeter Systems Evaluated at D_{max}							
C1-1	0.092	1.6	0.15	GEN	18	3.47	0.26
C1-2	0.092	1.6	0.15	GEN	24	3.47	0.26
C1-3	0.092	1.6	0.15	GEN	30	3.47	0.26
C1-4	0.092	1.6	0.15	GEN	36	3.47	0.26
C1-5	0.092	1.6	0.15	GEN	42	3.47	0.26
Reinforced Concrete Special Moment Frame Space Frame Systems Evaluated at D_{max}							
C2-1	0.092	3.3	0.30	GEN	18	3.47	0.26
C2-2	0.092	3.3	0.30	GEN	24	3.47	0.26
C2-3	0.092	3.3	0.30	GEN	30	3.47	0.26
C2-4	0.092	3.3	0.30	GEN	36	3.47	0.26
C2-5	0.092	3.3	0.30	GEN	42	3.47	0.26
C2-3U	0.092	3.3	0.30	GEN-UB	30	3.47	0.26
C2-3B	0.092	3.3	0.30	GEN-LB	30	3.47	0.26
Reinforced Concrete Special Moment Frame Space Frame Systems Evaluated at D_{min}							
C3-1	0.077	3.7	0.28	RB	9	3.18	0.09
C3-2	0.077	3.7	0.28	FP	6	2.78	0.11

The Code-Conforming archetypes include systems that meet all code requirements for the superstructures (C1, C2 and C3). Isolation system design meets all code requirements with the exception that moat wall gap distances in C1-1, C1-2, C2-1 and C2-2, would typically not meet code requirements unless special stability analyses were performed.

Table 10-5 summarizes the design properties of the Non-Code-Conforming Archetypes. These isolated structures evaluate the effects of modifying code requirements for (a) superstructure strength and (b) superstructure ductility. Variation in superstructure strength includes some structures, such as NC1, that exceed code strength requirements, while others, such as NC2, do not meet code strength requirements.

Table 10-5 Isolated Structure Design Properties for Non-Code-Conforming Archetypes

Arch. ID	Isolated Structure Archetype Design Properties						
	Superstructure			Isolation System		Isolated Structure	
	V_s/W	Ω	V_{max}/W	Gap (in.)	Type	T_M (sec.)	S_{MT} (sec.)
Reinforced Concrete Special Moment Frame Space Frame Systems Evaluated at D_{max}							
NC1-1	0.164	2.8	0.46	18	GEN	3.47	0.26
NC1-2	0.164	2.8	0.46	24	GEN	3.47	0.26
NC1-3	0.164	2.8	0.46	30	GEN	3.47	0.26
NC1-4	0.164	2.8	0.46	42	GEN	3.47	0.26
NC2-1	0.046	5.2	0.24	18	GEN	3.47	0.26
NC2-2	0.046	5.2	0.24	24	GEN	3.47	0.26
NC2-3	0.046	5.2	0.24	30	GEN	3.47	0.26
NC2-4	0.046	5.2	0.24	42	GEN	3.47	0.26
Reinforced Concrete Ordinary Moment Frame Space Frame Systems Evaluated at D_{max}							
NC3-1	0.246	1.9	0.47	30	GEN	3.47	0.26
NC3-2	0.246	1.9	0.47	42	GEN	3.47	0.26
NC4-1	0.164	1.8	0.30	30	GEN	3.47	0.26
NC4-2	0.164	1.8	0.30	42	GEN	3.47	0.26
NC5-1	0.092	1.9	0.17	30	GEN	3.47	0.26
NC5-2	0.092	1.9	0.17	42	GEN	3.47	0.26

While reinforced concrete ordinary moment frame systems from Chapter 9 are used for the purpose of investigating the effects of superstructure ductility, it should be noted that ASCE/SEI 7-05 does not permit isolated systems with a reinforced concrete ordinary moment frame superstructure in

regions of high seismicity. The 2006 IBC does, however, allow isolation systems with either a steel ordinary moment frame or steel OCBF (braced frame) in regions of high seismicity when designed in accordance with AISC 341-05 and $R_I = 1.0$.

10.3.5 Nonlinear Static Analysis for Period-Based Ductility, SSFs, Record-to-Record Variability and Overstrength

The Methodology requires a nonlinear static (pushover) analysis to determine the overstrength of the archetype and to evaluate values of period-based ductility ($\mu_T = \delta_u/\delta_{y,eff}$) for determining the spectral shape factor, *SSF*, and, in certain instances, record-to-record variability, β_{RTR}. Although the overstrength parameter, Ω_0, is not used in isolation design, pushover analysis provides a useful tool for evaluating the strength of the superstructure relative to the level of lateral force in the isolation system.

Pushover Analysis of Isolated Systems

Nonlinear static analysis is performed on isolated structures with the isolation system free to displace. Pushover forces are based on a uniform pattern of lateral load emulating the approximate pattern of uniform lateral displacement of the isolated structure (at displacements up to significant yielding of the superstructure). Figure 10-11 illustrates results of nonlinear static analysis for an isolated structure and for the same superstructure on a fixed-base.[3] Approximately the same ultimate strength is obtained from the two analyses, but the isolated structure effectively shares system ductility between displacement of the isolation system and displacement of the superstructure.

It is also noted that pushover analysis of isolated systems is performed without the moat wall springs (as the sudden increase in stiffness associated with the moat wall is inconsistent with the assumptions used in developing the relationship between μ_T and *SSF* in Appendix B).

Superstructure Overstrength Properties

A static pushover analysis of each of the archetype superstructures listed in Table 10-3 and Table 10-4 was performed to determine the actual maximum strength, V_{max}, and to compare actual strength with design strength, V_s. Values of normalized design strength (V_s/W) and normalized maximum strength (V_{max}/W) are plotted in Figure 10-12.

[3] Nonlinear static analysis of the fixed-base structure is based on the lateral load pattern prescribed by Equation 12.8-13 of ASCE/SEI 7-05.

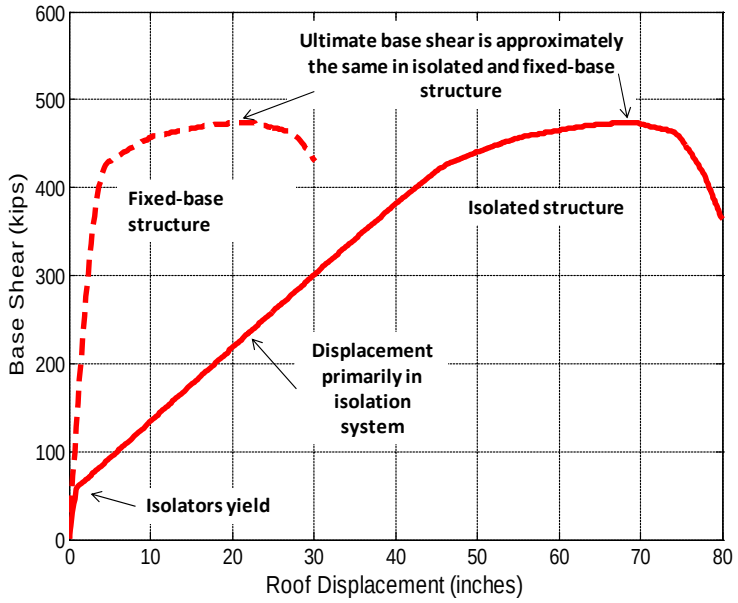

Figure 10-11 Pushover curves of a non-code-conforming isolated structure (NC1) and the same superstructure on a fixed base.

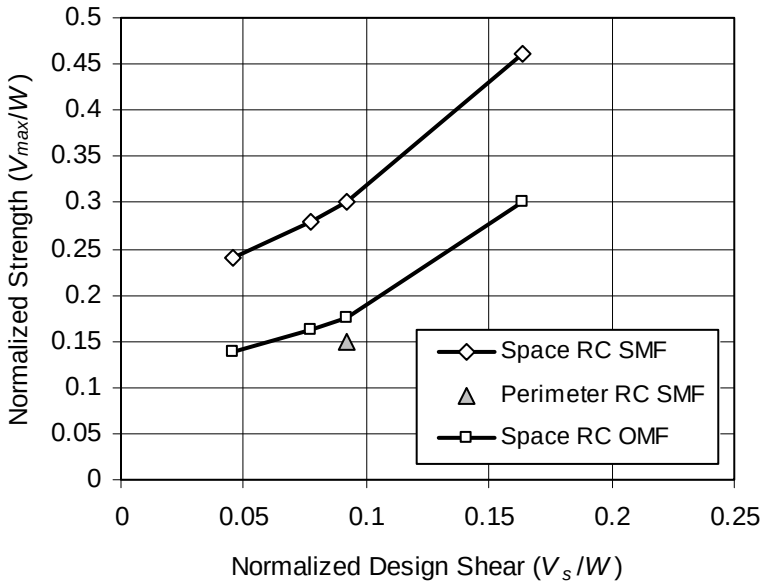

Figure 10-12 Normalized design shear (V_s/W) and maximum strength (V_{max}/W) of superstructures.

As Figure 10-12 shows, the maximum strength of the superstructure is system dependent and does not decrease in proportion to design base shear. When designed with a base shear of 0.092*W*, the perimeter reinforced concrete special moment frame has an ultimate strength 0.15*W*, the space reinforced concrete special moment frame has an ultimate strength of 0.30*W* and the space reinforced concrete ordinary moment frame has an ultimate strength of 0.17*W*. Space frames typically have higher overstrength (relative

to the design lateral load) than perimeter frames due to the higher contribution of gravity loads in space frame designs. Reinforced concrete ordinary moment frame systems typically have lower overstrength because of a lack of capacity-design provisions. The relative strength of the superstructure and isolation system can have a significant influence on the performance of isolated structures under extreme loading.

System Period-Based Ductility and Spectral Shape Factor (SSF)

Pushover analysis of the isolated system (including both isolator and superstructure) is used for determining period-based ductility, $\mu_T = \delta_u/\delta_{y,eff}$, for computation of the *SSF*. The calculation of μ_T is illustrated in Figure 10-13.

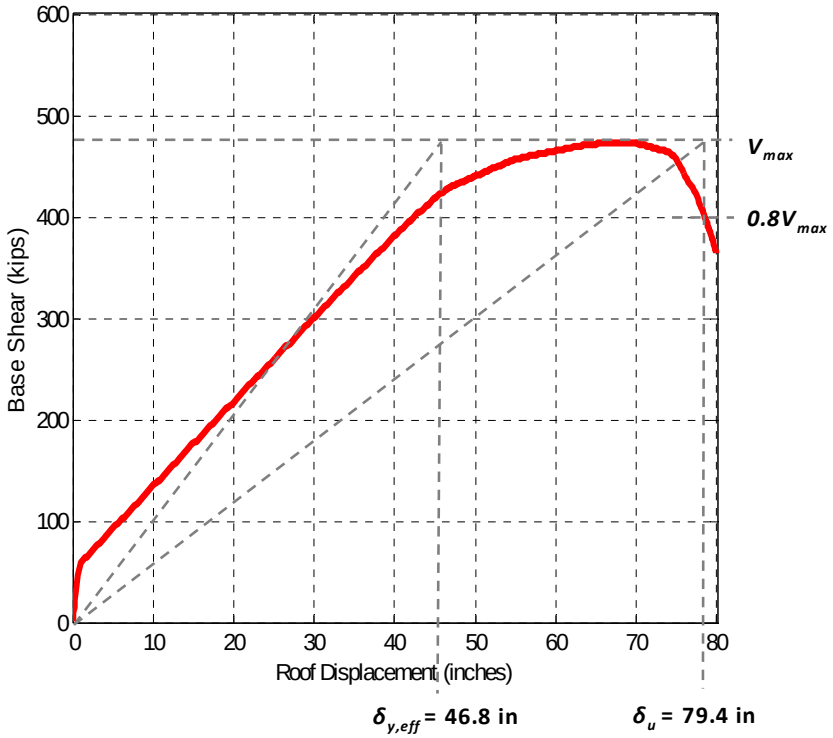

Figure 10-13 Illustration of calculation of period-based ductility, μ_T, for isolated system NC-1, where $\mu_T = \delta_u/\delta_{y,eff}$.

Calculation of the effective yield roof drift displacement, $\delta_{y,\text{eff}}$, for base isolated systems is given by the formula:

$$\delta_{y,eff} = \frac{V_{\max}}{W}\left[\frac{g}{4\pi^2}\right]T_M^2 \qquad (10\text{-}6)$$

which is based on Equation 6-7 for values of the modal coefficient, $C_0 = 1.0$ and fundamental period, $T = T_1 = T_M$. The modal coefficient, C_0, is defined by Equation 6-8 and generally has values near unity for isolated structures

with roof drift displacement dominated by lateral displacement of the isolation system displacement. In the limiting case of roof drift displacement equal to isolation system displacement (i.e., no drift in the superstructure), the ultimate roof drift displacement, δ_u, would be equal to the effective yield roof drift displacement, $\delta_{y,\text{eff}}$.

Due to inherent flexibility in isolated systems, period-based ductility is smaller for base isolated systems than for fixed base systems because base isolated systems have a larger effective yield roof drift displacement, $\delta_{y,\text{eff}}$, relative to the ultimate roof displacement, δ_u. For fixed-base special moment frames in SDC D_{max}, μ_T is approximately equal to 11, whereas for isolated special moment frames, μ_T ranges between 1.4 and 2.5. The period-based ductility values obtained in this study are relatively large due to the flexibility of reinforced concrete frame superstructures. Typically, isolated buildings would not have as much displacement in the superstructure.

Record-To-Record Uncertainty (β_{RTR})

For most conventional (fixed-base) structures, the period-based ductility, μ_T is greater than or equal to 3.0, and record-to-record variability, β_{RTR}, is equal to 0.40. Isolated systems have limited period-based ductility (i.e., $\mu_T \leq 3.0$), and Equation 7-2 is used to calculate β_{RTR} for these systems. Values of β_{RTR} calculated for base isolated systems using Equation 7-2 range from 0.24 to 0.35, with an average value of 0.27.

Values of *SSF* and β_{RTR} for isolated systems were computed in accordance with Table 7-1 and Equation 7-2, respectively, which were derived for conventional fixed-base structures. The resulting values of *SSF* and β_{RTR} showed good agreement with values of spectral shape adjustment and record-to-record variability obtained directly from collapse assessment of isolated systems.

10.3.6 Collapse Evaluation Results

Evaluation Process and Acceptance Criteria

The base isolated systems listed in Tables 10-4 and 10-5 are analyzed and evaluated, as described in Chapter 5 through Chapter 7. Nonlinear dynamic analyses are used with the Far-Field record set to determine the median spectral acceleration at which the structure collapses ($\hat{S}_{CT}$). The collapse margin ratio, *CMR*, is computed as the ratio of the median collapse capacity, $\hat{S}_{CT}$, and the MCE demand, S_{MT}. These results are reported in Tables 10-6 and 10-7.

Note that for base isolated reinforced concrete ordinary moment frames, *CMR* accounts for both the sidesway simulated collapse modes and non-simulated column shear failure modes not included in simulation models. Collapse due to column shear failure is predicted when the column loses its vertical-load-carrying capacity, on the basis of component fragility functions as described in Chapter 9. Section 10.2 describes the procedure for incorporating non-simulated failure modes.

Acceptance criteria are based on the adjusted collapse margin ratio (*ACMR*) which is the *CMR* modified by the spectral shape factor, *SSF*, to account for the unique spectral shape of rare ground motions. The computed values of period-based ductility, μ_T, for base isolated systems are reported in Table 10-6 and Table 10-7. The spectral shape factor is determined from Table 7-1 as a function of μ_T and building period ($T > 1.5$ seconds for all the isolated systems).

The composite (total) uncertainty, β_{TOT}, associated with collapse must be assessed in order to compare the *ACMR* to the acceptance criteria. Isolated archetypes with ductile (reinforced concrete special moment frame) superstructures are assigned ratings of (B) Good for modeling, (B) Good for test data, and (A) Superior for design requirements. The isolated archetypes with non-ductile (reinforced concrete ordinary moment frame) superstructures have ratings of (C) Fair for modeling, (B) Good for test data, and (A) Superior for design requirements.

For isolated structures, which have limited period-based ductility (i.e., $\mu_T < 3.0$), record-to-record variability, β_{RTR} , is calculated using Equation 7-2. Values of record-to-record variability range from 0.2 to 0.3 for the isolated archetypes of this study. These smaller values are supported by a special study on record-to-record variability described in Appendix A.

Record-to-record variability is combined with other sources of uncertainty (i.e., modeling, test data and design requirements, respectively) to determine total composite uncertainty, β_{TOT}, in accordance with Equation 7-5. For the isolated systems considered, β_{TOT} ranges from 0.375 to 0.475. The acceptable *ACMR* in Chapter 7 will depend on the total uncertainty for each isolated system archetype.

Since design of isolated structures is based on building-specific testing and evaluation, archetype systems are not grouped into performance groups in this study. Instead, each archetype is evaluated individually in comparison with the acceptable *ACMR*. In judging acceptability of each isolation system archetype, the computed *ACMR* is compared to the acceptable *ACMR*

associated with a 10% probability of collapse, $ACMR_{10\%}$. The use of the 10% criteria for evaluating the performance of an individual building is consistent with recommendations contained in Appendix F.

Collapse Results for Code-Conforming Archetypes

Collapse results for the Code-Conforming base isolation system archetypes are tabulated in Table 10-6a, Table 10-6b, and Table 10-6c.

Table 10-6a Collapse Results for Code-Conforming Archetypes: Various Gap Sizes

Arch. No.	Gap Size (in.)	Computed Collapse Margin Ratio				Acceptable *ACMR*	
		CMR	μ_T	*SSF*	*ACMR*	β_{TOT}	$ACMR_{10\%}$
Perimeter Reinforced Concrete Special Moment Frame Systems Evaluated at D_{max}

Table 10-6c Collapse Results for Code-Conforming Archetypes: Minimum Seismic Criteria (SDC D_{min})

Arch. No.	Isolator Props.	Computed Collapse Margin Ratio				Acceptable *ACMR*	
		CMR	μ_T	*SSF*	*ACMR*	β_{TOT}	$ACMR_{10\%}$
Reinforced Concrete Special Moment Frame Space Frame Systems Evaluated at D_{max} - 30-inch Gap							
C3-1	RB	4.01	1.94	1.15	4.60	0.425	1.72
C3-2	FP	4.86	2.54	1.18	5.75	0.475	1.84

Comparison of computed and acceptable values of the *ACMR* reveals that the code-conforming base isolation systems all easily meet the acceptance criteria in this Methodology. The perimeter frame system (C1) has consistently smaller *ACMR*s than the space frame system (C2) due to the smaller lateral overstrength inherent in perimeter frame systems. This study indicates that base isolated systems have comparable levels of safety to code-conforming, conventional fixed-base structures.

Results summarized in Table 10-6a and plotted in Figure 10-14 illustrate the effect of the moat wall clearance distance or gap size. The smallest gap sizes (18 in. and 24 in.) would generally not be allowed by Chapter 17 of ASCE/SEI 7-05, and are not code-compliant. These results are included for comparison purposes only. It is noted, however, that even systems with moat clearances less than the code minimum are acceptable according to the collapse criteria of the Methodology. There may be some benefit to increasing the gap size even beyond 30 inches in SDC D_{max}. This benefit is especially apparent for the space frame systems, which have sufficient overstrength to avoid significant nonlinear behavior even when the forces in the isolator are large. These results indicate that the code criteria for base isolated systems are adequate, and may be conservative in the case of moat wall clearance criteria for structures that have sufficient overstrength.

As shown in Table 10-6b, variation in isolator properties does not have a significant effect on the computed collapse margin ratio. Variation in isolator properties is based on ASCE/SEI 7-05 Section 17.8.4.3, which specifies that there not be more than a 20% change in initial stiffness during testing of a prescribed range of prototypes. This variation is not intended to account for differences between modeled and actual behavior, such as softening and damping loss due to heating effects. When upper-bound (GEN-UB) and lower-bound (GEN-LB) isolator properties are used, *ACMR*s are very close to the results for the nominal properties (GEN).

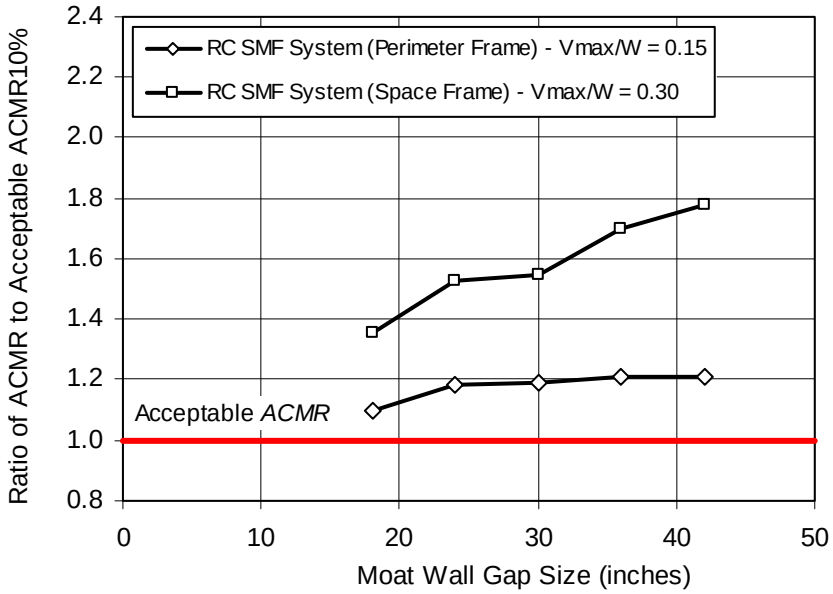

Figure 10-14 Ratios of computed *ACMR* to acceptable $ACMR_{10\%}$ for reinforced concrete special moment frame Code-Conforming isolated archetypes with various moat wall gap sizes, evaluated for SDC D_{max} seismic criteria.

Whereas Tables 10-6a and 10-6b report collapse margins evaluated for SDC D_{max} seismic criteria, Table 10-6c reports collapse margin ratios computed for RB and FP systems in SDC D_{min}. As observed in Chapter 9, the collapse margins tend to increase as the seismic criteria decreases such that *ACMR*s in Table 10-6c are large, and high seismic criteria (SDC D_{max}) govern the acceptability of this system.

Collapse Results for Non-Code-Conforming Archetypes

Collapse results for the Non-Code-Conforming isolation archetypes are summarized in Tables 10-7a and 10-7b. Computed *CMR*s include both simulated and non-simulated failure modes for the reinforced concrete ordinary moment frame structures.

In this study, Non-Code-Conforming archetypes are systems that violate or exceed certain code provisions in order to examine the effects of superstructure strength (i.e., superstructures designed for a higher or lower base shear than required according to ASCE/SEI 7-05) and superstructure ductility (i.e., superstructures designed as ordinary moment frames without the ductile detailing requirements for special moment frame systems). All results in this section are for SDC D_{max}.

Table 10-7a Collapse Results for Isolated Archetypes with Ductile Superstructures and Normalized Design Shear Values (V_s/W) Not Equal to the Code-Required Value (V_s/W = 0.092)

Arch. No.	Gap Size (in.)	Computed Collapse Margin Ratio				Acceptable *ACMR*	
		CMR	μ_T	*SSF*	*ACMR*	β_{TOT}	$ACMR_{10\%}$

NC5-2	42	1.27	1.89	1.22	1.55	0.500	1.90

The effect of superstructure strength is demonstrated by the *ACMR* results shown in Table 10-7a. Figure 10-15 shows trends in the ratio of calculated *ACMR* to acceptable $ACMR_{10\%}$. For a reinforced concrete special moment frame space frame (NC1-3) with a design base shear of V_s/W = 0.164 (above Code minimum) and gap size of 30 inches, the computed *ACMR* is 2.57, a factor of approximately 1.7 times the limit on acceptable *ACMR*. When the design base shear is V_s/W = 0.092 (C1-3), the minimum value required by

ASCE/SEI 7-05, the computed *ACMR* is slightly smaller, approximately 1.6 times the limiting *ACMR*. For a smaller design base shear, $V_s/W = 0.046$ (NC2-3), below Code minimum, the computed *ACMR* is 1.5 times the limiting *ACMR*. These results suggest that a large difference in the design base shear (varying between 0.046 and 0.164 times the weight of the structure) has only a modest impact on the collapse results.

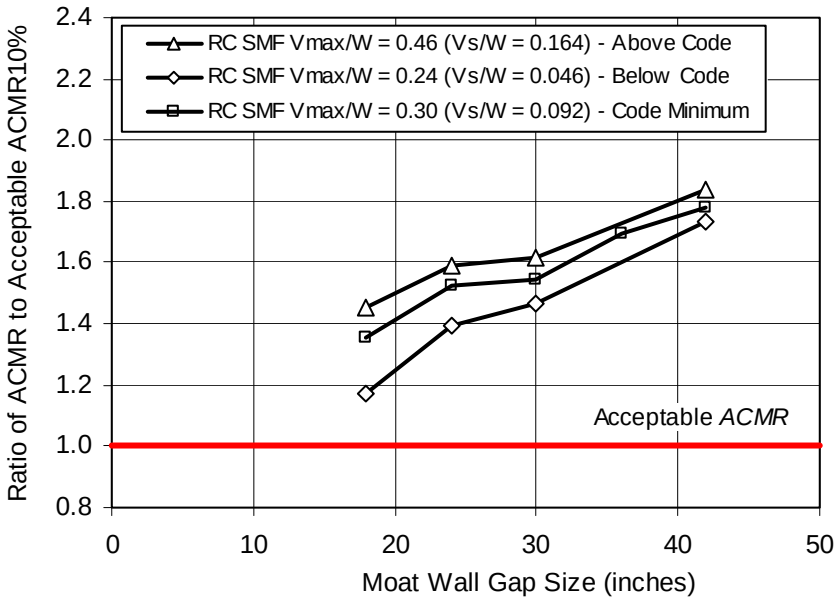

Figure 10-15 Ratios of computed *ACMR* to acceptable $ACMR_{10\%}$ for reinforced concrete special moment frame isolated archetypes with various superstructure strengths and moat wall gap sizes, evaluated for SDC D_{max} seismic criteria

The reason the design base shear does not have a greater impact on the *ACMR* is that the maximum strength of these structures is not linearly related to the design base shear (as shown in Figure 10-12). The design rules for special moment frame systems require capacity design and strong-column-weak-beam requirements such that the actual strength is much larger than the design strength, particularly for space frame systems which have significant gravity loads providing additional overstrength. As a result, the structure designed with $V_s/W = 0.046$ has a true strength of $V_{max}/W = 0.24$, accounting for its high collapse capacity. These observations indicate that the maximum strength of the structure (V_{max}/W) is a much better indicator of collapse performance of isolated structures than the base shear used for design of the superstructure (V_s/W).

Figure 10-16 shows the assessed collapse performance of reinforced concrete special moment frame and reinforced concrete ordinary moment frame isolated archetypes as a function of the strength of the superstructure

(V_{max}/W). These isolated systems have a peak MCE response of approximately 0.25 g. Reinforced concrete special moment frame archetypes that have a superstructure strength greater than 0.25 g have approximately the same *ACMR* (as indicated by flattening of the curves with increasing strength). For lower strength values, systems with less strength have progressively lower values of *ACMR*. Due to their ductility, reinforced concrete special moment frame systems with superstructure strength that is significantly less than the MCE demand meet the acceptance criteria of the Methodology.

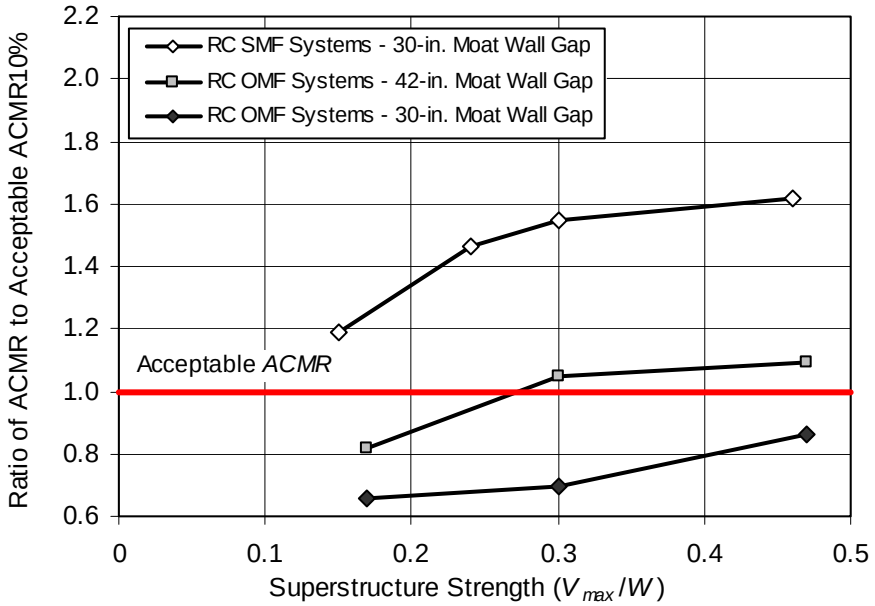

Figure 10-16 Ratios of computed *ACMR* to acceptable $ACMR_{10\%}$ for reinforced concrete special moment frame and reinforced concrete ordinary moment frame isolated archetypes with different superstructure strengths, evaluated for SDC D_{max} seismic criteria.

The isolated archetypes in Table 10-7b are all reinforced concrete ordinary moment frame systems, which are not permitted for use in regions of high seismicity (SDC C and D) by Table 12.2-1 of ASCE/SEI 7-05. The collapse results for reinforced concrete ordinary moment frame systems are shown in Figure 10-16 as a function of superstructure strength, and Figure 10-17 as a function of moat wall gap size.

Only two of the reinforced concrete ordinary moment frame systems in Table 10-7b are found to have acceptable collapse performance. This result indicates that certain less-ductile superstructures may not provide adequate collapse safety for isolated buildings, even with large moat wall clearance. However, isolated buildings with strong superstructures (e.g., significant overstrength), and large moat wall clearances, do have acceptable collapse

performance (as indicated by archetypes NC3-2 and NC4-2), even when the superstructures are less ductile.

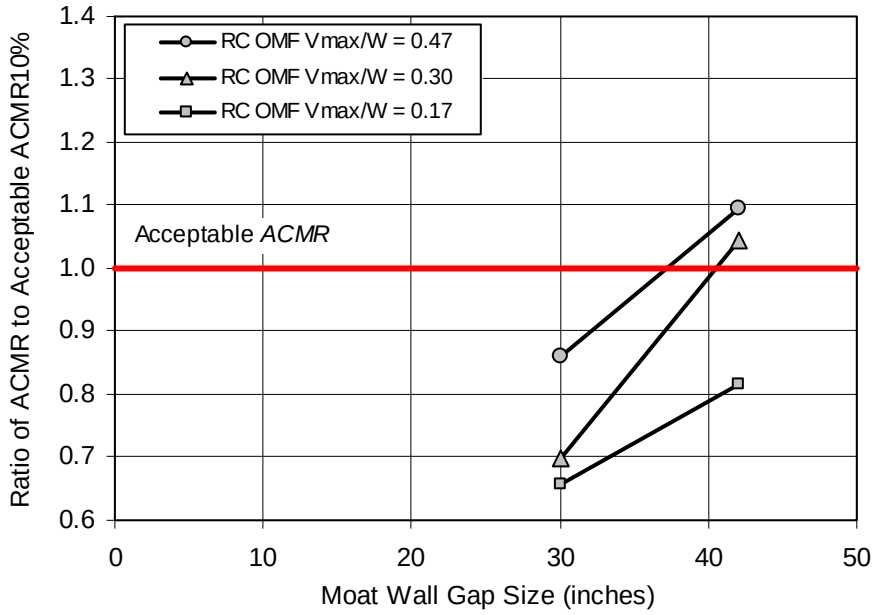

Figure 10-17 Ratios of computed *ACMR* to acceptable $ACMR_{10\%}$ for reinforced concrete ordinary moment frame isolated archetypes with various moat wall gap sizes, evaluated for SDC D_{max}

Reinforced concrete ordinary moment frame systems that fail to meet the acceptance criteria (NC3-1, NC4-1, NC5-1 and NC5-2) have *ACMRs* between 15% and 35% lower than the minimum acceptable value. Increasing the moat wall clearance, increasing superstructure strength, or improving the ductility of ordinary moment frame superstructures would likely improve their performance sufficiently to meet the acceptance criteria. Where large moat wall clearance is provided (e.g., 42 inches), analyses suggest that reinforced concrete ordinary moment frame systems with superstructure strength V_{max}/W greater than approximately 0.25 g would be acceptable. For smaller moat wall clearances, a significantly stronger or more ductile structure would be required (see Figure 10-16). This study also did not investigate the use of less ductile systems for lower levels of seismicity (e.g., SDC D_{min}), where superstructure strength and ductility demands are lower.

The effect of reinforced concrete ordinary moment frame superstructure ductility on collapse performance can be investigated by examining how the seismic performance of isolated reinforced concrete ordinary moment frame systems change if design rules are modified such that brittle shear failure of columns is prevented. Assuming all other design requirements remain unchanged, *ACMR*s for these structures are recalculated assuming brittle shear failure of columns is prevented. Results are plotted in Figure 10-18.

On average, preventing column shear failure in these example archetypes increased *ACMRs* by 25%. Figure 10-18 shows that this design change is sufficient to improve the collapse performance of reinforced concrete ordinary moment frame systems with a 30-inch gap such that the calculated *ACMRs* meet (or nearly meet) the acceptability criteria of the Methdology.

These results suggest the desirability of a comprehensive study of limited ductility systems on isolators, as collapse performance depends on superstructure design rules. A more detailed examination of base isolated reinforced concrete ordinary moment frame systems may also be warranted with shear failure and post-shear failure degradation incorporated directly into the models (rather than using non-simulated failure modes).

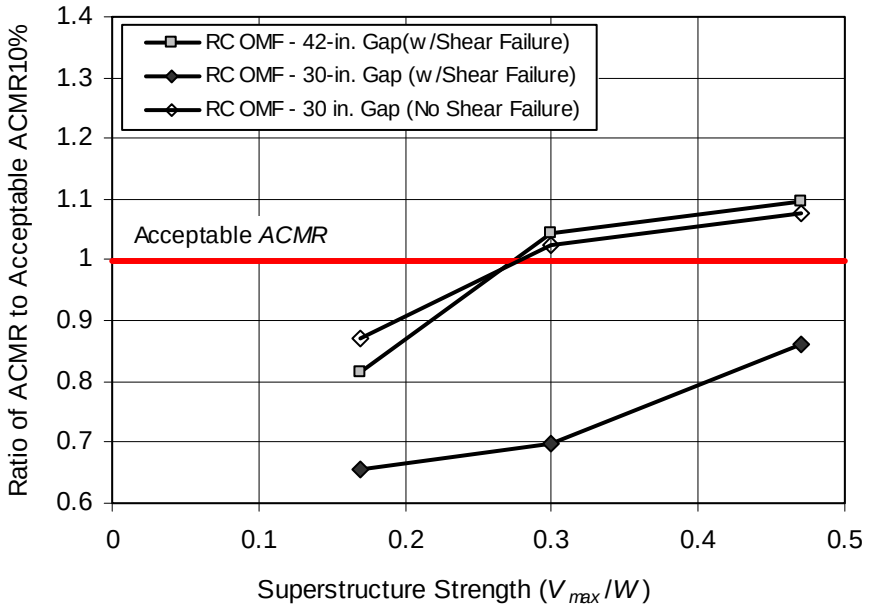

Figure 10-18 Ratios of computed *ACMR* to acceptable $ACMR_{10\%}$ for reinforced concrete ordinary moment frame isolated archetypes with various moat wall gap sizes, evaluated for SDC D_{max}, illustrating the effect of column shear failure on assessed collapse performance.

10.3.7 Summary and Conclusion

This study illustrates application of the Methodology to isolated structures, which have fundamentally different dynamic response characteristics, performance properties and collapse failure modes than those of conventional, fixed-base structures. It demonstrates that, when evaluated in accordance with the Methodology, base isolated systems provide levels of safety against collapse that are comparable to conventional, fixed-base structures. When compared to conventional structures, the major benefit of

isolating structures is in reduced earthquake damage and loss, but these effects have not been quantified in this study.

This study also demonstrates the potential use of the Methodology as a tool for assessing validating and developing improvements to current design requirements, in this case requirements for isolated structures. In particular, the Methodology can be used to investigate and possibly improve on apparent conservatisms or limitations for isolated structures related to the following:

Superstructure Design Strength. Performance of isolated structures is much more closely related to the "true" maximum strength, V_{max}, than the design strength, V_s, of the superstructure due to inherent differences in the overstrength of different systems (and designs). For systems with high inherent overstrength, such as the special space frame designs, low design base shears can be used. Other systems with less overstrength may behave differently when isolated. Design base shear requirements of ASCE/SEI 7-05 may be conservative for highly ductile structures which have large amounts of inherent overstrength. Rather than relying on generic values of the R_I factor (and unknown amounts overstrength), to define design strength, the Methodology could be used to establish appropriate criteria for design based on maximum strength, verified by pushover analysis.

Less Ductile (Non-Complying) Superstructures. In a similar process, the Methodology could also be used to establish appropriate levels of true strength for less ductile (non-complying) systems not currently permitted for use with isolated buildings in high seismic regions. While the process would be the same, true strength required for design of less ductile systems would likely be significantly higher than that required for more ductile systems to achieve the same acceptable level of collapse performance.

Moat Wall Gap Clearance (Displacement Restraint System). In the case of moat wall clearance, superstructures with sufficient strength and ductility were observed to be relatively insensitive to the size of the clearance. This suggests that moat wall clearance requirements of ASCE/SEI 7-05 might be conservative for highly ductile superstructures. The Methodology could be used to design isolation systems with limited displacement capacity for less intense, more common, earthquake ground motions. If the moat wall or other displacement restraint mechanism is used to limit excessive displacement of isolators for rare (MCE) ground motions, isolators could then be smaller and more economical, and provide a more practical solution in regions of very high seismic demands.

Chapter 11

Conclusions and Recommendations

This recommended Methodology provides a rational basis for establishing global seismic performance factors (SPFs), including the response modification coefficient, *R* factor, the system overstrength factor, Ω_0, and the deflection amplification factor C_d of new seismic-force-resisting systems proposed for inclusion in model building codes. The Methodology also provides a more reliable basis for re-evaluation of seismic performance factors of seismic-force-resisting systems currently available in model building codes and reference standards.

This chapter describes assumptions and limitations of the Methodology, summarizes observations and conclusions resulting from its development, discusses an adaptation of the Methodology to collapse performance evaluation for an individual building, and provides recommendations for further study.

11.1 Assumptions and Limitations

The Methodology is intended to apply broadly to all buildings, recognizing that this objective may not be fully achieved for certain seismic environments and building configurations. Likewise, the Methodology has incorporated certain simplifying assumptions deemed appropriate for reliable evaluation of seismic performance. Key assumptions and potential limitations of the Methodology are summarized in the following sections.

11.1.1 Far-Field Record Set Ground Motions

The Methodology specifies the same set of ground motions (i.e., Far-Field record set) for collapse performance evaluation of all systems. Records of the Far-Field record set are unambiguously defined (including scaling) to avoid any subjectivity in the ground motions used for nonlinear dynamic analyses. The Far-Field record set is a robust sample of strong motion records from large magnitude events. Even so, these records have inherent limitations for certain buildings.

Buildings at Sites near Active Faults

Two sets of ground motion data, the Far-Field record set (records at sites at least 10 km from fault rupture) and the Near-Field record set (records at sites within 10 km of fault rupture) were developed. An internal study, documented in Appendix A, found that the collapse margin ratio, *CMR*, was somewhat smaller for a system designed for "near-fault" (SDC E) seismic criteria, and evaluated using the Near-Field record set, than for same system designed for SDC D seismic criteria, and evaluated using the Far-Field record set. This implies that somewhat smaller values of the response modification coefficient, *R*, would be appropriate for design of buildings near active faults.

Various alternatives were considered, including the development of a separate set of seismic performance factors for design of buildings near active faults. For simplicity, as well as consistency with ASCE/SEI 7-05, a single set of seismic performance factors based on collapse assessments using the Far-Field record set was chosen. In so doing, the Methodology implicitly accepts somewhat greater life safety risk for buildings located close to active faults. This is consistent with the approach in ASCE/SEI 7-05, which implicitly accepts somewhat greater life safety risk for buildings near active faults by limiting MCE ground motions to deterministic values of seismic hazard.

Although the Methodology uses the Far-Field record set to establish seismic performance factors for a new seismic-force-resisting systems, the Near-Field record set would be more appropriate for verifying life safety performance of an individual building located near an active fault.

Buildings at Sites in the Central and Eastern United States or Subject to Deep Subduction Earthquakes

The Far-Field record set is a robust sample of all strong motion records from large magnitude events recorded at sites greater than 10 km from fault a rupture. No attempt was made to limit records based on tectonic setting or fault mechanism during the record selection process. The Far-Field record set is dominated by shallow crustal earthquakes, representative of areas in the Western United States. It does not include strong motions records from deep subduction earthquakes, or from Central and Eastern United States earthquakes, since such records do not exist.

Duration of strong shaking is an important parameter in collapse analyses of degrading systems, and strong motion records were purposely selected from large magnitude events to adequately capture shaking duration. Very large

magnitude earthquakes associated with deep subduction zone events would be expected to have longer durations of strong shaking, on average. Central and Eastern United States events could have different shaking characteristics also affecting the collapse margin ratio and related seismic performance factors. In spite of limitations in available deep subduction zone, or Central and Eastern United States earthquake records, actual earthquake records, rather than artificial or theoretical ground motions, were selected as the basis for collapse assessment.

Buildings with Very Long Periods

The usefulness of earthquake records at very long periods is limited by the ability of strong motion instruments to accurately record long-period vibration. Records from older instruments may only be accurate to one or two seconds, while records from the newer instruments are typically accurate to at least 10 seconds. The Far-Field and Near-Field record sets include only those records deemed accurate to a period of at least 4 seconds by the agency responsible for processing the record. Most records in these sets are accurate to a period of at least 10 seconds.

The Methodology conservatively limits the elastic period of index archetype configurations to a period not greater than 4 seconds to ensure valid evaluations of collapse performance. Records from the Far-Field and Near-Field record sets should be used with caution to evaluate collapse performance of buildings with elastic periods greater than 4 seconds (i.e., very tall buildings), since the spectral content of some records may not be valid, and the associated value of the spectral shape factor, *SSF*, may be overstated by the Methodology.

11.1.2 Influence of Secondary Systems on Collapse Performance

The Methodology evaluates collapse performance of the seismic-force-resisting system, ignoring the influence of secondary systems, such as gravity systems and nonstructural components, which are not included in the designation of the seismic-force-resisting system. Such systems can either improve or diminish the collapse performance of a system of interest.

Potential for Improved Performance

For many buildings, elements of the gravity or nonstructural systems can significantly improve collapse performance by providing additional resistance to lateral forces. This is particularly true when the secondary system has a larger lateral capacity than that of that of the primary system (FEMA, 2009).

Incorporation of elements of the gravity or nonstructural systems in index archetype configurations was considered. It was ultimately decided to limit participating elements to those defined as part of the seismic-force-resisting system. It was considered inappropriate to take the beneficial effects of elements and components that would not be subject to regulation under the earthquake design provisions. As an alternative, it was considered permissible to include elements of the gravity or nonstructural systems in the assessment, if they were also included in the definition of the seismic-force-resisting system, and subject to the criteria contained within the system design requirements.

Potential for Reduced Performance

Partial collapse of buildings has occurred when elements of the gravity or nonstructural systems are not able to sustain lateral deformations of the seismic-force-resisting system. Options for explicitly modeling and evaluating gravity system performance were considered. Ultimately it was considered to be problematic, and not completely relevant to the evaluation of seismic performance factors for a seismic-force-resisting system, which must be qualified for use with many different secondary systems. Rather, displacement compatibility requirements of ASCE/SEI 7-05 are relied upon to protect secondary systems from collapse failure.

It should be noted that current displacement compatibility requirements of Section 12.12.4 of ASCE/SEI 7-05 may not be adequate to protect against premature failure of a gravity system. They only apply to SDC D (and SDC E and F) structures, and are based on design story drift, which is substantially less than the peak inelastic story drift of ductile seismic-force-resisting systems at the point of incipient collapse.

11.1.3 Buildings with Significant Irregularities

Significant irregularities, including torsion (horizontal structural irregularity Types 1a and 1b, Table 12.3-1, ASCE/SEI 7-05) and soft/weak story (vertical structural irregularity Types 1a and 1b, Table 12.3-2, ASCE/SEI 7-05), are known contributors to building collapse. Options for explicit modeling of irregularity were considered, but internal studies showed this to be unnecessary for evaluating collapse margins and related seismic performance factors for generic seismic-force-resisting systems. Limits on the use of equivalent lateral force (ELF) analysis given in Table 12.6-1 of ASCE/SEI 7-05, and related design conservatisms of the ELF procedure (e.g., accidental torsion, P-delta effects), were considered adequate to either limit the effects of significant irregularities, or require more detailed, dynamic analysis.

It should be noted that limits on the use of the ELF procedure are more restrictive for SDC D (and SDC E and F) structures, and certain design requirements (e.g., amplification of accidental torsion) do not apply to SDC B structures, so that there may be some additional life safety risk due to irregularity inherent to systems designed for either SDC B or SDC C criteria.

11.1.4 Redundancy of the Seismic-Force-Resisting System

Section 12.3.4.2 of ASCE/SEI 7-05 requires the seismic-force-resisting system of structures assigned to Seismic Design Categories D, E, and F to be designed for seismic loads increased by the redundancy factor, ρ, where ρ = 1.3, unless the configuration meets certain requirements for redundancy. Options for explicit modeling of non-redundant systems were considered, but internal studies showed this to be unnecessary for evaluating collapse margins and related seismic performance factors for generic seismic-force-resisting systems. The Methodology assumes ρ = 1.0 for design of structural system archetypes, since larger values of ρ would be unconservative for collapse evaluation of archetypes that generally meet redundancy requirements of Table 12.3-3 of ASCE/SEI 7-05.

11.2 Observations and Conclusions

In the development of this Methodology, selected seismic-force-resisting systems were evaluated to illustrate the application of the Methodology and verify its methods. Results of these studies provide insight into the collapse performance of buildings and appropriate values of seismic performance factors. Observations and conclusions in terms of generic findings applicable to all systems, and specific findings for certain types of seismic-force-resisting systems are described below. These findings should be considered generally representative, but not necessarily indicative of all possible trends, given limitations in the number and types of systems evaluated.

11.2.1 Generic Findings

The following generic findings and conclusions apply to seismic-force-resisting systems in general.

Systems Approach

Collapse performance (and associated seismic performance factors) must be evaluated in terms of the behavior of the overall seismic-force-resisting system, and not the behavior of individual components or elements of the system. Collapse failure modes are highly dependent on the configuration and interaction of elements within a seismic-force-resisting system. Seismic

performance factors should be considered as applying to an entire seismic-force-resisting system, and not elements comprising it.

Precision of Seismic Performance Factors

In general, there is no practical difference in the collapse performance of systems designed with fractional differences in the response modification coefficient, *R*. For example, collapse performance of structures designed for $R = 6$ and $R = 6.5$ is essentially the same, all else being equal. There is a discernible, but modest difference in collapse performance for systems designed for moderately different values of *R*, for example $R = 6$ and $R = 8$. There is, however, a significant difference in collapse performance for systems designed using different multiples of *R*, as in $R = 3$ versus $R = 6$. Current values of *R* provided in Table 12.2-1 (e.g., 3, 3-1/4 and 3-1/2) reflect a degree of precision that is not supported by results of example collapse evaluations.

Spectral Content of Ground Motions

Consideration of spectral content (spectral shape) of ground motions can be very important to the evaluation of collapse performance of ductile structures. Epsilon-neutral earthquake records that are scaled to represent very rare ground motions (ground motions corresponding to large positive values of epsilon) can significantly overestimate demand on ductile structures. The Methodology incorporates a spectral shape factor, *SSF*, that adjusts calculated response to account for the spectral content of rare earthquake ground motions and avoid overestimation of nonlinear response.

Short-Period Buildings

Consistent with prior research, values of collapse margin ratio are consistently smaller for short-period buildings, regardless of the type of seismic-force-resisting system. Unless they have adequate design strength, short-period buildings generally do not meet collapse performance objectives of the Methodology.

These findings suggest a possible need for period-dependent seismic performance factors, such as a short-period value and a 1-second value of the response modification coefficient, *R*, for each system. At present, the Methodology determines a single value of each seismic performance factor, independent of period, and consistent with the design requirements of ASCE/SEI 7-05. It could, however, be modified to determine period-dependent values of each factor.

Governing Seismic Design Category

Values of collapse margin ratio for a seismic-force-resisting system designed and evaluated for SDC D are generally smaller than corresponding values of collapse margin ratio for the same seismic-force-resisting system designed and evaluated for SDC C, all else being equal.

This trend is attributed to the increasing role of gravity loads in the strength of seismic-force-resisting components as the level of seismic design decreases. The size and strength of seismic-force-resisting components supporting both seismic and gravity loads is not necessarily proportional to a decrease in seismic design loads, since gravity loads do not decrease. The role of gravity loads in the strength of the seismic-force-resisting system is directly related to system overstrength, Ω, which also tends to increase as the level of seismic design decreases.

These findings suggest that the response modification coefficient, *R*, will generally be governed by the Seismic Design Category with the strongest ground motions for which the system is proposed for use (e.g., SDC D for seismic-force-resisting systems that are permitted for use in all SDCs). In general, *R* factors based on SDC D evaluations are conservative for design of the same seismic-force-resisting system designed for SDC C or SDC B seismic criteria.

These findings also suggest a possible need for seismic load-dependent seismic performance factors. For example, a system designed for SDC C could be assigned a larger value of *R* than would be required for the same system designed for SDC D. At present, the Methodology determines a single value of each seismic performance factor, independent of seismic design criteria, and consistent with the design requirements of ASCE/SEI 7-05. It could, however, be modified to determine SDC-specific values of each factor.

Overstrength

Consistent with prior research, values of collapse margin ratio are strongly related to calculated values of overstrength, regardless of the type of seismic-force-resisting system. For larger values of overstrength, larger values of collapse margin ratio are observed.

Calculated values of overstrength for different index archetype models vary widely, depending on configuration and Seismic Design Category. Results suggest that current values of system overstrength, Ω_O, given in Table 12.2-1 of ASCE/SEI 7-05 are not representative of the actual overstrength present in seismic-force-resisting systems. Values in the table generally vary between 2

and 3 for all systems (except cantilevered structures), while calculated values of Ω varied from as low as 1.5 to over 6 for structural system archetypes evaluated in the development of the Methodology.

Distribution of Inelastic Response

Consistent with prior research, values of collapse margin ratio are strongly related to the distribution of inelastic response over the height of a structure, regardless of the type of seismic-force-resisting system. Values of collapse margin ratio are significantly larger for systems in which the inelastic response is more evenly distributed throughout the system.

11.2.2 Specific Findings

The following key findings and conclusions apply specifically to reinforced-concrete moment frame systems, wood light-frame systems, and base-isolated systems that were evaluated as part of the development of the Methodology.

Example Application – Reinforced Concrete Special Moment Frame Systems

Evaluation of reinforced concrete special moment frame systems found that, in general, designs based on current ASCE/SEI 7-05 requirements (R = 8) meet the collapse performance objectives of this Methodology. However, trends in collapse margin ratio results suggested a potential collapse deficiency for taller buildings that did not meet minimum base shear requirements consistent with requirements in the predecessor document, ASCE 7-02. This information was made available to the ASCE 7 Seismic Committee, and a special code change proposal was passed in 2007 (Supplement No. 2), amending the minimum base shear requirements of ASCE/SEI 7-05 to correct for this potential deficiency.

The root cause of the potential deficiency in collapse performance of reinforced concrete special moment frame systems is the localization of large lateral deformations in the lower stories, and the associated detrimental P-delta effects on post-yield behavior. While imposing a minimum value of design base shear eliminated the potential deficiency for these systems, other approaches could have been used, including the introduction of height limits (which would not be practical), enhancement of P-delta and strong-column-weak-beam design criteria (which would require additional study), or the development of period-dependent response modification coefficients, R (which would effectively increase the design base shear for taller buildings).

Example Application - Reinforced-Concrete Ordinary Moment Frame Systems

Example evaluation of reinforced concrete ordinary moment frame systems found that, in general, designs based on current ASCE/SEI 7-05 requirements (R = 3) meet the collapse performance objectives of this Methodology, considering that these systems are only permitted for use in SDC B structures.

Example Application - Wood Light-Frame Systems

Example evaluations of wood light-frame systems found that, in general, designs based on current ASCE/SEI 7-05 requirements (R = 6) meet the collapse performance objectives of this Methodology.

Supporting Study - Seismically-Isolated Structures

A special study of seismically-isolated buildings focused on the performance of isolated special and ordinary reinforced concrete frame systems. This study found that code-conforming isolated structures with ductile superstructures (e.g., special moment frame systems) generally meet collapse performance objectives, but that isolated structures with non-ductile superstructures (e.g., ordinary moment frame systems) may not. However, it also found that with higher strengths, superstructures of isolated systems did not need to have the full ductility capacity required of conventional buildings to achieve acceptable collapse performance. This is an important finding for the introduction of more economically detailed superstructures of isolated buildings, although more comprehensive studies would be required to develop appropriate code requirements.

Pushover evaluations of isolated structures found poor correlation between the true (maximum) strength of the superstructure and the design strength. This suggests that nonlinear static (pushover) analyses would be more appropriate for verifying adequate overstrength of the superstructure than selecting superstructure strength based on the approximate values of R_I, and would also provide a more reliable and economical basis for design.

11.3 Collapse Evaluation of Individual Buildings

Although developed as a tool to establish seismic performance factors for generic seismic-force-resisting systems, the Methodology could be readily adapted for collapse assessment of an individual building system. As such, it could be used to demonstrate adequate collapse performance of the structural system of a building designed using performance-based design methods, permitted by Section 11.1.4 of ASCE/SEI 7-05. Specific methods for

collapse evaluation of an individual building system are described in Appendix F.

11.3.1 Feasibility

It is anticipated that buildings designed using performance-based methods will likely be large or important structures. Projects using performance-based design methods typically utilize detailed models for linear and nonlinear analyses of the building, and peer review is commonly required. Such projects are already set up to utilize many components of the Methodology.

11.3.2 Approach

The Methodology is based on the concept of collapse level ground motions, defined as the level of ground motions that cause median collapse (i.e., one-half of the records in the set cause collapse). For a building to meet the collapse performance objectives of this Methodology, the median collapse capacity must be an acceptable amount above the MCE ground motion demand level (i.e., the adjusted collapse margin ratio, *ACMR*, must exceed acceptable values).

By starting with an acceptable collapse probability (for MCE ground motions) and working backwards through the Methodology, values of the spectral shape factor, *SSF*, and collapse margin ratio, *CMR*, can be evaluated to determine the level of ground motions corresponding to median collapse. The Methodology can be "reverse engineered" to determine the level of ground motions for which not more than one-half of the records should cause collapse. By scaling the record set to this level, trial designs for a subject building can be evaluated. If the analytical model of the trial design survives one-half or more of the records without collapse, then the building has a collapse probability that is equal to (or less than) the acceptable collapse probability (for MCE ground motions), and meets collapse performance objective of the Methodology.

11.4 Recommendations for Further Study

The following recommendations are provided for possible future studies that would help to: (1) further improve or refine the Methodology; or (2) utilize the Methodology to investigate and develop potential improvements to the seismic provisions of ASCE/SEI 7-05.

11.4.1 Studies Related to Improving and Refining the Methodology

Comprehensive Evaluation of Existing Systems

The primary objective of this study would be to "beta test" the Methodology to further verify that this procedure will reliably and reasonably quantify building seismic performance for the various building systems that are, or will eventually become adopted by current building codes and standards organizations.

The Methodology could also be used to set minimum acceptable design criteria for standard code-approved systems and to provide guidance in the selection of appropriate design criteria for other systems when linear design methods are applied. It is possible that the Methodology could then be used to modify or eliminate those systems or requirements that cannot reliably meet, or do not relate, to these objectives.

Component Qualification

The Methodology thus far has been developed to comprehensively evaluate entire building systems, including variations in system configuration. This study would be intended to modify and simplify the procedure so that it can be used on individual building components.

The need for a simplified component methodology has been identified by construction materials industries and codes and standards organizations for the purpose of reliably and accurately quantifying seismic performance of various building components that currently are, or will eventually become available for use as seismic-force-resisting components within building systems.

Simplified Methods

Collapse simulation is a detailed, data-intensive process, which has a high degree of uncertainty. In order to comprehensively evaluate entire building systems, and all permissible variations in system configuration, the Methodology is necessarily complex. This study would investigate and test possible short cuts in the process to simplify the overall application of the Methodology for use when more comprehensive evaluations are not necessarily warranted.

Modeling of Short-Period Structures

The Methodology does not currently provide any specific guidance for modeling foundation flexibility and considering possible beneficial effects of soil-structure-interaction on the collapse performance of short-period

structures. This study would investigate these effects and, if justified, develop guidance for explicitly modeling of foundation flexibility and adjustment factors (similar to *SSF*) that would adjust collapse margin ratios as function of period, for evaluation of structural system archetypes assumed to be fixed on a rigid base.

11.4.2 Studies Related to Advancing Seismic Design Practice and Building Code Requirements (ASCE/SEI 7-05)

Period-Dependent and Seismic Load-Dependent R factors

The equivalent lateral force (ELF) procedure of ASCE/SEI 7-05 defines base shear in terms of a single value of *R* for a given seismic-force-resisting system, independent of the period of the structure or the level of seismic design criteria. Studies show that designs based on a single value of *R* do not necessarily have consistent collapse performance, and that such inconsistencies could be reduced or eliminated by specifying period-dependent or seismic load-dependent values of *R*.

Use of period-dependent and load-dependent values of *R* would require substantial revision to the equivalent lateral force method and related requirements in seismic design codes and standards, but could provide a basis for more efficient and economical design. The Methodology could be used to investigate period and seismic load dependency of *R*, and the feasibility of incorporating such factors. Potential benefits would be greater in regions of lower seismicity, where seismic load-dependent values of *R* are likely to be larger than those now specified for the same system in regions of high seismicity.

Consideration of Gravity and Nonstructural Systems and Components

The Methodology could be used to investigate the importance of the gravity system and certain nonstructural components to collapse performance, and investigate the feasibility of enhancing current seismic design requirements to more appropriately incorporate these systems in the seismic design process. This would include accounting for both the possible beneficial and detrimental effects of these systems on collapse performance. Comparisons of collapse results for archetypical models both with and without selected gravity system components could be made to quantify the results.

Structural Irregularities and Redundancy

The Methodology could be used to investigate the importance of structural system regularity and redundancy to collapse performance, and investigate possible changes to current seismic design requirements with regard to these

characteristics. Comparisons of collapse results for archetypical models both with and without features of regularity and redundancy could be made to quantify the effects.

Structures with Isolation and Damping Systems

Due to limited U.S. experience in strong earthquakes, code development committees have necessarily and appropriately imposed certain conservative restrictions on design requirements for seismically isolated and damped structures. The Methodology could be used to evaluate the importance of current design requirements for isolated systems, and investigate the feasibility of removing unnecessary conservatism. Comparisons of collapse results of archetypical models with non-ductile superstructures of varying strength levels could be made to quantify required strength for meeting collapse performance objectives. Removal of unnecessary conservatism would reduce system cost and support greater use of these types of protective systems.

Appendix A
Ground Motion Record Sets

This appendix describes the selection of ground motion record sets for collapse assessment of building structures using nonlinear dynamic analysis (NDA) methods. It summarizes the characteristics of the Far-Field and Near-Field record sets and defines the scaling methods appropriate for collapse evaluation of building archetypes based on incremental dynamic analysis. The Methodology utilizes the Far-Field record set for nonlinear dynamic analysis and related collapse assessment of archetype models.

Both the Far-Field and Near-Field record sets have average epsilon values that are lower than expected for Maximum Considered Earthquake (MCE) ground motions, and therefore can substantially underestimate calculated collapse margin ratios without appropriate adjustment for spectral shape effects. Adjustment of results from nonlinear dynamic analysis using these record sets is described in Section A.4 (and Appendix B).

Three ground-motion-related studies are included at the end of this appendix. The first study (Section A.11) compares collapse performance for archetypes evaluated using Far-Field and Near-Field record sets, respectively, and shows that collapse margins are somewhat smaller for the Near-Field set record. The second study (Section A.12) addresses the robustness of the Far-Field record set and shows that the selection criteria of Section A.7 yield a sufficiently large number of representative records (for sites not close to fault rupture). The third study (Section A.13) investigates record-to-record variability, β_{RTR}, of collapse results and develops a simple relationship for estimating β_{RTR} as a function of period-based ductility, μ_T, for systems that have limited period elongation.

A.1 Introduction

Ground motion record sets include a set of ground motions recorded at sites located greater than or equal to 10 km from fault rupture, referred to as the "Far-Field" record set, and a set of ground motions recorded at sites less than 10 km from fault rupture, referred to as the "Near-Field" record set. The Near-Field record set includes two subsets: (1) ground motions with strong pulses, referred to as the "NF-Pulse" record subset, and (2) ground motions without such pulses, referred to as the "NF-No Pulse" record subset.

A.2 Objectives

The Methodology requires a set of records that can be used for nonlinear dynamic analysis of buildings and evaluation of the probability of collapse for Maximum Considered Earthquake (MCE) ground motions. These records meet a number of conflicting objectives, described below.

- **Code (*ASCE/SEI 7-05*) Consistent** – The records should be consistent (to the extent possible) with the ground motion requirements of Section 16.1.3.2 of ASCE/SEI 7-05 *Minimum Design Loads for Buildings and Other Structures* (ASCE, 2006a) for three-dimensional analysis of structures. In particular, "ground motions shall consist of pairs of appropriate horizontal ground motion acceleration components that shall be selected and scaled from individual recorded events."
- **Very Strong Ground Motions** – The records should represent very strong ground motions corresponding to the MCE motion. In high seismic regions where buildings are at greatest risk, few recorded ground motions are intense enough, and significant upward scaling of the records is often required.
- **Large Number of Records** – The number of records in the set should be "statistically" sufficient such that the results of collapse evaluations adequately describe both the median value and record-to-record (RTR) variability of collapse capacity.
- **Structure Type Independent** – Records should be broadly applicable to collapse evaluation of a variety of structural systems, such as systems that have different dynamic response properties or performance characteristics. Accordingly, records should not depend on period, or other building-specific properties of the structure.
- **Site Hazard Independent** – The records should be broadly applicable to collapse evaluation of structures located at different sites, such as sites with different ground motion hazard functions, site and source conditions. Accordingly, records should not depend on hazard de-aggregation, or other site- or hazard-dependent properties.

No single set of records can fully meet all of the above objectives due, in part, to inherent limitations in available data. Large magnitude events are rare, and few existing earthquake ground motion records are strong enough to collapse large fractions of modern, code-compliant buildings. In the United States, strong-motion records date to the 1933 Long Beach earthquake, with only a few records obtained from each event until the 1971 San Fernando earthquake.

Even with many instruments, strong motion instrumentation networks (e.g., Taiwan and California) provide coverage for only a small fraction of all regions of high seismicity. Considering the size of the earth and period of geologic time, the available sample of strong motion records from large-magnitude earthquakes is still quite limited (and potentially biased by records from more recent, relatively well-recorded events).

A.3 Approach

The Methodology requires a set of ground motion records for collapse assessment of archetypical models that are appropriate for incremental dynamic analysis (Vamvatsikos and Cornell, 2002), as adapted herein. Incremental dynamic analysis (IDA) makes use of multiple response history analyses for a given ground motion record of increasing intensity until collapse occurs or the model otherwise reaches a collapse limit state. This process is repeated for a set of ground motion records of sufficient number to determine median collapse and record-to-record variability.

The Methodology follows the IDA concept of increasing ground motion intensity to collapse, but applies each sequential increase in intensity, collectively, to the entire set of ground motion records. Similar to IDA, the Methodology characterizes intensity in terms of response spectral acceleration at the fundamental period, T, of the system of interest, except that intensity is defined collectively by the median spectral acceleration of the record set, S_T, rather than by different intensities for each record. Record set intensity, S_T, is the parameter used to define record set intensity when the record set is scaled to a particular level of ground motions (e.g., MCE spectral acceleration). The median value of collapse spectral acceleration, $\hat{S}_{CT}$, is the value of S_T when the record set is scaled such that one-half of the records affect collapse.

To ensure broad representation of different recorded earthquakes, sets of ground motions contain records selected from all large-magnitude events in the PEER NGA database (PEER, 2006a). The PEER NGA database is described in Section A.6. A sufficient number of the strongest ground motion records are selected from each event to permit statistical evaluation of record-to-record variability.

Record selection does not distinguish ground motion records based on either site condition or source mechanism. However, distance to fault rupture is used to develop separate Far-Field and Near-Field record sets (for examination of potential differences in collapse fragility due to near-source directivity and pulse effects).

A.4 Spectral Shape Consideration

Spectral shape, i.e., frequency content of ground motions, can significantly influence the calculation of collapse fragility and the collapse margin ratio of "ductile" structures. Baker and Cornell (2006) have shown that rare ground motions in the Western United States, such as those corresponding to the MCE, have a distinctive spectral shape that, for a given fundamental-period spectral acceleration, causes the record to be less damaging than other records of less intensity.

In essence, the shape of the spectrum of rare ground motions drops off more rapidly at periods both greater and less than the fundamental period of interest (i.e., has less energy), as compared to spectra of other (less rare) records. The amount by which spectral shape can influence the collapse ratio is a function of the "rareness" of the ground motions. For ductile structures located in coastal California, accounting for this spectral shape effect can cause a 40% to 60% increase in the collapse margin ratio (i.e., median collapse capacity).

The ground motion record sets do not directly incorporate the effect of spectral shape. Direct incorporation of spectral shape would necessarily require records to be selected based on the fundamental period of the structure, resulting in a different set of records for each structure of differing period. Rather, collapse margin ratios calculated using the ground motion record sets are adjusted for spectral shape effects based on structure deformation capacity and seismic design category, described in Chapter 7, using factors developed in Appendix B.

A.5 Maximum Considered Earthquake and Design Earthquake Demand (*ASCE/SEI 7-05*)

The seismic provisions of ASCE/SEI 7-05 specify ground motions and design requirements in terms of the structure's Seismic Design Category (SDC), which is a function of the level of design earthquake (DE) ground motions and the Occupancy Category of the structure. The Methodology is based on life safety and assumes all structures to be either Occupancy Category I or II (i.e., structures that do not have special functionality requirements). Seismic Design Categories for Occupancy I and II structures vary from SDC A in regions of very low seismicity (which is of least interest) to SDC E in regions of highest seismicity near active faults.

The seismic provisions of ASCE/SEI 7-05 define MCE demand in terms of mapped values of short-period spectral acceleration, S_S, and 1-second spectral acceleration, S_1, site coefficients, F_a and F_v, and a standard response

spectrum shape. For seismic design of the structural system, ASCE/SEI 7-05 defines the DE demand as two-thirds of the MCE demand. Archetypical systems are designed for DE ground motions and evaluated for collapse using the corresponding set of MCE ground motions.

Mapped values of spectral acceleration vary greatly by seismic region. The Methodology defines MCE and DE ground motions by the range of spectral accelerations associated with Seismic Design Categories B, C, and D, respectively. For each SDC, maximum and minimum ground motions are based on the respective upper-bound and lower-bound values of DE spectral acceleration, as given in Table 11.6-1 of ASCE/SEI 7-05, for short-period response, and in Table 11.6-2 of ASCE/SEI 7-05, for 1-second response. MCE spectral accelerations are derived from DE spectral accelerations for site coefficients corresponding to Site Class D (stiff soil) following the requirements of Section 11.4 of ASCE/SEI 7-05.

Tables A-1A and A-1B list values of spectral acceleration, site coefficients and design parameters for maximum and minimum ground motions of Seismic Design Categories B, C, and D. Figure A-1 shows MCE response spectra for these ground motions.

Table A-1A Summary of Mapped Values of Short-Period Spectral Accelerations, Site Coefficients, and Design Parameters Used for Collapse Evaluation of Seismic Design Categories D, C, and B Structure Archetypes

Seismic Design Category		Maximum Considered Earthquake			Design
Maximum	Minimum	SS (g)	Fa	SMS (g)	SDS (g)
D		1.5	1.0	1.5	1.0
C	D	0.55	1.36	0.75	0.50
B	C	0.33	1.53	0.50	0.33
	B	0.156	1.6	0.25	0.167

Table A-1B Summary of Mapped Values of 1-Second Spectral Accelerations, Site Coefficients, and Design Parameters Used for Collapse Evaluation of Seismic Design Categories D, C, and B Structure Archetypes

Seismic Design Category		Maximum Considered Earthquake			Design
Maximum	Minimum	S1 (g)	Fv	SM1 (g)	SD1 (g)
D		0.60	1.50	0.90	0.60
C	D	0.132	2.28	0.30	0.20
B	C	0.083	2.4	0.20	0.133
	B	0.042	2.4	0.10	0.067

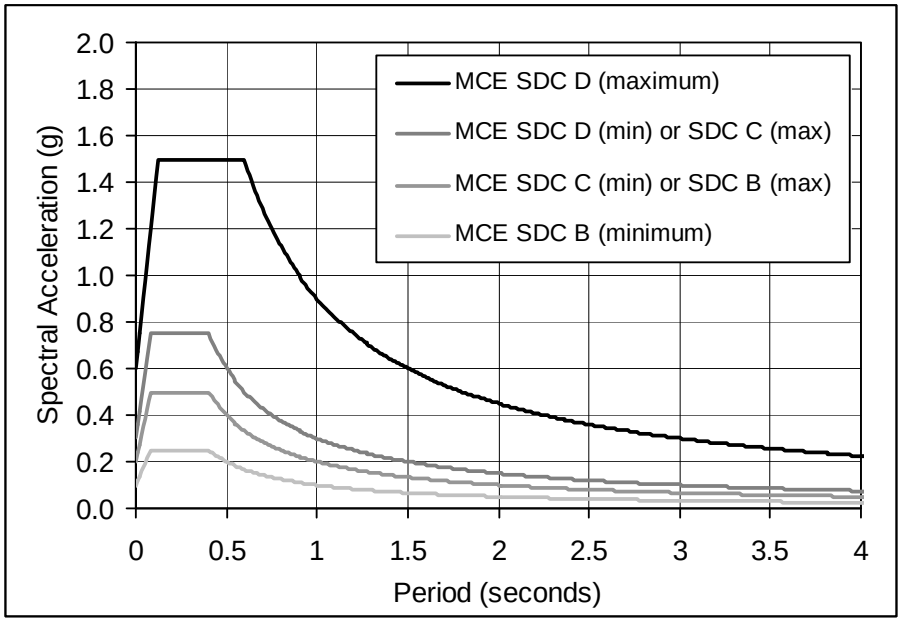

Figure A-1 Plots of MCE response spectral accelerations used for collapse evaluation of Seismic Design Categories D, C, and B structure archetypes.

The 1-second value of spectral acceleration shown in Table A-1B, $S_1 = 0.60$, is rounded upward slightly for convenience, and should be taken as $S_1 < 0.60$g, for the purpose of evaluating minimum base shear design requirements, i.e., Equation 12.8-6 of ASCE/SEI 7-05 should not be used for design of index archetypes.

Maximum values of seismic criteria for SDC D ($S_s = 1.5$ g and $S_1 = 0.60$ g) are based on the effective boundary between deterministic (near-source) and probabilistic regions of MCE ground motions, as defined in Section 21.2 of ASCE/SEI 7-05. The Methodology purposely excludes SDC D structures at deterministic (near-source) sites defined by 1-second spectral acceleration equal to or greater than 0.60 g, i.e., Section 11.6 of ASCE/SEI 7-05 defines SDC D structures as having 1-second spectral acceleration values as large as 0.75 g.

The seismic response coefficient, C_s, is used for design of the structure archetypes. This coefficient is based on the fundamental period, T, which is computed using Equation A-1. T is the code-defined period, and not the period computed using eigenvalue analysis of the structural model.

$$T = C_u T_a = C_u \quad C_t \quad h_n^x \geq 0.25 \text{ seconds} \tag{A-1}$$

where h_n is the height, in feet, of the building above the base to the highest level of the structure, and values of the coefficient, C_u, are given in Table 12.8-1 and values of period parameters, C_t and x, are given in Table 12.8-2 of ASCE/SEI 7-05.

Period parameters, C_t and x are a function of structure type, distinguishing between steel moment frames, reinforced concrete moment frames, eccentrically braced steel frames and all other stiff structural systems. Example values of the fundamental period, T, and corresponding MCE spectral acceleration, S_{MT}, are given in Table A-2 for concrete moment resisting frame structures of various heights, ranging from 1-story to 20-stories. Table A-2 lists example values of the fundamental period and MCE spectral acceleration corresponding to maximum and minimum seismic criteria of Seismic Design Categories B, C, and D.

Table A-2 Example values of the Fundamental Period, T, and Corresponding MCE Spectral Acceleration, S_{MT}, for Reinforced Concrete Moment Frame Structures of Various Heights

System Properties		Seismic Design Category (SDC) Max and Min Seismic Criteria							
		SDC D_{max}		SDC C_{max}		SDC B_{max}		SDC B_{min}	
				SDC D_{min}		SDC C_{min}			
No. of Stories	Height (ft.)	T (sec.)	S_{MT} (g)	T (sec.)	S_{MT} (g)	T (sec.)	S_{MT} (g)	T (sec.)	S_{MT} (g)
1	15	0.26	1.50	0.27	0.75	0.30	0.50	0.31	0.25
2	28	0.45	1.50	0.48	0.62	0.52	0.38	0.55	0.183
4	54	0.81	1.11	0.87	0.34	0.95	0.21	0.99	0.101
8	106	1.49	0.60	1.60	0.188	1.74	0.115	1.81	0.055
12	158	2.13	0.42	2.29	0.131	2.49	0.080	2.59	0.039
20	262	3.36	0.27	3.60	0.083	3.92	0.051	4.08	0.024

Section A.8 discusses scaling of record sets and provides factors for scaling the Far Field record set to match MCE spectral acceleration, S_{MT}, for Seismic Design Categories B, C and D, respectively.

A.6 PEER NGA Database

The PEER NGA database is an extension of the earlier PEER Strong Motion Database that was first made publicly available in 1999. The PEER NGA database is composed of over 3,550 ground motion recordings that represent over 160 seismic events (including aftershock events) ranging in magnitude from M4.2 to M7.9.

Each ground motion recording includes two horizontal components of acceleration; the vertical acceleration component is also available for many records. In addition, the rotated fault-normal and fault-parallel motion components are also available. This database contains records from a wide range of domestic and international sources including the United States Geological Survey, the California Division of Mines and Geology, the Central Weather Bureau, the Earthquake Research Department of Turkey, and many others.

The PEER NGA database was chosen for use in this study for several reasons, including the large number of ground motion records, and the availability of fault-normal and fault-parallel components of ground motion. This report utilizes version 6.0 of the PEER NGA database. After this work was completed, version 7.3 of the database was released, and some ground motion parameters differ slightly in the new version, such as PGV. Even so, the variations are small and have no tangible impact on the FEMA P695 Methodology.

A.7 Record Selection Criteria

This section describes record selection criteria developed to meet Methodology objectives. Each criterion is listed, followed by a brief discussion of the intent of the rule.

- **Source Magnitude.** Large-magnitude events pose the greatest risk of building collapse due to inherently longer durations of strong shaking and larger amounts of energy released. Ground motions of smaller magnitude ($M < 6.5$) events can cause building damage (typically of a nonstructural nature), but are not likely to collapse new structures. Even when small magnitude events generate strong ground motions, the duration of strong shaking is relatively short and the affected area is relatively small. In contrast, large-magnitude events can generate strong, long duration, ground motions over a large region, affecting a much larger population of buildings.
- **Source Type.** Record sets include ground motions from earthquakes with either strike-slip or reverse (thrust) sources. These sources are typical of shallow crustal earthquakes in California and other Western United States locations. Few strong-motion records are available from other source mechanisms.
- **Site Conditions.** Record sets include ground motions recorded on either soft rock (Site Class C) or stiff soil (Site Class D) sites. Records on soft soil (Site Class E) or sites susceptible to ground failure (Site Class F) are

not used. Relatively few strong-motion records are available for Site Class B (rock) sites.

- **Site-Source.** The 10 km source-to-site distance boundary between Near-Field and Far-Field records is arbitrary, but generally consistent with the "near fault" region of MCE design values maps in ASCE/SEI 7-05. Several different measures of this distance are available. For this project, the source-to-site distance was taken as the average of Campbell and Joyner-Boore fault distances provided in the PEER NGA database.
- **Number of Records per Event.** Strong-motion instruments are not evenly distributed across seismically active regions. Due to the number of instruments in place at the time of the earthquake, some large-magnitude events have generated many records, while others have produced only a few. To avoid potential event-based bias in record sets, not more than two records are taken from any one earthquake for a record set. The two-record limit was applied separately to the Near-Field "Pulse" and "No Pulse" record sets, respectively. When more than two records of an event pass the other selection criteria, the two records with highest peak ground velocity are selected.
- **Strongest Ground Motion Records**. The limits of greater than 0.2 g on PGA and greater than 15 cm/sec on PGV are arbitrary, but generally represent the threshold of structural damage (for new buildings) and capture a large enough sample of the strongest ground motions (recorded to date) to permit calculation of record-to-record variability.
- **Strong-Motion Instrument Capability.** Some strong-motion instruments, particularly older models, have inherent limitations on their ability to record long-period vibration accurately. Most records have a valid frequency content of at least 8 seconds, but some records do not, and records not valid to at least 4 seconds are excluded from the record sets. The record sets are considered valid for collapse evaluation of tall buildings with elastic fundamental periods up to about 4 seconds.
- **Strong-Motion Instrument Location.** Strong-motion instruments are sometimes located inside buildings (e.g., ground floor or basement) that, if large, can influence recorded motion due to soil-structure-foundation interaction. Instead, instruments located in free-field location or on ground floor of a small building should be used.

A.8 Scaling Method

Scaling of ground motion records is a necessary element of nonlinear dynamic analysis, since few, if any, available unscaled records are strong

enough to collapse modern buildings. The scaling process of the Methodology involves two elements: normalization and scaling.

Normalization of Records. Individual records of a given set are normalized by their respective peak ground velocities. In essence, some records are factored upwards (and some factored downwards), while maintaining the same overall ground motion strength of the record set. Normalization by peak ground velocity is a simple way to remove unwarranted variability between records due to inherent differences in event magnitude, distance to source, source type and site conditions, while still maintaining the inherent aleatory (i.e., record-to-record) variability necessary for accurately predicting collapse fragility.

Normalization is done with respect to the value of peak ground velocity computed in the PEER NGA database (PGV_{PEER}), which is the geometric mean of PGV of the two horizontal components considering different record orientations. The geometric mean (or geomean) is the square root of the product of the two horizontal components and is a common parameter used to characterize ground motions.

The following formulas define the normalization factor, NM_i, and calculation of normalized horizontal components of the i^{th} record, respectively:

$$NM_i = \text{Median}(PGV_{PEER,i})/PGV_{PEER,i} \quad \text{(A-2)}$$

$$NTH_{1,i} = NM_i \times TH_{1,i}$$
$$NTH_{2,i} = NM_i \times TH_{2,i} \quad \text{(A-3)}$$

where:

NM_i = Normalization factor of both horizontal components of the i^{th} record (of the set of interest),

$PGV_{PEER,i}$ = Peak ground velocity of the i^{th} record (PEER NGA database),

Median ($PGV_{PEER,i}$) = Median of $PGV_{PEER,i}$ values of records in the set,

$NTH_{1,i}$ = Normalized i^{th} record, horizontal component 1,

$NTH_{2,i}$ = Normalized i^{th} record, horizontal component 2,

$TH_{1,i}$ = Record i, horizontal component 1 (PEER NGA database), and

$TH_{2,i}$ = Record i, horizontal component 2 (PEER NGA database).

Records and their corresponding values of PGV_{PEER} are taken directly from the PEER NGA database. For Near-Field records, the components rotated to the fault normal (FN) and fault parallel (FP) directions are utilized. Horizontal components of Far-Field records are not rotated based on the orientation with respect to the fault and their as-recorded orientation is used. Horizontal components of each record are normalized by the same normalization factor, NM_i, to maintain the relative, as-recorded strength of the two components (which can be important for analysis of three-dimensional archetype models.

Table A-3 provides median values of 5%-damped spectral acceleration, $\hat{S}_{NRT}$, of normalized Far-Field and Near-Field record sets, respectively. The Far-Field record set is described in Section A.9 and the Near-Field record set is described in Section A.10, and Tables A-4D and A-6D summarize normalization factors for each record of the Far-Field and Near-Field ground motion sets, respectively.

Scaling of Record Sets. For collapse evaluation, the Methodology requires the set of normalized ground motion records to be collectively scaled upward (or downward) to the point that causes 50 percent of the ground motions to collapse the archetype analysis model being evaluated. This approach is used to determine the median collapse capacity, $\hat{S}_{CT}$, of the model. Once this has been established, the Methodology requires that the collapse margin ratio, *CMR*, be computed between median collapse capacity, $\hat{S}_{CT}$, and MCE demand, S_{MT}.

In the same manner, record sets can be scaled to a specific level of ground motions e.g., MCE spectral acceleration. Record normalization and record set scaling to match a particular level of ground motions parallels the ground motion scaling requirements of Section 16.1.3.2 of ASCE/SEI 7-05, with the notable exception that the median value of the scaled record set need only match the MCE demand at the fundamental period, *T*, rather than over the range of periods required by ASCE/SEI 7-05.

Table A-3 provides scaling factors for anchoring the normalized Far-Field record set to the MCE demand level of interest. Scaling factors (for anchoring the normalized Far-Field record set to MCE demand) depend on the fundamental period of the building, *T*, which is shown in the left column of the table. Figure A-2 illustrates the median spectrum of the normalized Far-Field record set anchored to various levels of MCE demand at a period of 1 second.

Table A-3 **Median 5%-Damped Spectral Accelerations of Normalized Far-Field and Near-Field Record Sets and Scaling Factors for Anchoring the Normalized Far-Field Record Set to MCE Spectral Demand[1].**

Period $T = C_u T_a$ (sec.)	Median Value of Normalized Record Set $\hat{S}_{NRT}$ (g)		Scaling Factors for Anchoring Far-Field Record Set to MCE Spectral Demand

1. Spectral acceleration values and scaling factors may be based on linear interpolation for periods not listed in the table.

In Figure A-2, the median spectrum of the normalized Far-Field record set is factored by 2.59 to match the maximum MCE spectral acceleration of SDC D_{max} at a period of 1 second, and factored by 0.86 to match the minimum MCE spectral acceleration of SDC D_{min} at a period of 1 second. The figure shows that the median spectrum of the Far-Field record set tends to match

MCE spectral acceleration at periods near the "anchor" period, but can substantially deviate from MCE spectra at other periods. Such deviations are unavoidable due to the approximate shape of code-defined spectra.

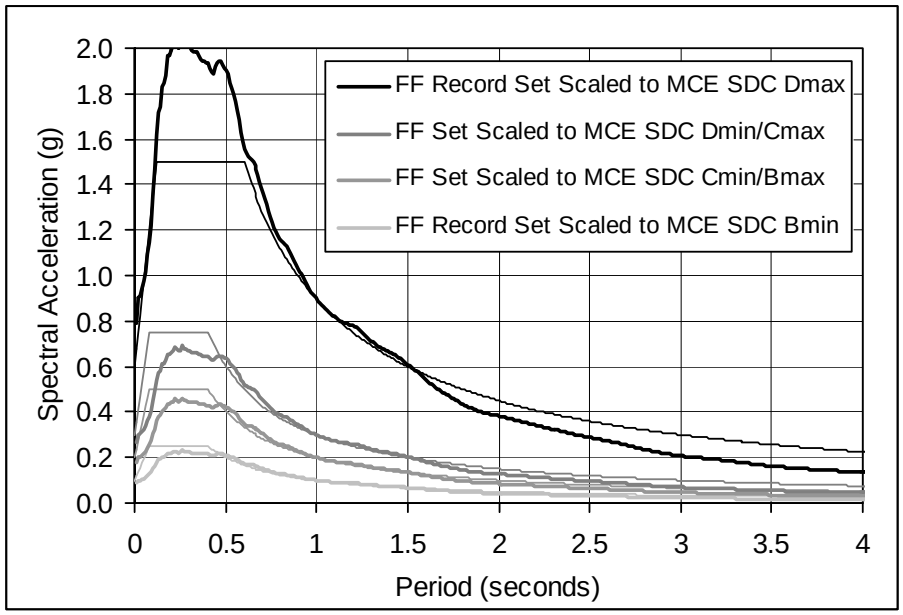

Figure A-2 Example anchoring of median spectrum of the Far-Field record set to MCE spectral acceleration at 1 second for maximum and minimum seismic criteria of Seismic Design Categories B, C and D.

A.9 Far-Field Record Set

The Far-Field record set includes twenty-two records (44 individual components) selected from the PEER NGA database using the criteria from Section A.7 of this appendix.

For each record, Table A-4A summarizes the magnitude, year, and name of the event, as well as the name and owner of the station. The twenty-two records are taken from 14 events that occurred between 1971 and 1999. Of the 14 events, eight were California earthquakes and six were from five different foreign countries. Event magnitudes range from M6.5 to M7.6 with an average magnitude of M7.0 for the Far-Field record set.

For each record, Table A-4B summarizes site and source characteristics, epicentral distances, and various other measures of site-source distance. Site characteristics include shear wave velocity and the corresponding *NEHRP* Site Class. Sixteen sites are classified as Site Class D (stiff soil sites) and the remaining six are classified as Site Class C (very stiff soil sites). Fifteen records are from events of predominantly strike-slip faulting and the

remaining seven records are from events of predominantly thrust (or reverse) faulting.

Table A-4A Summary of Earthquake Event and Recording Station Data for the Far-Field Record Set

ID No.	Earthquake			Recording Station	
	M	Year	Name	Name	Owner

Site-source distances are given for the closest distance to fault rupture, Campbell R distance, and Joyner-Boore horizontal distance to the surface projection of the rupture. Based on the average of Campbell and Boore-Joyner fault distances, the minimum site-source distance is 11.1 km, the maximum distance is 26.4 km and the average distance is 16.4 km for the Far-Field record set.

Table A-4B Summary of Site and Source Data for the Far-Field Record Set

ID No.	Site Data		Source (Fault Type)	Site-Source Distance (km)			
	NEHRP Class	Vs_30 (m/sec)		Epicentral	Closest to Plane	Campbell	Joyner-Boore
1	D	356	Thrust	13.3	17.2	17.2	9.4

22	C	425	Thrust	20.2	15.8	15.8	15

For each record, Table A-4C summarizes key record information from the PEER NGA database. This record information includes the record sequence number and file names of the two horizontal components, as well as the lowest frequency (longest period) for which frequency content is considered fully reliable.

Maximum values of as-recorded peak ground acceleration, PGA_{max}, and peak ground velocity, PGV_{max}, are also given for each record. The term "maximum" implies that the larger value of the two components is reported. Peak ground acceleration values vary from 0.21 g to 0.82 g with an average PGA_{max} of 0.43 g. Peak ground velocity values vary from 19 cm/second to 115 cm/second with an average PGV_{max} of 46 cm/second.

Table A-4C Summary of PEER NGA Database Information and Parameters of Recorded Ground Motions for the Far-Field Record Set

ID No.	PEER-NGA Record Information				Recorded Motions	
	Record Seq. No.	Lowest Freq (Hz.)	File Names - Horizontal Records		PGA_{max} (g)	PGV_{max} (cm/s.)

For each record, Table A-4D summarizes the 1-second spectral acceleration of both horizontal components, peak ground velocity reported in the PEER NGA database, PGV_{PEER}, normalization factors, NM_i, and values of PGA_{max} and PGV_{max} after normalization by PGV_{PEER}.

Table A-4D Summary of Factors Used to Normalize Recorded Ground Motions, and Parameters of Normalized Ground Motions for the Far-Field Record Set

ID No.	As-Recorded Parameters			Normaliz-ation Factor	Normalized Motions	
	1-Sec. Spec. Acc. (g)		PGVPEER (cm/s.)		PGA_{max} (g)	PGV_{max} (cm/s.)
	Comp. 1	Comp. 2				
1	1.02	0.94	57.2	0.65	0.34	41
2	0.38	0.63	44.8	0.83	0.40	38
3	0.72	1.16	59.2	0.63	0.52	39
4	0.35	0.37	34.1	1.09	0.37	46
5	0.26	0.48	28.4	1.31	0.46	43
6	0.24	0.23	36.7	1.01	0.39	43
7	0.31	0.29	36.0	1.03	0.53	39
8	0.33	0.23	33.9	1.10	0.26	42
9	0.43	0.61	54.1	0.69	0.25	41
10	0.11	0.11	27.4	1.36	0.30	54
11	0.50	0.33	37.7	0.99	0.24	51
12	0.20	0.36	32.4	1.15	0.48	49
13	0.46	0.28	34.2	1.09	0.58	38
14	0.27	0.38	42.3	0.88	0.49	39
15	0.35	0.54	47.3	0.79	0.40	43
16	0.31	0.25	42.8	0.87	0.31	40
17	0.33	0.34	31.7	1.17	0.53	42
18	0.54	0.39	45.4	0.82	0.45	36
19	0.49	0.95	90.7	0.41	0.18	47
20	0.30	0.43	38.8	0.96	0.49	38
21	0.25	0.15	17.8	2.10	0.44	40
22	0.25	0.30	25.9	1.44	0.50	44

Normalization factors vary from 0.41 to 2.10. After normalization, peak ground acceleration values vary from 0.18 g to 0.58 g with an average PGA_{max} of 0.40 g. Peak ground velocity values vary from 36 cm/second to 54 cm/second with an average PGV_{max} of 42 cm/second. Table A-5 shows that normalization of the records (by PGV_{PEER}) has reduced the dispersion in PGV_{max} to a level consistent with that of PGA_{max} without appreciably affecting average values of PGA_{max} or PGV_{max} for the record set.

Table A-5 **Far-Field Record Set (as-Recorded and After Normalization): Comparison of Maximum, Minimum and Average Values of Peak Ground Acceleration (PGA_{max}) and Peak Ground Velocity (PGV_{max}), Respectively**

Parameter Value	PGA_{max} (g)		PGV_{max} (g)	
	As-Recorded	Normalized	As-Recorded	Normalized
Maximum	0.82	0.58	115	54
Minimum	0.21	0.18	19	36
Max/Min Ratio	3.9	3.2	6.1	1.5
Average	0.43	0.43	46	42

Figure A-3 shows response spectra of individual records of the normalized Far-Field record set, as well as the median and one and two standard deviation spectra of the set in log format. Figure A-4 shows median and one-standard deviation spectra, as well as a plot of the standard deviation (natural log of spectral acceleration) of the normalized Far-Field record set in linear form.

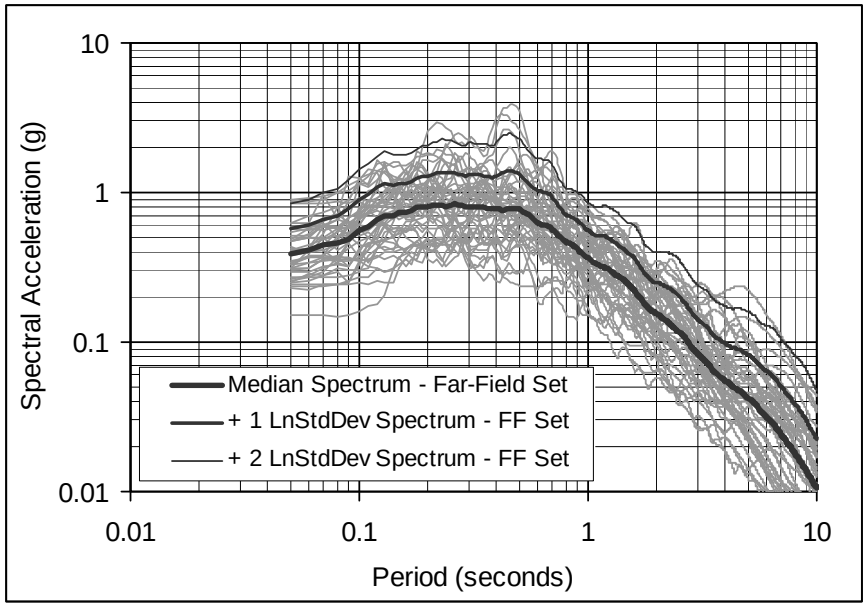

Figure A-3 Response spectra of the forty-four individual components of the normalized Far-Field record set and median, one and two standard deviation response spectra of the total record set.

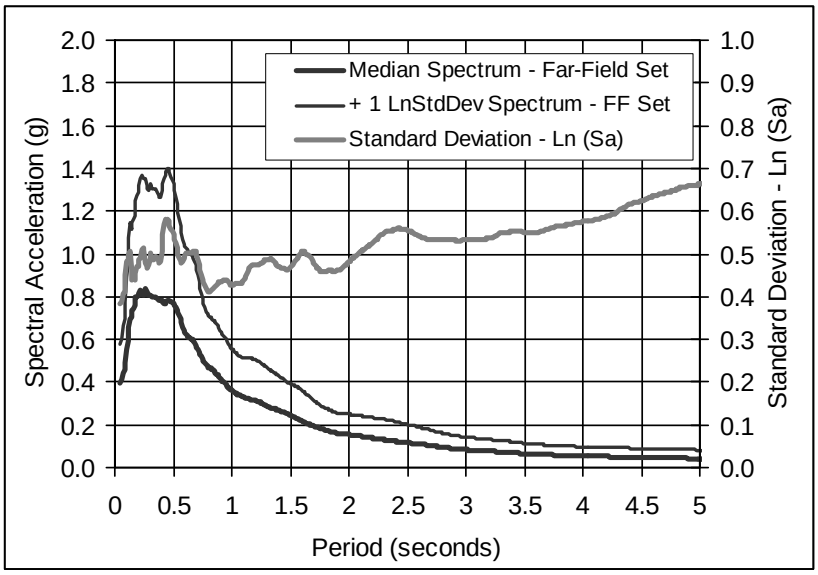

Figure A-4 Median and one standard deviation response spectra of the normalized Far-Field record set, and plot of the standard deviation (natural log) of response spectral acceleration.

The median spectrum of the normalized Far-Field record set has frequency content consistent with that of a large magnitude (M7) event recorded at 15 km from fault rupture. The median spectral acceleration at short periods is about 0.8 g and median spectral acceleration at 1-second is about 0.35 g. The domain of "constant acceleration" transitions to the domain of "constant velocity" at about 0.5 second, consistent with soft rock and stiff soil site response. Record-to-record variability (standard deviation of the logarithm of spectral acceleration) ranges from about 0.5 at short periods to about 0.6 at long periods, consistent with the values of dispersion from common ground motion attenuation relations (e.g., see Figure 8, Campbell and Borzorgnia, 2003).

Recent research has shown that spectral shape is an important aspect of collapse capacity prediction (Baker and Cornell, 2006) and that this is related to a parameter called epsilon, ε. Epsilon is defined as the number of standard deviations between the observed spectral value and the median prediction from an attenuation function such that it depends on both the period and the attenuation function used. Figure A-5 is a plot of the median value of ε calculated for the forty-four components of the Far-Field record set. These values are based on the attenuation relationship developed by Abrahamson and Silva (1997).

Median values of ε are generally small and near zero at all periods beyond 1 second, indicating that the Far-Field record set is approximately "ε-neutral."

Accordingly, collapse margin ratios (*CMR*s) based on incremental dynamic analysis using these records do not account for the effects of spectral shape, discussed in Section A.4, and are later increased to account for these effects, using the factors described in Section 7.4 and developed in Appendix B.

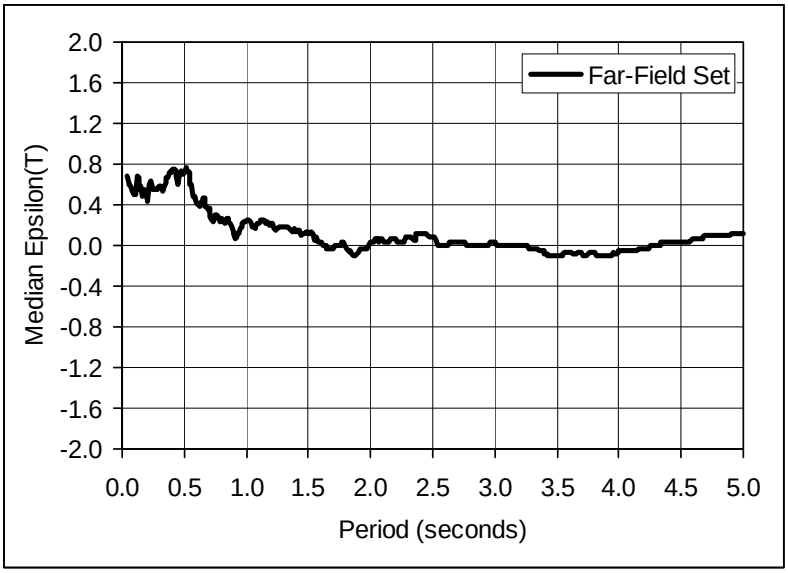

Figure A-5 Plot of median value of epsilon for the Far-Field record set.

A.10 Near-Field Record Set

The Near-Field record set includes twenty-eight records (56 individual components) selected from the PEER NGA database using the criteria from Section A.7 of this appendix. Fourteen records have pulses (Pulse subset) and fourteen records do not have pulses (No-Pulse subset), as judged by wavelet analysis classification of the records (Baker, 2007).

For each record, Table A-6A summarizes the magnitude, year and name of earthquake events and the name and owner of the station. The twenty-eight records are taken from 14 events that occurred between 1976 and 2002. Of the 14 events, seven were United States earthquakes (six in California) and seven were from five different foreign countries. Event magnitudes range from M6.5 to M7.9 with an average magnitude of M7.0.

Table A-6A Summary of Earthquake Event and Recording Station Data for the Near-Field Record Set

ID No.	Earthquake			Recording Station	
	M	Year	Name	Name	Owner

For each record, Table A-6B summarizes site and source characteristics, epicentral distances, and various measures of site-source distance. Site characteristics include shear wave velocity and the corresponding NEHRP Site Class. Eleven sites are classified as Site Class D (stiff soil sites), fifteen are classified as Site Class C (very stiff soil sites), and the remaining two are classified as Site Class B (rock sites). Fourteen records are from events of predominantly strike-slip faulting and the remaining fourteen records are from events of predominantly thrust (or reverse) faulting.

Based on the average of Campbell and Boore-Joyner fault distances, the minimum site-source distance is 1.7 km, the maximum distance is 8.8 km, and the average distance is 4.2 km.

Table A-6B Summary of Site and Source Data for the Near-Field Record Set

For each record, Table A-6C summarizes key record information from the PEER NGA database. This record information includes the record sequence number and the file names of the two horizontal components as well as the lowest frequency (longest period) for which frequency content is considered fully reliable.

Maximum values of as-recorded peak ground acceleration, PGA_{max}, and peak ground velocity, PGV_{max}, are given for each record. The term "maximum" implies the larger peak ground velocity of the two components is reported. Peak ground acceleration values range from 0.22 g to 1.43 g with an average PGA_{max} of 0.60 g. Peak ground velocity values range from 30 cm/second to 167 cm/second with an average PGV_{max} of 84 cm/second.

27	2.54	0.86	90.3	0.62	0.72	71.5
28	0.69	0.82	98.5	0.57	0.19	72.0

Normalization factors vary from 0.57 to 2.79. After normalization, peak ground acceleration values range from 0.19 g to 1.50 g with an average PGA_{max} of 0.60 g. Peak ground velocity values range from 50 cm/second to 115 cm/second with an average PGV_{max} of 80 cm/second. Table A-7 shows that normalization of the records (by PGV_{PEER}) has substantially reduced the dispersion in PGV_{max} without greatly affecting average values of PGA_{max} or PGV_{max}, or the dispersion in PGA_{max}.

Table A-7 Near-Field Record Set (As-Recorded and After Normalization): Comparison of Maximum, Minimum and Average Values of Peak Ground Acceleration (PGA_{max}) and Peak Ground Velocity (PGV_{max}), Respectively

Parameter Value	PGA_{max} (g)		PGV_{max} (g)	
	As-Recorded	Normalized	As-Recorded	Normalized
Maximum	1.43	1.50	167	115
Minimum	0.22	0.19	30	50
Max/Min Ratio	6.5	7.9	5.6	2.3
Average	0.60	0.60	84	80

Figure A-6 shows response spectra of individual records of the normalized Near-Field record set, as well as the median and one and two standard deviation spectra of the set in log format. Figure A-7 shows median and one-standard deviation spectra, as well as a plot of the standard deviation (natural log of spectral acceleration) of the normalized Near-Field record set in linear format.

The median spectrum of the normalized Near-Field record set has frequency content consistent with a large magnitude (M7) event recorded relatively close (5 km) to the fault rupture. The median spectral acceleration at short periods is about 1.0 g and median spectral acceleration at 1-second is about 0.6 g. Record-to-record variability (standard deviation of the logarithm of spectral acceleration) ranges from about 0.4-0.5 at short periods to about 0.6 at long periods, generally consistent (except at very short periods) with the values of dispersion from common ground motion (attenuation) relations (e.g., see Figure 8, Campbell and Borzorgnia, 2003).

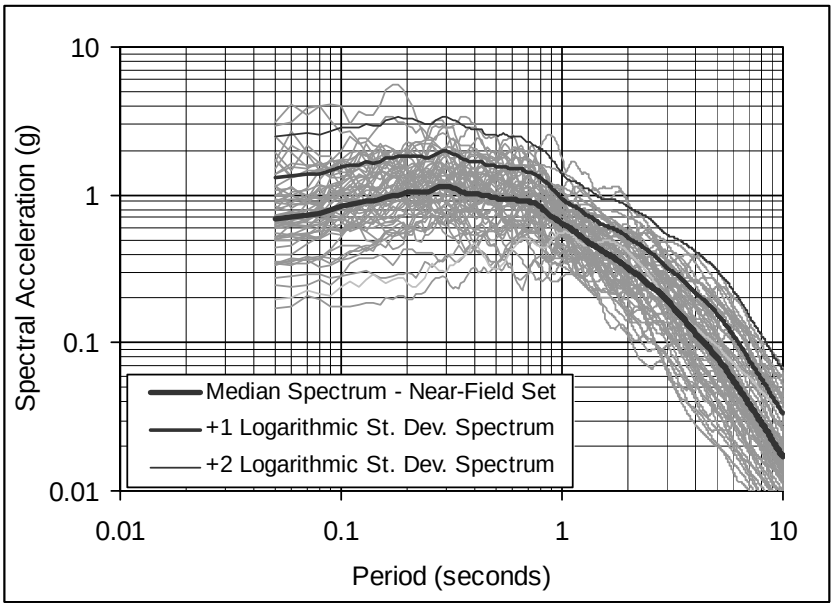

Figure A-6 Response spectra of the fifty-six individual components of the normalized Near-Field record set, and median, one and two standard deviation response spectra of the total record.

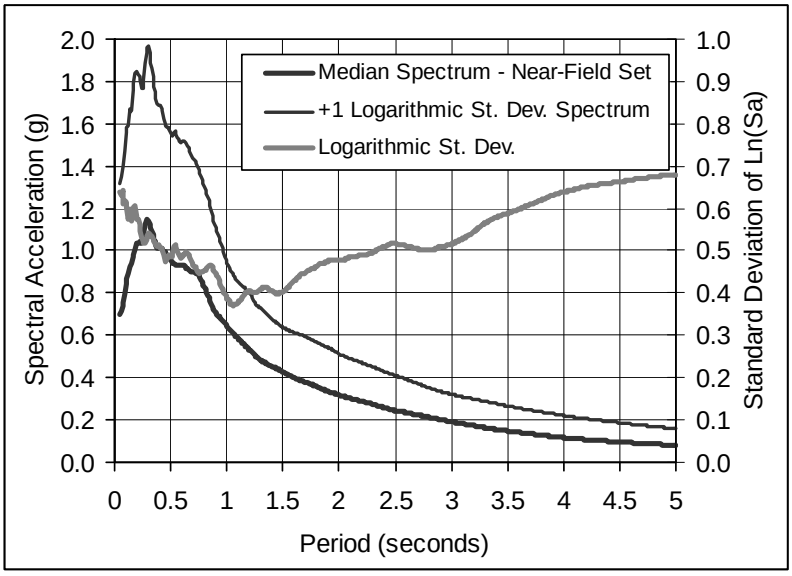

Figure A-7 Median and one standard deviation response spectra of the normalized Near-Field record set, and plot of the standard deviation (natural log) of response spectral acceleration.

Figure A-8 is a plot of the median value of epsilon calculated for the fifty-six components of the Near-Field record set. For comparison, Figure A-8 also shows the median value of ε calculated for the Far-Field record (from Figure A-5). These values are based on the attenuation relationship developed by

Abrahamson and Silva (1997). Median values of ε are generally small and near zero at all periods, with mildly positive ε values occurring at periods of 2.5 to 4.5 seconds, indicating that the Near-Field record set is approximately "epsilon neutral." Accordingly, collapse margin ratios (*CMR*s) based on incremental dynamic analysis using these records do not account for the effects of spectral shape, discussed in Section A.4, and are later increased to account for these effects, using the factors of Section 7.4 and Appendix B.

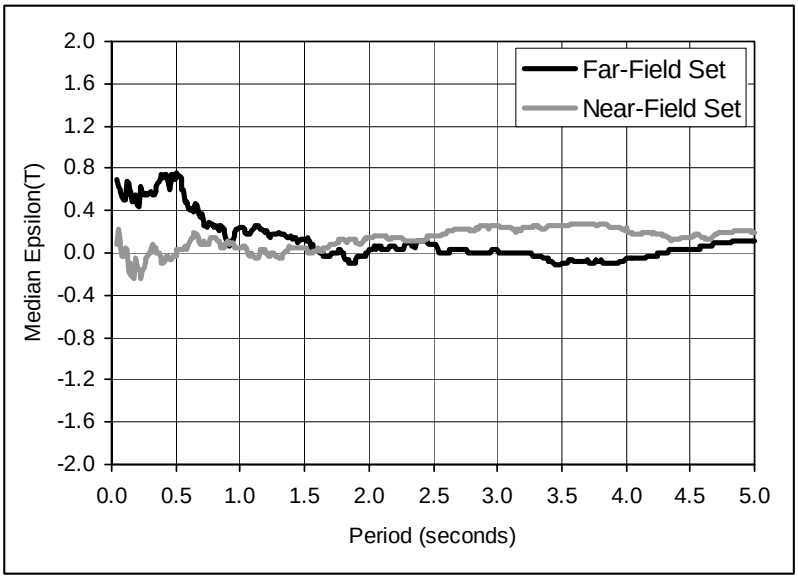

Figure A-8 Median value of epsilon for the Near-Field record set (and plot of median value of epsilon for the Far-Field record set for comparison).

A.11 Comparison of Far-Field and Near-Field Record Sets

This section compares median response spectra of the Far-Field and Near-Field record sets and collapse margin ratios (*CMR*s) calculated using these record sets. Comparisons of collapse margin ratios are made to determine if margins are, in general, substantially less for SDC E structures subjected to near-fault seismic demands than for SDC D structures subjected to SDC D_{max} seismic demands. These comparisons necessarily consider that higher seismic loads are required for design of SDC E structures (than for SDC D structures).

The three record sets used in this section to evaluate collapse margin are: (1) Far-Field record set (full set of 44 records); (2) Near-Field record set (full set of 56 records); and (3) Near-Field subset of pulse records in the fault normal (FN) direction (14 Near-Field records that are oriented in the fault normal direction and which have pulses). All records are normalized and scaled as

described in Section A.8. These sets permit assessment of the effect of differences in frequency content and response characteristics of records on collapse margin. For example, are collapse margins similar for Far-Field and Near-Field record sets (when both sets are anchored to the same level of SDC E seismic criteria)? Similarly, are collapse margins substantially lower for Near-Field FN-Pulse records than for the full Near-Field record set?

Figure A-9 shows unscaled median response spectra for Near-Field and Far-Field record sets, respectively, and the ratio of these spectra. The ratio of median spectra varies from about 1.2 at short periods to about 1.6 at a period of 1-second (and over 2.0 at periods beyond 2 seconds) consistent with mapped values of ground motion required by ASCE/SEI 7-05, and other codes, for structural design near active sources. For example, the near-source coefficients of the 1997 UBC (ICBO, 1997), summarized in Table A-8, increase seismic design loads by 1.2 in acceleration domain and 1.6 in velocity domain for structures located 5 km of an active fault capable of generating large magnitude earthquakes. Corresponding increases in MCE seismic criteria are used for evaluation of collapse margin for SDC E seismic demands.

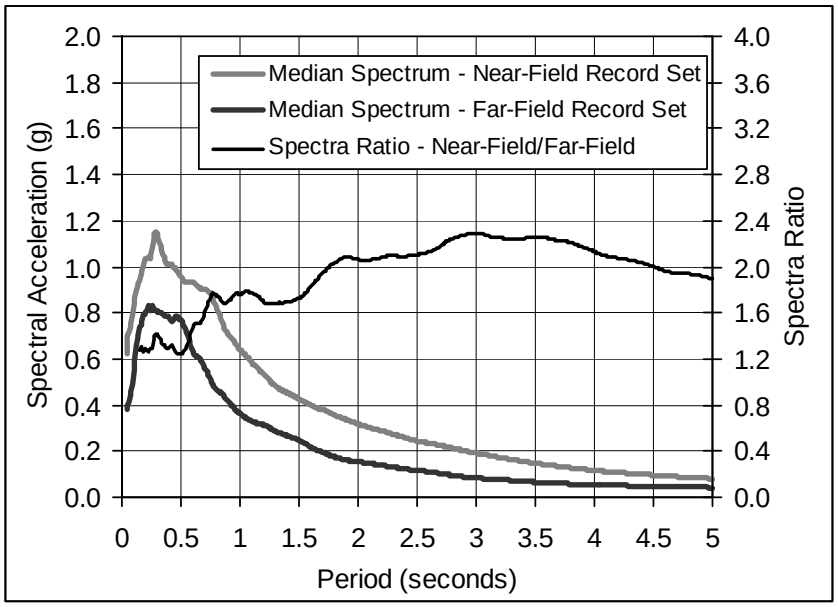

Figure A-9 Median response spectra of normalized Near-Field and Far-Field record sets, and the ratio of these spectra.

Table A-8 Near-Source Coefficients of the 1997 UBC (from Tables 16-S and 16-T, ICBO, 1997)

Spectral Domain	Closest Distance to Fault			
	≤2 km	5 km	10 km	≥15 km
Acceleration	1.5	1.2	1.0	1.0
Velocity	2.0	1.6	1.2	1.0

Figure A-10 compares unscaled median response spectra of the Far-Field record set, the full Near-Field record set, and the fault normal records of the Near-Field Pulse subset. At short periods, the three response spectra are similar, but they diverge significantly at long periods. As expected, at long periods, the median response spectrum of fault normal records of the Near-Field Pulse subset shows substantially greater seismic demand than both the Near-Field and Far-Field record sets.

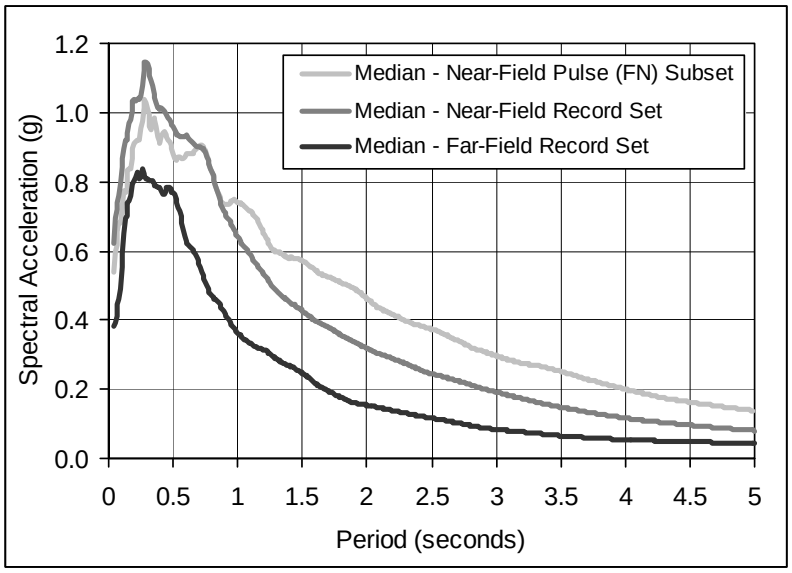

Figure A-10 Median response spectra of the normalized Near-Field record set, the Far-Field record set, and fault normal records of the Near-Field Pulse subset.

Potential differences in collapse margin ratio due to differences in the frequency content of the three record sets are investigated using archetypes of reinforced-concrete special moment-frame structures (i.e., archetypes of Chapter 9, perimeter frame and 30-foot bay configuration). Three archetype heights are considered: 1-story, 4-story and 20-story. In the case of the 20-story archetype, two designs are prepared. One design, 20-Story–NL, is without lower-bound limits on design base shear (i.e., design ignores Equation 12.8-6 of ASCE/SEI 7-05). The other design, 20-Story-02, has

lower-bound base shear limits, including also the base shear limit of Equation 9.5.5.2.1-3 of ASCE 7-02 (ASCE, 2003).

Each reinforced concrete special moment frame archetype is designed in accordance with ASCE/SEI 7-05 criteria for both SDC D_{max} and SDC E design requirements (i.e. one design is prepared for SDC D_{max} and another for SDC E), respectively, with certain exceptions for 20-story archetypes. Note that the SDC E demands were not previously defined in Table A-1, since SDC E is not used in the basic assessment Methodology of this document; SDC E is only used for this comparison, so the SDC E demands are given in Table A-9.

Table A-9 summarizes fundamental periods and seismic design coefficients for each of the eight archetypes. As shown, the seismic coefficients of archetypes designed for SDC E requirements are 20% to 60% greater than those of archetypes designed for SDC D_{max} requirements.

Table A-9 Summary of Key Reinforced-Concrete Special Moment Frame Archetype Properties and Seismic Coefficients Used to Evaluate the Collapse Margin Ratio (*CMR*)

Building Archetype			Seismic Coefficient, C_s		
Height - ID	T (sec.)	C_s Limits	SDC D_{max}	SDC E	Ratio
1-Story	0.26	NA	0.125	0.15	1.2
4-Story	0.81	NA	0.092	0.149	1.6
20-Story - 02	3.36	ASCE/SEI 7-02[1]	0.044[1]	0.053[2]	1.2
20-Story - NL	3.36	None[3]	0.022	0.036	1.6

1. Archetype design includes lower-bound limit of ASCE 7-02, Equation 9.5.5.2.1-3.
2. Archetype design slightly less than $C_s = 0.06$ limit of ASCE/SEI 7-05, Equation 12.8-6.
3. Archetype design ignores lower-bound limit of ASCE/SEI 7-05, Equation 12.8-6.

Tables A-10A and A-10B summarize collapse margin ratios (*CMR*'s) for the eight archetypes of Table A-9. In both tables, *CMR*s of the four archetypes designed and evaluated for SDC D_{max} (far-field) sites are compared with *CMR*'s of the same four archetypes designed and evaluated for SDC E (near-field) sites.

Table A-10A compares two *CMR* values computed for SDC E sites, against the baseline *CMR* values (for SDC D_{max} design assessed using the far-field ground motion set). The SDC E *CMR* values are computed both (a) using the Far-Field ground motion set, and (b) using the Near-Field ground motion set. Both sets are anchored to SDC E demands (from Table A-9) according to section A.8. Note that the near-field record set should be used when

assessing performance at a SDC E (near-field) site; the far-field set is only used for comparison and to help explain the observed differences between the computed *CMR* values for SDC E and SDC D_{max} sites.

Table A-10A Summary of Selected Collapse Margin Ratios (*CMR*s) for Reinforced-Concrete Special Moment Frame Archetypes – Comparison of *CMR*s for Far-Field and Near-Field Record Sets

Building Archetype	Far-Field Baseline (Sdc D_{max})	Near-Field Designs Evaluated For Sdc E Seismic Demand (Mce)			
		Near-Field Record Set		Far-Field Record Set	
Height - ID	*CMR*	*CMR*	*CMR*/ Baseline	*CMR*	*CMR*/ Baseline
1-Story	1.26	0.86	68%	1.03	82%
4-Story	1.98	1.32	67%	1.55	78%
20-Story - 02	1.62	1.34	83%	1.39	86%
20-Story - NL	0.82	1.01	123%	0.91	111%

Table A-10A shows the *CMR* values for SDC E sites, computed using both the Far-Field and Near-Field record sets. When the Near-Field record set is used for the SDC E evaluation, the *CMR* is an average of 30% lower as compared to SDC D_{max} (with the exception of the 20-Story-NL archetype, which will be discussed later).

This 30% difference is caused by two aspects: (1) the higher seismic demand of SDC E (it has been shown in Chapter 9 that *CMR* values are typically lower for buildings designed and assessed for higher seismic demands) and (2) the use of the Near-Field record set instead of the Far-Field set. To clearly separate these two effects, columns two and five show the *CMR* values for SDC D_{max} and SDC E, respectively, both evaluated using the Far-Field record set. This shows that the *CMR* values are an average of 20% lower for SDC E, simply due to SDC E having higher seismic demand. This shows that the use of Near-Field records, rather than Far-Field records, only leads to an average 10% reduction in the *CMR*.

Table A-10B shows how low the *CMR* could become if one used only the subset of Near-Field motions which are fault-normal and have pulses. However, this is not recommended for performance evaluation. For comparison, this table also replicates the results from the full Near-Field set. This table shows that the resulting CMR values are an average of 45% lower than the baseline SDC D_{max} case, and 15% lower than the values computed when the full Near-Field set is utilized.

Table A-10B Summary of Selected Collapse Margin Ratios (*CMR*s) for Reinforced-Concrete Special Moment Frame Archetypes - Comparison of *CMR*s for the Near-Field Record Set and the Near-Field Pulse FN Record Subset

Building Archetype	Far-Field Baseline (SDC D_{max})	Near-Field Designs Evaluated for SDC E Seismic Demand (MCE)			
		Near-Field Record Set		NF - Pulse FN Subset	
Height - ID	*CMR*	*CMR*	*CMR*/ Baseline	*CMR*	*CMR*/ Baseline
1-Story	1.26	0.86	68%	0.67	53%
4-Story	1.98	1.32	67%	0.99	50%
20-Story - 02	1.62	1.34	83%	0.92	57%
20-Story - NL	0.82	1.01	123%	0.70	85%

The 20-Story-NL archetype is the only building that does not follow the trends described in the preceding discussion. One possible reason for this is that the minimum base shear limit was not imposed in this design, which caused the design strengths to become very low (C_s = 0.022 g to 0.036 g), and the collapse capacity of extremely weak structures becomes more sensitive to changes in design strength. Another possible contributing factor is that the fundamental period, T_1, is longer for this design, and the spectral shapes change slightly for periods above 3.5 seconds (see Figure A-9).

In summary, as compared to Far-Field motions, when a structure is subjected to the full set of Near-Field records, the *CMR* is typically 10% lower. However, when a structure is subjected to the subset of FN pulse-type records, the *CMR* is decreased by about 25%. This shows that the increase in the seismic response coefficient, C_s, required for design of structures located near faults does not appear sufficient to result in performance comparable to that of the same system (i.e., same *R* factor) located further away from fault rupture.

Tables A-10A and A-10B also show that without lower-bound limits on design base shear, collapse margins for the 20-Story-NL archetype are very low; but with lower-bound limits, collapse margins for the 20-Story-02 archetype are approximately the same as the 4-Story archetype. While the margins for the 20-Story-NL archetype are very low, it should be noted that a 60% increase in SDC E design strength affects comparable or better performance than the baseline (SDC D) archetype. In fact, a 60% increase in design base shear is able to cause about the same collapse margin for the 20-Story-NL (SDC E) archetype, when evaluated with fault normal components of the Near-Field pulse records, as that of the 20-Story-NL archetype (SDC D) evaluated with Far-Field records (Table A-10B).

A.12 Robustness of Far-Field Record Set

The purpose of this Methodology is to assess the collapse safety of newly proposed structural systems. To this end, the record selection criteria of section A.7 result in an appropriate set of strong ground motions that are representative of those that may cause collapse of a new building (to the extent possible, given the limited number of recordings available).

This section evaluates the "robustness" of the ground motion selection criteria to demonstrate that the final collapse capacity predictions are not highly sensitive to small changes to the selection criteria. Specifically, the peak ground acceleration (PGA) > 0.2g and peak ground velocity (PGV) > 15cm/s limits are evaluated, as well as the requirement that the two highest PGV records be selected when there are many candidate records for an event. The other selection criteria are not investigated here because they are less subjective, or in the case of magnitudes larger than M6.5, small changes to this requirement are expected to have minimal impact on the collapse capacity predictions.

A.12.1 Approach to Evaluating Robustness

To investigate the effects of the PGA and PGV selection criteria, a set of 192 records is selected based on liberal criteria (PGA > 0.05g and PGV > 3cm/s). To reduce the number of ground motions, and still maintain the selection criteria, 20 pairs of motions are randomly selected from each event. This affected the records from Chi-Chi (261 candidate records), Loma Prieta (53 records), Northridge (70 records), and Landers (24 candidate records).

To evaluate the quantitative differences between ground motion sets, each set is used to predict the median collapse capacity (the *CMR* and *ACMR*) of three reinforced concrete special moment frame building archetypes. To cover the range of structural periods, the following building archetypes are utilized in these comparisons: 1-story reinforced concrete special moment frame (T = 0.26 s), 4-story reinforced concrete special moment frame (T = 0.81 s), and a 12-story reinforced concrete special moment frame (T = 2.13 s). These are three archetypes are taken from the reinforced concrete special moment frame example of Section 9.2. Each archetype is a perimeter-frame systems designed for SDC D_{max} seismic criteria. Table A.11 summarizes design properties and collapse margin results for these archetypes.

Table A-11 Summary of Design Properties and Collapse Margins of the Three Reinforced Concrete Special Moment Frame Building Archetypes Used to Evaluate Far-Field Record Set Robustness

Archetype Design ID No.	Design Configuration and Properties				Collapse Margin	
	No. of Stories	Framing Type	Seismic SDC	Period *T* (sec.)	*CMR*	*ACMR*
2061[1]	1	P	D_{max}	0.26	1.96	2.61
1003[1]	4	P	D_{max}	0.81	1.61	2.27
1013[2]	12	P	D_{max}	2.13	1.45	2.33

1. Design data and collapse margins taken from Tables 9-2, 9-3 and 9-8.
2. Design data and collapse margins taken from Tables 9-9 and 9-10.

A.12.2 Effects of PGA Selection Criteria Alone

Table A-12 shows the effects that the minimum PGA requirement has on the computed values of *CMR*. This table includes results for PGA > 0.05g (192 records), PGA > 0.10g (105 records), PGA > 0.15g (62 records), and PGA > 0.20g (36 records). These results clearly show that the *CMR* values increase as the minimum PGA limit is increased. Comparing the PGA limit of 0.05g and 0.20g, the *CMR* increases 31% for the 1-story building, 19% for the 4-story building, and 10% for the 12-story building, with an overall average value of 20%. The PGA limit, unsurprisingly, has a more significant effect on shorter-period structures.

Table A-12 Effects of the PGA Selection Criterion on the Computed *CMR* Values for Three Reinforced Concrete Special Moment Frame Buildings

Selection Criteria and Number of Selected Records				
Min PGA (g)	0.05	0.10	0.15	0.20
Min PGV (cm/s)	3.0	3.0	3.0	3.0
No. of Records	192	105	62	36
Arch. ID No.	*CMR*			
2061	1.76	1.97	2.24	2.31
1003	1.26	1.36	1.39	1.51
1013	1.41	1.46	1.49	1.56
Mean Value	**1.48**	**1.60**	**1.71**	**1.79**

However, the *CMR* is not the appropriate parameter for use in a complete comparison of the ground motion sets. The Adjusted Collapse Margin Ratio (ACMR) value should be used because it is the complete collapse capacity result after accounting for the effects of spectral shape. In order to compute the *ACMR* values, we must compute the Spectral Shape Factor values, as

discussed in Appendix B. The following discussion provides the rationale for approximate *SSF* values that can be used to compute approximate values of *ACMR* for this comparison.

Appendix B will show that the *SSF* value is, in part, based on the mean ε values of the ground motion set. Figure A-11 shows these mean ε values for the Far-Field ground motion set, and it can be reasoned that the mean ε values of the PGA > 0.20 g set (36 records) should be similar due to the similarities in the selection criteria of the two sets. In contrast, the PGA > 0.05 g (192 records) set is more representative of all possible records, so the mean ε values is expected to be approximately zero at all periods. This observation suggests that the high PGA limit used for the Far-Field set is causing the observed mean $\varepsilon = 0.6$ at short periods.

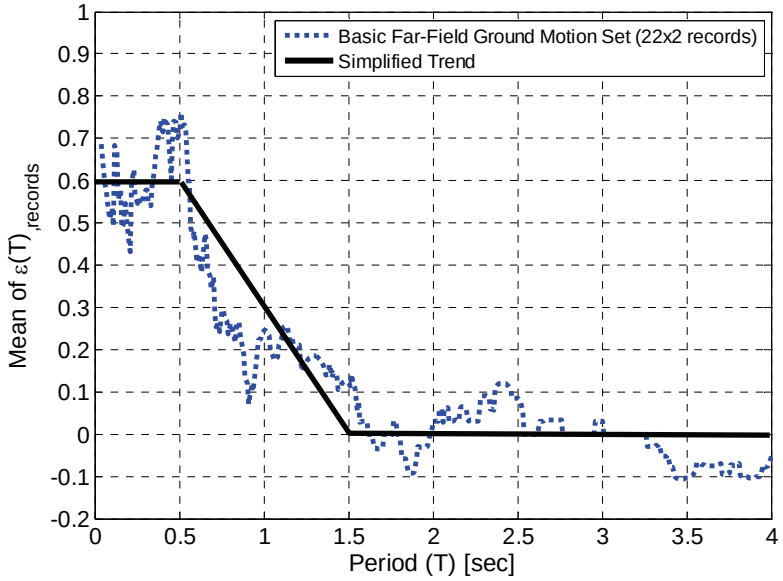

Figure A-11 Mean ε values, $\bar{\varepsilon}(T)_{,\text{records}}$, for the Far-Field ground motion set (duplicated from Figure B-3 of App. B).

Using the above rationale, Table A-13 presents the approximate *SSF* and *ACMR* values for the sets selected with PGA > 0.05 g (192 records) and PGA > 0.20 g (36 records). This shows that the differences in the mean ε values counteract much of the trend seen with the *CMR* values. For the three buildings considered here, the *ACMR* value increases by an average of 8% when the ground motions are selected based on PGA > 0.20 g rather than a more liberal selection using PGA > 0.05 g.

Table A-13 **Effects of the PGA Selection Criterion on the Approximate *ACMR* Values for Three Reinforced Concrete Special Moment Frame Buildings**

Selection Criteria and Number of Selected Records				
Min PGA (g)	0.05	0.20	0.05	0.20
Min PGV (cm/s)	3.0	3.0	3.0	3.0
No. of Records	192	36	192	36
Arch. ID No.	**approx. *SSF***		**approx. *ACMR***	
2061	1.61	1.33	2.83	3.07
1003	1.61	1.41	2.04	2.12
1013	1.61	1.61	2.27	2.51
Mean Value	**1.61**	**1.45**	**2.38**	**2.57**

A.12.3 Effects of PGV Selection Criteria Alone

Similar to previous PGA comparisons, Table A-14 shows the effect that the minimum PGV requirement has on the CMR. This shows that the impacts of the PGV requirement vary for the three buildings considered. Comparing the PGV limit of 3 cm/s and 15 cm/s, the CMR decreases 14% for the 1-story building, decreases 2% for the 4-story building, and increases 5% for the 12-story building, with an overall average decrease of 5%.

Table A-14 **Effects of the PGV Selection Criterion on the Computed *CMR* Values for Three RC SMF Buildings**

Selection Criteria and Number of Selected Records				
Min PGA (g)	0.05	0.05	0.05	0.05
Min PGV (cm/s)	3.0	5.0	10.0	15.0
No. of Records	192	186	130	85
Arch. ID No.	**approx. *SSF***		**approx. *ACMR***	
2061	1.76	1.73	1.59	1.50
1003	1.26	1.26	1.20	1.24
1013	1.41	1.42	1.47	1.48
Mean Value	**1.48**	**1.47**	**1.42**	**1.41**

For evaluating the PGV selection criterion, comparing the *CMR* value is sufficient (comparison of *ACMR* is not needed) because the PGV value is expected to affect the mean ε values at moderate or long periods. Since Figure A-11 showed that even the Far-Field set (selected for high PGV > 15 cm/s) has $\varepsilon = 0$ at moderate/long periods, it is expected that the other larger ground motion sets should also have $\varepsilon = 0$ at those periods. Therefore, the *SSF* values should approximately equal for each of the record sets shown in Table A-14.

A.12.4 Effects of both PGA and PGV Selection Criteria Simultaneously, as well as Selection of Two Records from Each Event

The previous sections investigated the minimum PGA and PGV selection criteria *individually*, and showed that they have somewhat counteracting effects on the resulting collapse capacity predictions (*CMR* and *ACMR*). To create the Far-Field record set, these two criteria are imposed *simultaneously*, and then two records are selected from each event. To select the two records from each event, the records with highest PGV are used.

Table A-15 shows results of this progression to obtain the final Far-Field ground motion set (final Far-Field set results shown in bold-italic). The three ground motion sets used to produces the collapse results shown in this table were selected as follows:

Set 1. Set selected using liberal selection criteria, with PGA > 0.05 g and PGV > 3 cm/s, and 20 records selected randomly from each event (192 records).

Set 2. Set selected from the above set of 192, but with strict imposed selection criteria of PGA > 0.20g and PGV > 15 cm/s (32 records).

Set 3. Set selected using the strict selection criteria, of PGA > 0.20 g and PGV > 15 cm/s, and two records with the highest PGV selected from each event (22 records). This is the final Far-Field record set used in the Methodology. Note that due to slight differences in the scaling method, the *CMR* values do not match exactly with those reported elsewhere in this report, so relative comparisons should be made of values within this table.

The results in Table A-15 follow directly from the trends shown previously for PGA and PGV criteria alone. Comparing Set 1 and Set 2, the *CMR* value increased by an average of 18% (*CMR* = 1.48 versus 1.74), which is driven mostly by the effects of the PGA selection criterion and the resulting differences in spectral shape. The selection of two high-PGV records from each event make the difference reduce to 12% when comparing Set 1 to Set 3 (*CMR* = 1.48 versus 1.65).

Table A-15 **Effects of the PGA and PGV Selection Criteria on the Computed *CMR* and *ACMR* Values, for Three Reinforced Concrete Special Moment Frame Buildings, as well as The Effects of Selecting Two Records from Each Event**

Selection Criteria and Number of Selected Records									
Record Set No.	1	2	3	1	2	3	1	2	3
Min PGA (g)	0.05	0.20	0.20	0.05	0.20	0.20	0.05	0.20	0.20
Min PGV (cm/s)	3.0	15.0	15.0	3.0	15.0	15.0	3.0	15.0	15.0
Record Selection[1]	Rand	Rand	High	Rand	Rand	High	Rand	Rand	High
No. of Records	192	32	22	192	32	22	192	32	22
Arch. ID No.	***CMR***			**approx. *SSF***			**approx. *ACMR***		
2061	1.76	2.06	1.94	1.61	1.33	1.33	2.83	2.73	2.58
1003	1.26	1.53	1.43	1.61	1.41	1.41	2.04	2.16	2.01
1013	1.41	1.62	1.59	1.61	1.61	1.61	2.27	2.61	2.56
Mean Value	**1.48**	**1.74**	**1.65**	**1.61**	**1.45**	**1.45**	**2.38**	**2.50**	**2.38**

1. "Rand" indicates random selection from candidate records and "High" indicates biased selection from candidate records based on highest PGV values (Sec. A.7).

As with the previous comparisons of the PGA selection criterion, the differences in the *SSF* value account for most of the above differences in *CMR*, and cause the differences in *ACMR* to be much smaller. Comparing Set 1 and Set 2, *ACMR* increased by only an average of 5% (*CMR* = 2.38 versus 2.50). The selection of the two high-PGV records from each event eliminate the difference when comparing the Set 1 to Set 3 (*CMR* = 2.38 versus 2.38). Note that this average difference of 0% is rather coincidental, and the individual differences are non-zero, being -9%, -1%, and +13%, for the three buildings considered. Even the individual 1% to 13% differences in median collapse capacity are very small when comparing two sets of ground motions that were selected based on such different selection criteria.

A.12.5 Summary of the Robustness of the Far-Field Set

ACMR collapse capacity results are not highly sensitive to the PGA and PGV selection criteria or to the approach used to select the two motions from each event. More specifically, when comparing the Far-Field set (Set 3) to a set of records selected with much looser PGA and PGV criteria, the *ACMR* values vary between -9% to +13% for the three buildings considered, with an average difference of 0% which is partially coincidence when using such a small sample size. Relatively speaking, these differences of 0% to 13% are exceptionally small when comparing two ground motion sets selected using such differing criteria. This shows that the Far-Field ground motion set can be considered robust with respect to these selection criteria.

A.13 Assessment of Record-to-Record Variability in Collapse Fragility

According to the Methodology, the ground motion record set is scaled as described in Section A.8 in order to evaluate the median collapse capacity, $\hat{S}_{CT}$. To assess the collapse probability and accordingly the *ACMR* acceptance criteria, an estimate of the record-to-record variability in collapse capacity (β_{RTR}) is also needed. β_{RTR} is the lognormal standard deviation associated with uncertainty in response of an archetype structure due to differences in frequency content and other characteristics of ground motion records. Through the course of this project, it has become evident that β_{RTR} values are relatively consistent across different types of structures, so a fixed value of $\beta_{RTR} = 0.40$ is used in the Methodology for most structures. This section validates the choice of the 0.40 value, but shows that for structures that have limited period elongation before collapse, $\beta_{RTR} < 0.40$ is appropriate and provides guidance on how to determine β_{RTR} for these structures.

Record-to-record variability in the collapse fragility for a particular structure can be computed from the results of incremental dynamic analysis of the ground motion record set. The value of β_{RTR} obtained will depend on the scaling and normalization of the records. Two normalization and scaling methods are considered:

1. The PGV normalization method developed in this Methodology and described in Section A.8 normalizes the records by PGV and then scales the normalized record set as a group, in order to determine the median collapse capacity. An illustration of the scaled Far-Field record set is shown in Figure A-3.

2. An alternative method, termed S_a-component scaling, scales records according to the component spectral acceleration of each record individually evaluated at the period of the building. When this method is utilized, all records have exactly the same spectral acceleration at the period of interest. This is in contrast to the PGV normalization method, which maintains variability at all periods. This method is commonly used in research applications and is conceptually appealing because each individual record individually matches the target S_a level. In addition, this scaling method avoids double counting of uncertainties in prediction of the mean annual frequency of collapse, a frequently used metric of seismic performance.

The advantage of the PGV normalization method is that the entire record set can be scaled by the same scale factor, shown in Table A-3. This significantly reduces the complexity of the calculations for the user of this

Methodology. S_a-component scaling requires computing different scale factors for each record at each different period of interest.

Differences between the PGV normalization method and the S_a-component scaling method are illustrated in Figures A-12 and A-13. Figure A-12 compares the median of the record sets according to the two scaling methods. The median spectral acceleration of the records at all periods is virtually the same under the two scaling methods. Also, the median of the set under the S_a-component method does not depend on the period at which the scaling occurs. For this reason, it can be shown that the computed median collapse capacity will be the same regardless of which scaling procedure is used (see Appendix 6B of Haselton and Deierlein, 2007).

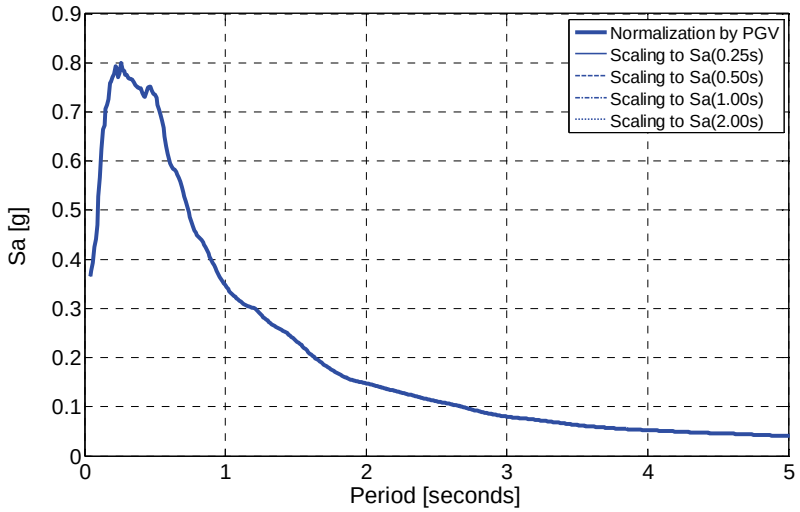

Figure A-12 Comparison of median spectra under the FEMA P695 normalization/scaling method and the S_a-component scaling method (scaled to four different periods: 0.25 s, 0.50 s, 1.0 s, and 1.2 s). The five curves on this plot are virtually indistinguishable.

Figure A-13 compares the logarithmic standard deviation of the spectral ordinates, $\sigma_{LN,Sa}$, for different scaling methods. The PGV normalization method gives relatively constant values of the $\sigma_{LN,Sa}$, regardless of the period of interest. For the S_a-component method, $\sigma_{LN,Sa}$ is zero at the period of interest, since all records have the same spectral ordinate. Away from the scaling period, $\sigma_{ln,Sa}$ values obtained from S_a-component scaling are similar to those obtained in the FEMA P695 approach.[1] Values of $\sigma_{LN,Sa}$ obtained from

[1] The $\sigma_{LN,Sa}$ values obtained by S_a-component scaling are notably larger at long periods away from the scaling period. The PGV normalization avoids this high uncertainty. Regardless, $\sigma_{LN,Sa}$ at long periods are not expected to significantly

S_a-component scaling indicate that the β_{RTR} for brittle structures, which collapse at periods close to the period of the building, T, is expected to be smaller than the β_{RTR} for structures that undergo significant period elongations before collapse. For brittle systems, S_a-component scaling avoids double-counting of record-to-record variability that occurs in the PGV normalization method due to the enforced variation in the record set at all periods.

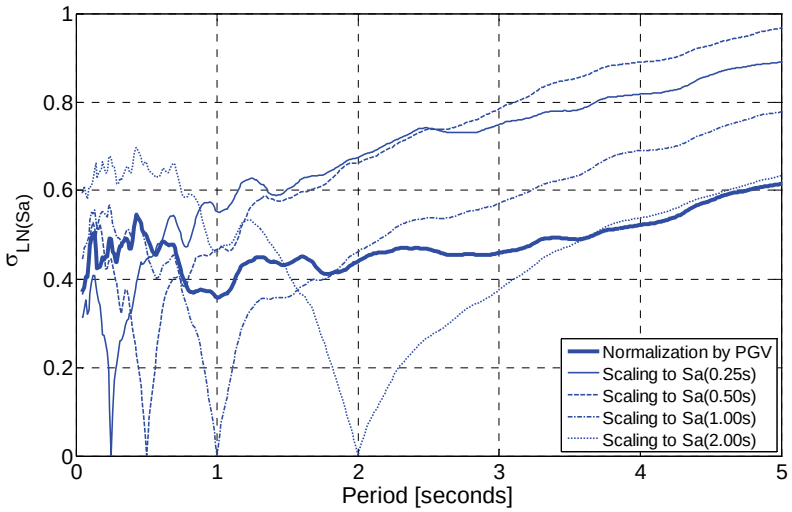

Figure A-13 Comparison of logarithmic standard deviation of spectral ordinates, $\sigma_{LN,Sa}$, for FEMA P695 scaling method and S_a-component scaling method at different periods.

To investigate the relationship between β_{RTR} and the building period elongation prior to collapse, β_{RTR} values were computed using the S_a-component scaling method for the reinforced concrete special moment frames and ordinary moment frames discussed in Chapter 9. Note that some ordinary moment frame data include hypothetical brittle non-simulated failure modes in order to get data points for very brittle systems. Period elongation is quantified by the period-based ductility parameter, μ_T, defined as the ratio of ultimate roof drift to the yield roof drift: $\mu_T = \delta_u/\delta_{y,eff}$ (see Appendix B and Chapter 7 for more details; period elongation prior to collapse would approximately be the square-root of this ratio).

The relationship between β_{RTR} and period-based ductility, μ_T, is shown in Figure A-14. The reinforced concrete special moment frames have an average period-based ductility, $\mu_T = 9$, and average $\beta_{RTR} = 0.4$ in the collapse fragility. Because these structures undergo significant period elongation

impact predicted structural response because the periods with high $\sigma_{ln,Sa}$ are far away from the scaling period (the elastic period of the building).

before collapse, they respond away from the pinched region of the spectrum. For reinforced concrete ordinary moment frames, which undergo less period elongation prior to collapse, Figure A-14 reveals smaller average β_{RTR} values, and shows that the β_{RTR} value clearly reduces as the building becomes less ductile (for $\mu_T < 3$).

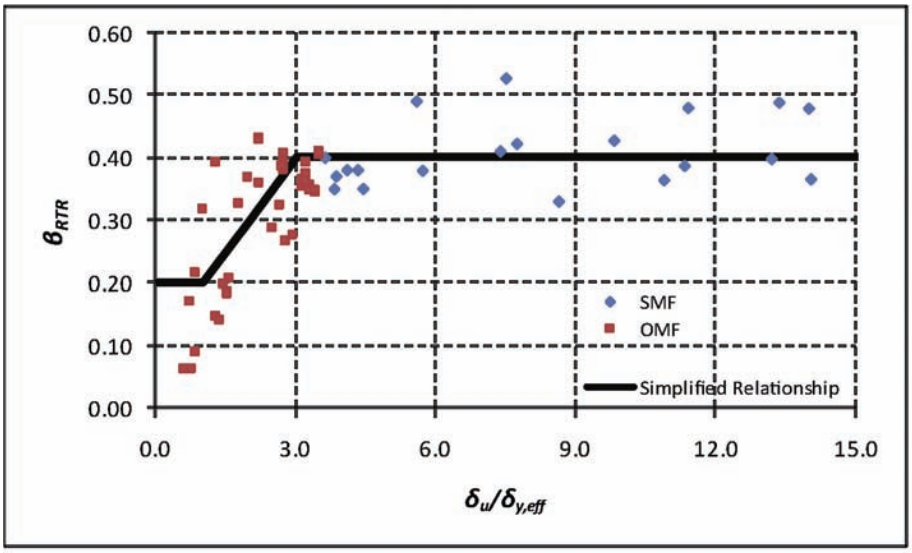

Figure A-14 Relationship between period-based ductility ($\mu_T = (\delta_u/\delta_{y,eff})$ and record-to-record variability (β_{RTR}) from collapse data for reinforced concrete frames. The FEMA P695 simplified relationship for predicting β_{RTR} is superimposed.

Figure A-14 also superimposes the FEMA P695 simplified relationship for predicting β_{RTR}. Most structures are relatively ductile and have $\mu_T > 3$. For these structures β_{RTR} should be taken as 0.40 and the totally system collapse uncertainty is given by Table 7-2. For structures with $\mu_T \leq 3$, β_{RTR} can be reduced according to Equation A-4:

$$\beta_{RTR} = 0.1 + 0.1\mu_T \leq 0.4 \quad \text{(A-4)}$$

where β_{RTR} must be greater than or equal to 0.2. If Equation A-4 is used, the total system collapse uncertainty can be computed according to Equation 7-4, repeated below:

$$\beta_{TOT} = \sqrt{\beta^2_{RTR} + \beta^2_{DR} + \beta^2_{TD} + \beta^2_{MDL}} \quad \text{(A-5)}$$

Values of β_{TOT} obtained should be rounded to nearest 0.05 for use in Table 7-3.

This reduction in β_{RTR} is expected to apply only to a limited number of structural systems that are either very brittle or unusual structures that have limited period elongation prior to collapse, such as base-isolated structures.

A.14 Summary and Conclusion

This appendix describes the Far-Field and Near-Field record sets and the scaling methods appropriate for collapse evaluation of building archetypes using IDA.

Both the Far-Field and Near-Field record sets have average ε values that are lower than expected for MCE motions, and therefore can substantially underestimate the *CMR* without appropriate adjustment for spectral shape effects. The adjustment method is discussed in Section 7.4 and Appendix B.

The Far-Field record set is generally appropriate for collapse evaluation of buildings, but can slightly overestimate the *CMR* of buildings at sites close to fault rupture (e.g., distances less than 10 km).

The Near-Field record set is generally appropriate for collapse evaluation of buildings at sites close to fault rupture (i.e., distances less than 10 km). Note that the Near-Field record set is not specifically required as part of the basic assessment Methodology. Even so, the Near-Field record set was developed for comparative purposes and is documented here to both substantiate the earlier comparisons and for use in other studies.

Appendix B

Adjustment of Collapse Capacity Considering Effects of Spectral Shape

This appendix describes the background and development of simplified spectral shape factors that depend on the fundamental period of the building, as well as the expected elongation of structural period as the structure collapses. These factors are used to adjust the collapse capacity to account for the frequency content (spectral shape) of the ground motion record set.

B.1 Introduction

A challenge associated with analytical prediction of structural collapse is the selection of ground motions for use in dynamic analysis. A characteristic of ground motions that can affect collapse capacity is the spectral shape. For rare ground motions in California, such as Maximum Considered Earthquake (MCE) ground motions, the spectral shape is much different than the shape of a structural design spectrum contained in ASCE/SEI 7-05 (ASCE, 2006a) or a uniform hazard spectrum (Baker, 2005; Baker and Cornell, 2006).

Figure B-1 shows the acceleration spectrum of a Loma Prieta ground motion[1] (PEER, 2006a). This motion has a MCE intensity at a period of 1.0 second, which is S_a(1.0 sec) = 0.9 g for this example. This spectrum is labeled as "2% in 50 year S_a" which is the same as the MCE for this site. This figure also shows the intensity predicted by the Boore et al. (1997) attenuation prediction, consistent with the event and site associated with this ground motion. These predicted spectra include the median spectrum and the plus/minus one and two standard deviation spectra, assuming that S_a values are lognormally distributed.

[1] This motion is from the Saratoga station and is owned by the California Department of Mines and Geology. For this illustration, this spectrum was scaled by a factor of +1.4, in order to make the S_a(1 s) demand the same as the MCE demand. For the purposes of this example, please consider this spectrum to be *unscaled*, since later values (e.g., ε) are computed using unscaled spectra.

In Figure B-1, this MCE motion has an unusual spectral shape with a "peak" from 0.6 to 1.8 seconds that is much different from the shape of a uniform hazard spectrum. This peak occurs around the period for which the motion is said to have an MCE intensity, and at this period the observed S_a(1 s) is much higher (0.9 g) than the mean expected S_a(1 s) from the attenuation function (0.3 g). This peaked shape makes intuitive sense because it seems unlikely that a ground motion with a much larger than expected spectral acceleration (meaning much higher than the mean expected) at one period would have similarly large spectral accelerations at all other periods.

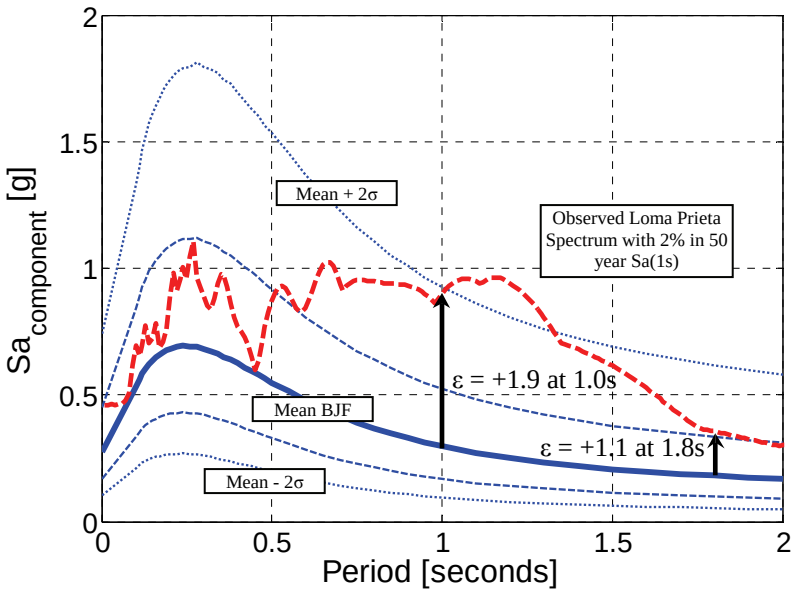

Figure B-1 Comparison of an observed spectrum with spectra predicted by Boore, Joyner, and Fumal (1997); after Haselton and Baker (2006).

Epsilon, ε, is defined as the number of logarithmic standard deviations between the observed spectral value and the median prediction from an attenuation function. At a period of 1.0 second, the spectral value is 1.9 logarithmic standard deviations above the predicted mean spectral value, so this record is said to have "ε = 1.9 at 1.0 second." Similarly, this record has ε = 1.1 at 1.8 seconds. Thus, the ε value is a function of the ground motion record, the period of interest, and the attenuation function used for ground motion prediction.

Trends shown in Figure B-1 are general to sites in coastal California where ε values ranging from 1.0 to 2.0 are typically expected for the MCE (or 2% in 50 year) ground motion level. These positive ε values come from the fact that the return period of the *ground motion* (i.e., 2,475 years for a 2% in 50 year motion) is much longer than the return period of the *event* that causes

the ground motion (i.e., 150-500 years for typical events in California). Record selection for structural analyses at such sites should reflect the expected ε for the site and the ground motion hazard level of interest.

It should be noted that the expected ε value is both hazard-level and site dependent. For example, for 50% in 5 year ground motions in coastal California, ε values ranging from 0.5 to -2.0 are expected (Haselton et al., 2007, chapter 4). In the eastern United States, ε values ranging from 0.25 to 1.0 are expected for a 2% in 50 year motion. Negative ε values for a 50% in 5 year motion stems from the fact that the return period of the *ground motion* (i.e., 10 years) is much shorter than the typical return period of the *event* that causes the ground motion (e.g., 150 to 500 years). The Eastern United States has low positive ε values because seismic events are less frequent than in California, but the return periods are still shorter than the return period of a 2% in 50 year motion (i.e., 2,475 years).

Collapse capacity is defined as the $S_a(T_1)$ value that causes dynamic sidesway collapse (termed S_{CT1}). Research has shown that collapse capacity is higher for motions with a peaked spectral shape relative to motions without a peaked spectral shape. This is especially true when the peak of the spectrum is near the fundamental period of the building (T_1), and ground motions are scaled based on $S_a(T_1)$ (Haselton and Baker, 2006; Baker, 2006; Baker, 2005; Goulet et al., 2006; Zareian, 2006). Spectral accelerations at periods other than T_1 are often important to the collapse response of a building. For example, the period elongation as the building responds inelastically makes spectral values for period greater than T_1 to become important to collapse response. In addition, higher mode effects make periods less than T_1 to also become important to collapse response. Positive ε peaked spectra typically have lower spectral demands at periods away from T_1.

Past studies have shown that if $\varepsilon(T_1) = 0$ ground motions are used when $\varepsilon(T_1) = 1.5$ to 2.0 ground motions are appropriate, the median collapse capacity is under-predicted by a factor of 1.3 to 1.8 for relatively ductile structures. In cases where it is expected that the collapse-level ground motions will have high positive $\varepsilon(T_1)$ values, such as with modern buildings in high seismic areas of California, properly accounting for these values is critical.

The most direct approach to account for spectral shape is to select ground motions that have the appropriate $\varepsilon(T_1)$ expected for the site and hazard level of interest. This approach is difficult when assessing the collapse capacities of many buildings with differing T_1, because it would require a unique ground motion set for each building. To address this issue, this Appendix develops a simplified method which involves the use of a general set of

ground motion records (selected independent of ε values), and a correction to the median collapse capacity estimates to account for spectral shape. In this process, the spectral shape is quantified by the $\varepsilon(T_1)$ value expected for the site and hazard level of interest.

B.2 Previous Research on Simplified Methods to Account for Spectral Shape (Epsilon)

Several recent studies have focused on how spectral shape (ε) affects collapse capacity and pre-collapse structural responses (Baker, 2006; Baker, 2005; Goulet et al., 2006; Haselton and Baker, 2006; Zareian, 2006). This Appendix does not attempt to present a full literature review of this past work.

The purpose of this Appendix is to develop a simplified method to account for spectral shape, ε. One recent study by Haselton and Deierlein (2007, Chapter 3) developed such a method, and the following is an overview of their work.

To develop the simplified method, Haselton and Deierlein first predicted the collapse capacities (in terms of S_{CT1}) of 65 modern reinforced concrete special moment frame buildings. For the collapse assessment of each building, 80 ground motions were utilized, with the goal of finding a relationship between the collapse capacity, S_{CT1}, and $\varepsilon(T_1)$. For illustration purposes, Figure B-2 shows an example of representative findings for a single building[2]. This figure shows the results of linear regression analysis that is used to define the relationship: $\text{LN}[S_{CT1}] = \beta_0 + \beta_1\varepsilon$. The value of β_0 indicates the average collapse capacity when $\varepsilon = 0$, and the value of β_1 indicates how sensitive the collapse capacity, S_{CT1}, is to changes in the ε value. To achieve the goal of a simplified correction method, the β_1 value is a required ingredient. For this specific building, $\beta_1 = 0.315$.

It is observed from Figure B-2 that there is a great deal of scatter in the data. Even so, the p-value for the regression is $1.3\text{x}10^{-6}$, which shows that the trend between collapse capacity and $\varepsilon(T_1)$ is statistically significant (note that the p-value must only be less than 0.01-0.05 for the trend to be statistically defensible, and this value is orders of magnitude smaller). Additionally, similar statistically significant trends are observed for the 118 buildings considered in this study (discussed later in section B.3.3), so this adds

[2] This figure is representative of findings by Haselton and Deierlein, but this specific figure is taken from collapse analyses of a 5-story wood light-frame building, which was investigated as part of this current study (model No. 15; R = 6, wood-only), and is used in a later section of this Appendix.

confidence for utilizing these observed trends in an adjustment method to account for proper spectral shape, ε.

As a side note, this observed scatter in the data (Figure B-2) also suggests that using a spectral shape correction method will increase the overall uncertainty in the median collapse capacity estimate. This is true, but accounting for the trend with ε also decreases the record-to-record variability. To approximately account for both of these effects in a simple manner, we will (a) use a record-to-record variability of 0.4, which neglects the reduction in record-to-record variability associated with ε-selected records, and (b) neglect the additional uncertainty associated with the variability in the Figure B-2 regression line.

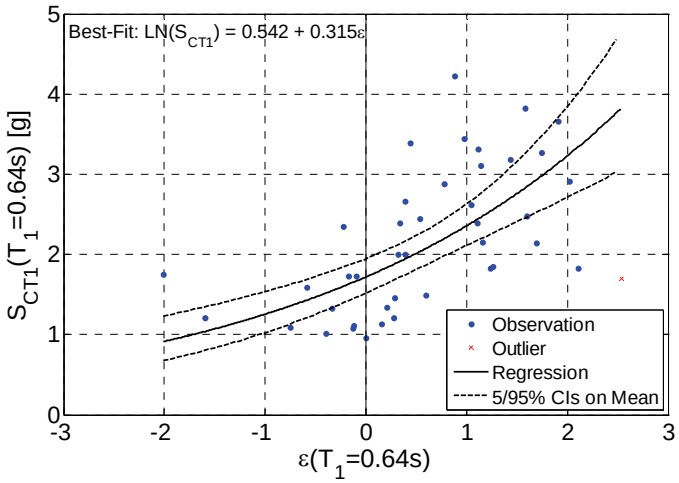

Figure B-2 Relationship between collapse spectral acceleration, S_{CT1}, and $\varepsilon(T_1)$ for a single 5-story wood light-frame building (No. 15; R = 6 design, wood-only model). This includes linear regression analysis results which relate LN[$S_{CT1}(T_1)$] to $\varepsilon(T_1)$, along with confidence intervals (CIs) for the best-fit line. For this example, β_0 = 0.524 and β_1 = 0.315.

The study by Haselton and Deierlein (2007) found an average value of β_1 = 0.29 to be exceptionally consistent for modern reinforced concrete special moment frame buildings with various heights (1-story to 20-stories) and various designs, such as perimeter frame, space frame, and various bay widths.

The relationship between β_1 and inelastic building deformation capacity was also investigated. For buildings with larger inelastic deformation capacity, the effective period elongates more prior to structural collapse. This causes spectral values at period above T_1 to have larger impact on collapse response, and subsequently causes the spectral shape of the ground motion to become

more important (thus increasing β_1). To investigate the impact of inelastic building deformation capacity, a set of 26 1967-era RC frame buildings was investigated in the same manner as the previous set of reinforced concrete special moment frame buildings. This revealed an average value of β_1 = 0.18, which is 35% lower than that of the reinforced concrete special moment frame buildings; this confirms that the ground motion spectral shape, ε, is less important for buildings with lower deformation capacity. To further add to the comparison, a set of 20 reinforced concrete ordinary moment frame buildings was also considered, which showed an average value of β_1 = 0.19, consistent with the finding for the 1967-era reinforced concrete frame buildings.

Using a subset of the above data, Haselton and Deierlein created a simplified equation that predicts β_1 based on the deformation capacity of the building (judged from static pushover) and the building height.

This Appendix expands on the work by Haselton and Deierlein, and proceeds to create an adapted version of their simplified methodology.

B.3 Development of a Simplified Method to Adjust Collapse Capacity for Effects of Spectral Shape (Epsilon)

The simplified method developed in this Appendix allows one to correct the collapse capacity distribution without needing to compute the $\varepsilon(T_1)$ values of the ground motion records, and without needing to perform a regression analysis. It involves using the Far-Field record set (Appendix A) for structural collapse analyses, and then applying an adjustment factor to the median collapse capacity ($\hat{S}_{CT}$).

The simplified correction factor depends on the following:

1. Differences between:
   a. the $\varepsilon(T)$ values of the ground motions used in the structural analyses (i.e., the Far-Field record set), and
   b. the $\varepsilon(T)$ value expected for the site and ground motion hazard level of interest.
2. How drastically the ground motion ε values affect the building collapse capacity; quantified by β_1, as described in section B.2. The ground motion ε values will have a greater effect on buildings with larger inelastic deformation capacity, which are those that have more extensive period elongation prior to collapse.

B.3.1 Epsilon Values for the Ground Motions in the Far-Field Set

To adjust collapse capacity predictions for spectral shape, the epsilon, $\varepsilon(T)$, values for the ground motion set used for collapse simulation are needed. Figure B-3 shows the mean $\varepsilon(T)$ values for the Far-Field record set, computed using the Abrahamson and Silva attenuation function (1997). The mean $\varepsilon(T)$ values computed using the Boore et al. (1997) attenuation function are similar but are not shown. For the Far-Field record set, mean $\varepsilon(T)$ values are approximately 0.6 for periods less than 0.5 seconds, and are nearly 0.0 for periods greater than 1.5 seconds.

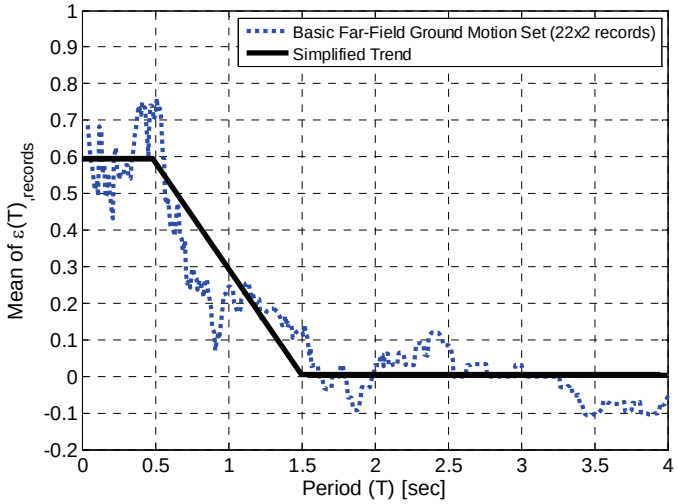

Figure B-3 Mean ε values for the Basic Far-Field ground motion set $\overline{\varepsilon}(T)_{,records}$.

The simplified trend from Figure B-3 can be express using Equation B-1:

$$\overline{\varepsilon}(T)_{,records} = (0.6)(1.5 - T) \qquad \text{(B-1)}$$

where $0.0 \le \overline{\varepsilon}(T)_{,records} \le 0.6$.

Note that for consistency with the Methodology, the period used for $\overline{\varepsilon}(T)_{,records}$ is the code-defined fundamental period ($T = C_u T_a$), and not the fundamental period computed from eigenvalue analysis (T_1).

B.3.2 Target Epsilon Values

The expected epsilon, $\overline{\varepsilon}_0$, value (used in this Appendix as the "target ε") depends on both the site and hazard level of interest. A target ε is needed in the process of adjusting the median collapse capacity to account for spectral shape.

To quantify the target ε for various seismic design categories around the United States, data from the United States Geological Survey (USGS) is

utilized. The USGS conducted the seismic hazard analysis for the United States and used dissagregation to determine the mean expected ε values ($\bar{\varepsilon}_0$) for various periods and hazard levels of interest (Harmsen et al., 2003; Harmsen 2001). Luco, Harmsen, and Frankel of the USGS provided electronic $\bar{\varepsilon}_0$ data for use in this study.

Figure B-4 shows a map of expected $\bar{\varepsilon}_0$(1s) for a 2% in 50 year motion in Western United States. Values of $\bar{\varepsilon}_0$(1s) = 0.50 to 1.25 are typical in areas other than the seismic regions of California. The values are higher in most of California, since the earthquake events have shorter return periods, with typical values being $\bar{\varepsilon}_0$(1s) = 1.25 to 1.75, and some values ranging upward to 3.0.

Figure B-5 shows a map of expected $\bar{\varepsilon}_0$(1s) for a 2% in 50 year motion in Eastern United States. It shows typical values of $\bar{\varepsilon}_0$(1s) = 0.75 to 1.0, with some values reaching up to 1.25. Expected $\bar{\varepsilon}_0$(1s) values fall below 0.75 for the New Madrid Fault Zone, portions of the eastern coast, most of Florida, southern Texas, and areas in the north-west portion of the map.

To illustrate the effects of period, Figure B-5b shows $\bar{\varepsilon}_0$(0.2s) instead of $\bar{\varepsilon}_0$(1s). This shows that typical $\bar{\varepsilon}_0$(0.2s) are slightly lower and more variable, having a typical range of 0.25 to 1.0. This is in contrast to the typical range of 0.75 to 1.0 for $\bar{\varepsilon}_0$(1s).

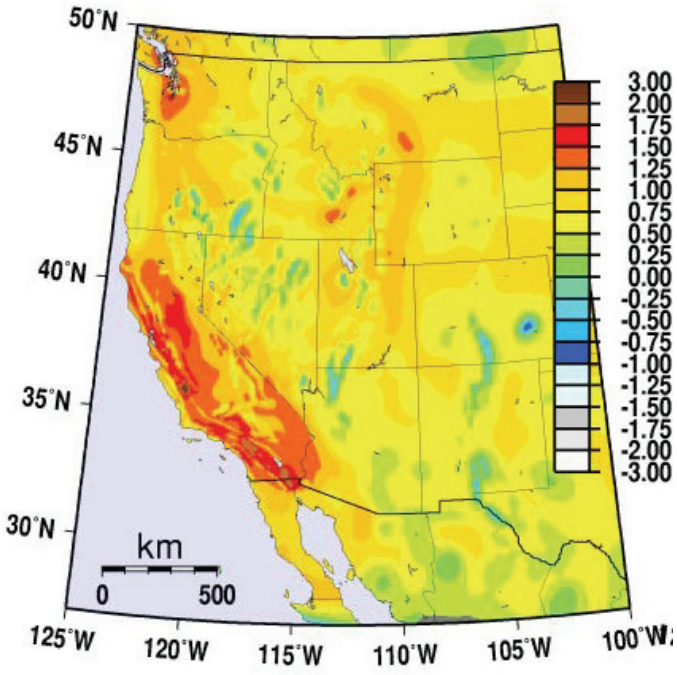

Figure B-4 Predicted $\bar{\varepsilon}_0$ values from dissagregation of ground motion hazard for Western United States. The values are for a 1.0 second period and the 2% exceedance in 50 year motion (Harmsen et al., 2003).

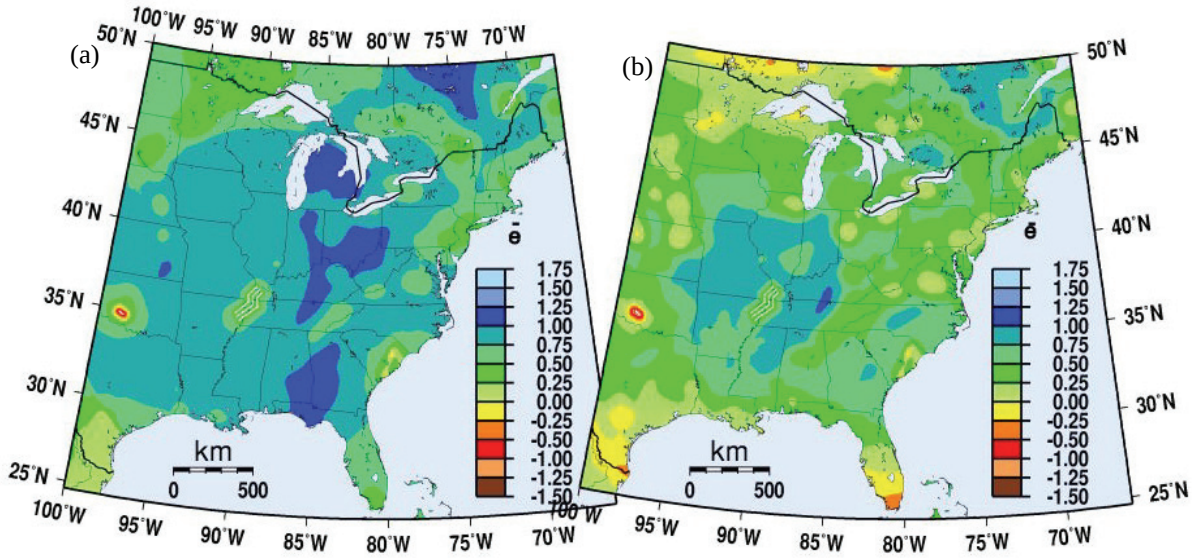

Figure B-5 Mean predicted $\bar{\varepsilon}_0$ values from dissagregation of ground motion hazard for Eastern United States. The values are for (a) 1.0 second and (b) 0.2 second periods and the 2% exceedance in 50 year motion (Harmsen et al., 2003).

To better quantify the $\bar{\varepsilon}_0$ values presented in the previous figures, Table B-1 and Table B-2 show the average $\bar{\varepsilon}_0$ and average spectral acceleration values for Seismic Design Categories B, C, and D. These data are given for four levels of ground motion: the motion with 10% exceedance in 50 years, 2% in 50 years, 1% in 50 years, and 0.5% in 50 years. These tables also show the number of zip code data points included in each SDC.

Table B-1 Tabulated $\bar{\varepsilon}_0$ Values for Various Seismic Design Categories

Seismic Design Category	Average ε Values								Number of Zip Code Data Points
	ε_0(0.2s)				ε_0(1.0s)				
	$\varepsilon_{10/50}$	$\varepsilon_{2/50}$	$\varepsilon_{1/50}$	$\varepsilon_{0.5/50}$	$\varepsilon_{10/50}$	$\varepsilon_{2/50}$	$\varepsilon_{1/50}$	$\varepsilon_{0.5/50}$	
SDC B	0.14	0.42	0.49	0.55	0.31	0.80	0.94	1.04	20,142
SDC C	0.11	0.51	0.63	0.75	0.23	0.74	0.88	1.00	7,456
SDC D	0.25	0.88	1.09	1.27	0.33	0.99	1.21	1.39	6,461
SDC D, $0.35 < S_1 < 0.599g$	0.32	0.97	1.21	1.41	0.39	1.01	1.24	1.45	1,305

Table B-2 Tabulated Spectral Demands for Various Seismic Design Categories

Seismic Design Category	Average Sa Values								Number of Zip Code Data Points
	Sa(0.2s) [g]				Sa(1.0s) [g]				
	$Sa_{10/50}$	$Sa_{2/50}$	$Sa_{1/50}$	$Sa_{0.5/50}$	$Sa_{10/50}$	$Sa_{2/50}$	$Sa_{1/50}$	$Sa_{0.5/50}$	
SDC B	0.06	0.18	0.26	0.39	0.02	0.06	0.08	0.11	20,142
SDC C	0.11	0.31	0.46	0.66	0.04	0.10	0.14	0.19	7,456
SDC D	0.50	1.05	1.35	1.68	0.18	0.38	0.49	0.62	6,461
SDC D, $0.35 < S_1 < 0.599$g	0.61	1.31	1.69	2.09	0.21	0.46	0.61	0.77	1,305

Seismic Design Category D is treated differently from the other categories, since it is the category with highest spectral demand and often controls the collapse performance assessment, as was shown in the Chapter 9 examples. Since the higher spectral demands often control the performance, sites in SDC D with higher values of S_1 (i.e., $0.35 < S_1 < 0.599$) are used to define the target ε.

It should be noted that the $\overline{\varepsilon}_0$ values in Table B-1 are a bit lower than some may expect for SDC D sites in seismic zones of California. This comes from the values in Table B-1 being *averages* for all SDC D sites in the United States. The SDC D sites are located in seismic regions of California, as well as in the Eastern United States. Seismic sources in these two regions have widely differing return periods, which causes $\overline{\varepsilon}_0$ values to vary, with the values in California being larger. Average 2% in 50 year and 0.5% in 50 year $\overline{\varepsilon}_0$ (1.0s) values are listed below for selected California cities. These values are averages over all SDC D zip codes in a given city, and are comparable to 0.99 and 1.39 values from Table B-1 which are for the entire United States. Since these values are averages over the city, the values at each specific site in the city may be higher or lower than these values.

- 1.5 and 1.9 in San Francisco (average over 16 zip codes)
- 1.7 and 2.1 in Oakland (average over 10 zip codes)
- 1.6 and 2.0 in Berkeley (average over 3 zip codes)
- 1.6 and 2.1 in San Jose (average over 29 zip codes)
- 1.3 and 1.7 in Los Angeles (average over 58 zip codes)
- 2.0 and 2.2 in Riverside (average over 8 zip codes)

Table B-1 presented both $\overline{\varepsilon}_0$ (0.2 s) and $\overline{\varepsilon}_0$ (1.0 s) values. The $\overline{\varepsilon}_0$ (1.0 s) values are used to develop the target ε values, since most building structures have periods closer to 1.0 second, or greater than 1.0 second. Buildings with periods near 0.2 seconds are relatively rare.

To complete the determination of target ε values for each Seismic Design Category, the proper ground motion hazard level must be established. Since the spectral shape, ε, adjustment will be used to modify the *median* collapse capacity the appropriate hazard level should be near this median. Table 7-3 shows that for typical uncertainty levels, the median collapse capacity must be roughly twice the MCE, for a structure to pass a 10% conditional collapse probability acceptance criterion. Therefore, the ground motion hazard level that should be used in establishing the target ε should have spectral acceleration demand that is twice (or more) of the 2% in 50 year demand (since the 2% in 50 year motion and MCE are considered to be identical for Seismic Design Categories B, C, and D). Table B-1 shows that the 0.5% in 50 year demand approximately meets this criterion, and is still conservative for SDC D, so the 0.5% in 50 year $\overline{\varepsilon}_0$ (1.0s) is used as the target ε. Based on this, the target ε value for Seismic Design Categories B and C is 1.0, and the target ε value for SDC D is 1.5.

SDC E must be treated differently, because the 2% in 50 year motion and the MCE can differ widely in near-fault regions. At sites close to a fault, the MCE motion has a shorter return period than the 2% in 50 year motion (i.e., 2,475 years). This is the result of the methodology used to construct the 1997 NEHRP maps, as explained in Appendix B of FEMA 369 (FEMA, 2001). In the near-field, the MCE is set to be 50% larger than the median predicted motion; this is approximately one logarithmic standard deviation greater than the median, so by definition $\varepsilon = 1.0$. To approximately account for the fact that the median collapse capacity is larger than the MCE motion, a target $\varepsilon = 1.2$ is used for SDC E.

B.3.3 Impact of Spectral Shape (ε) on Median Collapse Capacity

For buildings with larger inelastic deformation capacity, the effective period elongates more significantly before structural collapse, causing the spectral values at periods greater than T_1 to have more drastic impacts on collapse response. This subsequently causes the spectral shape, ε, of the ground motions to become more important. The β_1 value (defined in section B.2) is used to quantify how drastically the spectral shape, ε, affects the collapse capacity, so the β_1 is larger for buildings with larger deformation capacity. The purpose of this section is to create a predictive equation to estimate the

proper β_1 value for any building. This section presents data for 118 buildings, and then shows how the data were used to create the predictive equation for β_1.

Quantification of Building Period Elongation Prior to Collapse

Fundamentally, the spectral shape, ε, is important to the building collapse capacity because the building period elongates prior to collapse; this makes the building response become affected also by the spectral values at periods greater than the initial period T_1. In creating a predictive equation for β_1, it would be ideal to base the prediction directly on the expected amount of period elongation, such as a ratio of the near-collapse period to the initial undamaged period. However, the period near collapse is an ill-defined parameter, so this method instead uses a surrogate for period elongation.

To begin creating this surrogate for period elongation, the building deformation capacity is first quantified using a pushover analysis, in accordance with the guidelines of Section 6.3. Figure B-6 shows an idealized pushover curve and shows that, according to Section 6.3, the ultimate roof displacement (δ_u) is defined as the roof displacement associated with 20% loss of base shear strength. For illustration, Figure B-6 also shows the effective yield roof displacement ($\delta_{y,eff}$), but this term is actually computed from the building period, as will be described later in this section.

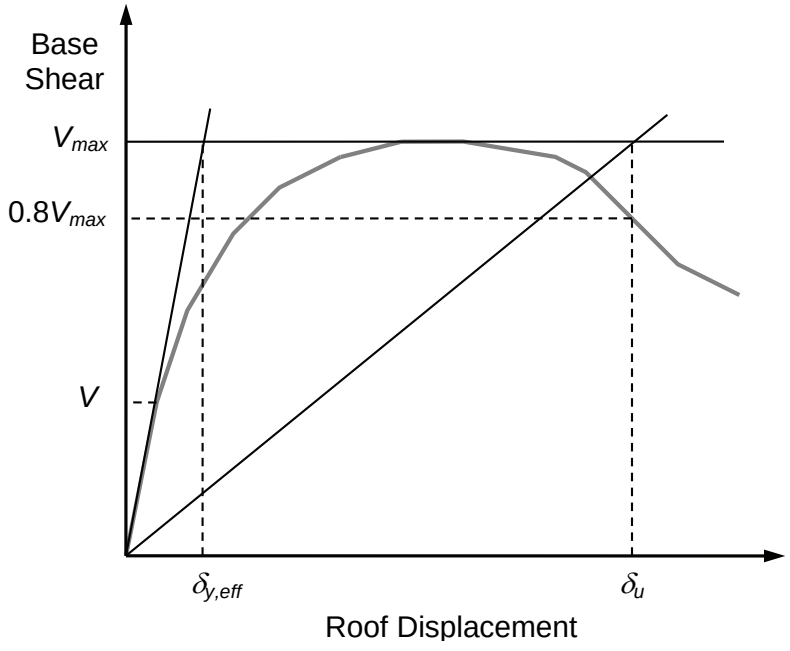

Figure B-6 Idealized nonlinear static pushover curve (from Section 6.3).

The ultimate building deformation capacity is divided by the yield deformation to compute the period-based ductility parameter, $\mu_T = \delta_u / \delta_{y,eff}$,

that is used as the surrogate for period elongation. The square root of μ_T can be approximately thought of as the ratio of the near-collapse period to the initial undamaged period. However, this is not precisely the case because the deformed shape of the building changes as the building is damaged. Even so, μ_T is an acceptable surrogate to approximately quantify the period elongation prior to collapse.

To compute the effective yield roof displacement ($\delta_{y,eff}$), the initial undamaged fundamental period of the building, T_1, is first computed using eigenvalue analysis for the undamaged structural model. This period is then converted into a roof displacement using the guidelines provided in Section 3.3.3.3.2 of ASCE/SEI 41-06 (ASCE, 2006b). To provide more stability to the Methodology, the code defined period of $T = C_u T_a$ must instead be used for cases when $T > T_1$. This requirement is imposed to ensure that analysts do not over-predict the value of β_1 by using a structural model that has an initial stiffness that is unreasonably large. The independent peer review panel should be careful to scrutinize the initial stiffness assumptions of the structural model.

Equation B-2 shows the ASCE/SEI 41-06 equation for effective yield roof displacement ($\delta_{y,eff}$), with the proper modifications for computing yield displacement (e.g., coefficients based on elastic response, and the use of yield base shear for S_a), and with the previously described period requirement. This equation is presented in Section 6.3 as Equation 6-7.

$$\delta_{y,eff} = C_0 \frac{V_{\max}}{W} \left[\frac{g}{4\pi^2} \right] (\max(T, T_1))^2 \qquad \text{(B-2)}$$

where C_0 relates the SDOF displacement to the roof displacement, computed according to ASCE/SEI 41-06 Section 3.3.3.3; V_{max}/W is the maximum base shear normalized by building weight, g is the gravity constant; T is the code-defined fundamental period (i.e., $C_u T_a$); and T_1 is the undamaged fundamental period of the structural model computed using eigenvalue analysis.

In summary, when creating the predictive equation for β_1, the period-based ductility parameter, μ_T, will be used as a surrogate for period elongation prior to collapse.

Predictive Equation for β_1: Database of Buildings Used as the Basis for Creating the Equation

In order to create a predictive equation for β_1, the first step is to understand what the β_1 values should be for various structural models that have various deformation capacities. To this end, the project team assembled a large

database of structural models and then, for each model, completed the collapse analyses and performed the regression to compute the β_1 value (as previously outlined in Section B.2). This section summarizes the set of structural models utilized, provides the important properties for each building, and report the β_1 values computed using regression for each model. The results from these structural models are utilized to develop the predictive equation for β_1, as discussed in the next section.

These five building sets include a total of 118 buildings, which are described in the following list. Partial documentation of the results for these models is provided in tables that follow this list.

- 30 code-conforming reinforced concrete special moment frame buildings from Haselton and Deierlein (2007, Chapter 6). These buildings range from 1-20 stories, and are representative of currently designed buildings (ASCE/SEI 7-02 and ACI 318-02) in high seismic regions of California. Eighteen of these buildings are included in an example in section 9.2 of this report, and the full results for these 18 buildings are included in Table B-3 below. More complete documentation is provided in Haselton and Deierlein (2007). The average β_1 for this set of buildings is 0.29 and the average μ_T is 11.5.
- 30 reinforced concrete special moment frame buildings that were designed and analyzed as part of a design sensitivity study completed by Haselton and Deierlein (2007, Chapter 7). This set of building designs includes variations in design strength (*R* value), design strong-column weak beam ratio, and design drift limits. These buildings are useful for this study because they include subsets of buildings that are identical, except for a single design change (such as the strong-column weak beam ratio, which affects the building deformation capacity); this allows trends to be seen more clearly. These data are not fully documented in this Appendix, though some of these data are used later in Figure B-7; the reader is referred to Chapter 7 of Haselton and Deierlein (2007) for full documentation.
    - 16 code-conforming reinforced concrete ordinary moment frame buildings, from Section 9.3 of this report. These buildings range from 2-12 stories, and are representative of currently designed buildings in the eastern United States. The full results for these 20 buildings are included in Table B-4 below. The average β_1 for this set of buildings is 0.19, and the average μ_T is 3.4. As expected, this set of buildings shows lower β_1 values being associated with buildings having lower deformation capacity.

- 26 non-ductile reinforced concrete frame buildings from Liel (2008). These buildings range from 2-12 stories, and are representative of existing 1967-era buildings in high seismic regions of California. The full results for these 26 buildings are included in Table B-5 below. The average β_1 for this set of buildings is 0.18, and the average μ_T is 2.9, consistent with the observation made from the set of reinforced concrete ordinary moment frame buildings, that lower β_1 values are to be expected for buildings with lower deformation capacity.
- 16 wood light-frame buildings, from Section 9.4 of this report. These buildings range from 1-5 stories, and are representative of currently designed buildings in high-seismic regions of the United States (SDC D). The full results for these 16 buildings are included in Table B-6 below. The average β_1 for this set of buildings is 0.33 and the average μ_T is 7.8. It is also observed that there is a modest difference between the β_1 values for the buildings designed for SDC D_{max} versus SDC D_{min}.

The following tables (Table B-3 through Table B-6) provide documentation of the results obtained using the above models. These tables include the β_1 values for each model, obtained from regression analysis, as well as the model properties that are important for prediction of β_1.

Predictive Equation for β_1: Development and Evaluation of Equation

Using the database of results for the 118 buildings, the goal is to create an equation that can be used to predict the value of β_1, without needing to perform a regression analysis. In an earlier section, it was already decided that β_1 will be predicted using the period-based ductility parameter, $\mu_T = \delta_u/\delta_{y,eff}$, as a surrogate for the period elongation that the building undergoes prior to collapse. Therefore, the goal of this section is to determine the proper form of this equation.

To most clearly see the relationship between β_1 and μ_T, Figure B-7 shows the trends using three sets of reinforced concrete special moment frame

buildings, each with constant height. These three sets of buildings are described as follows:

- Four-story perimeter frames, with the design *R* value varied from 4 to 12.
- Four-story space frames, with the design strong-column weak-beam ratio varied from 0.4 to 3.0.
- Twelve-story space frames, with the design *R* value varied from 4 to 12.

These data show a clear trend between period-based ductility (μ_T) and β_1 for observed μ_T values up to 8-9, and suggest that the effects are saturated for larger values of μ_T. For these buildings, the β_1 value saturates at 0.32 for two of the sets, and 0.26 for the third set. These observations suggest that the predictive equation for β_1 should saturate at a μ_T value somewhere between 8 and 11, and saturate at a value of β_1 that is between 0.26 and 0.32.

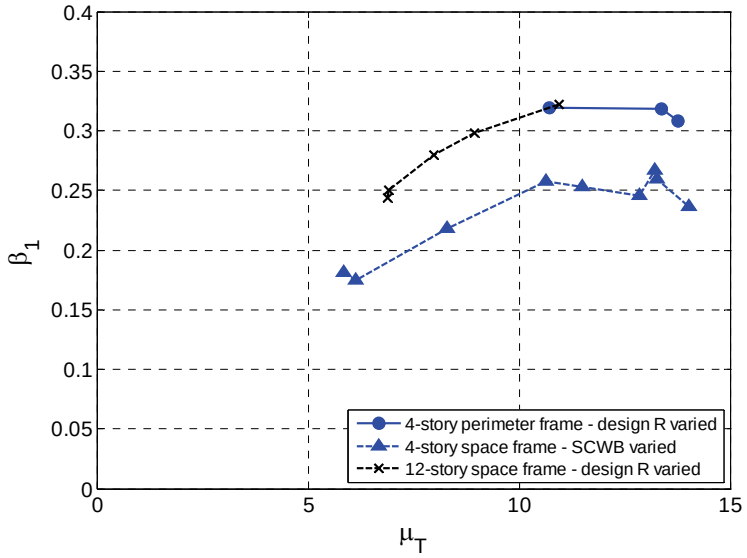

Figure B-7 Relationship between β_1 and period-based ductility, μ_T, for three sets of reinforced concrete special moment frame buildings of constant height within each set.

Considering both the reinforced concrete special moment frame data (Figure B-7 and Table B-3) and the wood light-frame data (Table B-6), it was decided that the predictive equation for β_1 should saturate at a value of β_1 = 0.32 for $\mu_T \geq 8$. This will accurately reflect the average values from the wood data, accurately reflect the saturation point for the reinforced concrete special moment frame data, and slightly over-predict the average β_1 values for the reinforced concrete special moment frame data.

Now that the saturation point has been established for the β_1 predictive equation, the equation can be created by choosing an appropriate functional

form, and then using the full set of data from the 118 buildings, with standard linear regression analysis to predict log(β_1) (Chatterjee et al., 2000). Several function forms were evaluated, and a power form was chosen, in order to best match the trends in the data, and enforce that $\beta_1 = 0.0$ when $\mu_T = 1.0$. Small corrections were then applied to the equation to enforce the desired saturation point of $\beta_1 = 0.32$ at $\mu_T = 8$, while still accurately fitting the data for lower values of μ_T.

The final relationship between β_1 and μ_T is shown in Equation B-3:

$$\hat{\beta}_1 = (0.14)(\mu_T - 1)^{0.42} \quad \text{(B-3)}$$

where the limit is enforced of $\mu_T \leq 8.0$.

Predictive Equation for β_1: Comparisons of Predictions and Observations

In order to evaluate the prediction accuracy of Equation B-3, Figure B-8 compares the predicted and observed values of β_1. Figure B-8a shows the data points for all of the 118 buildings used to create the equation, and Figure B-8b shows the average values for each of the building subsets. Overall, this shows that the equation accurately predicts the expected values of β_1. More specifically, this shows that the equation accurately predicts the β_1 values for non-ductile buildings, accurately predicts the values for wood buildings in SDC D_{max}, slightly under-predicts the values for wood buildings in SDC D_{min}, but still accurately predicts the values for wood buildings on average (with overall average $\mu_T = 7.4$ and $\beta_1 = 0.32$), and slightly over-predicts the values for ductile reinforced concrete special moment frame buildings.

B.4 Final Simplified Factors to Adjust Median Collapse Capacity for the Effects of Spectral Shape

Following the rationale above, the spectral shape factor, *SSF*, can be computed using Equation B-4.

$$SSF = \exp\left[\beta_1 \left(\bar{\varepsilon}_o(T) - \bar{\varepsilon}(T)_{,records}\right)\right] \quad \text{(B-4)}$$

where β_1 depends on building inelastic deformation capacity (Equation B-3); $\bar{\varepsilon}_0$ depends on SDC and is equal to 1.0 for SDC B/C, 1.5 for SDC D, and 1.2 for SDC E (Section B.3.2); and $\varepsilon(T)_{,records}$ is for the Far-Field record set (Section B.3.1).

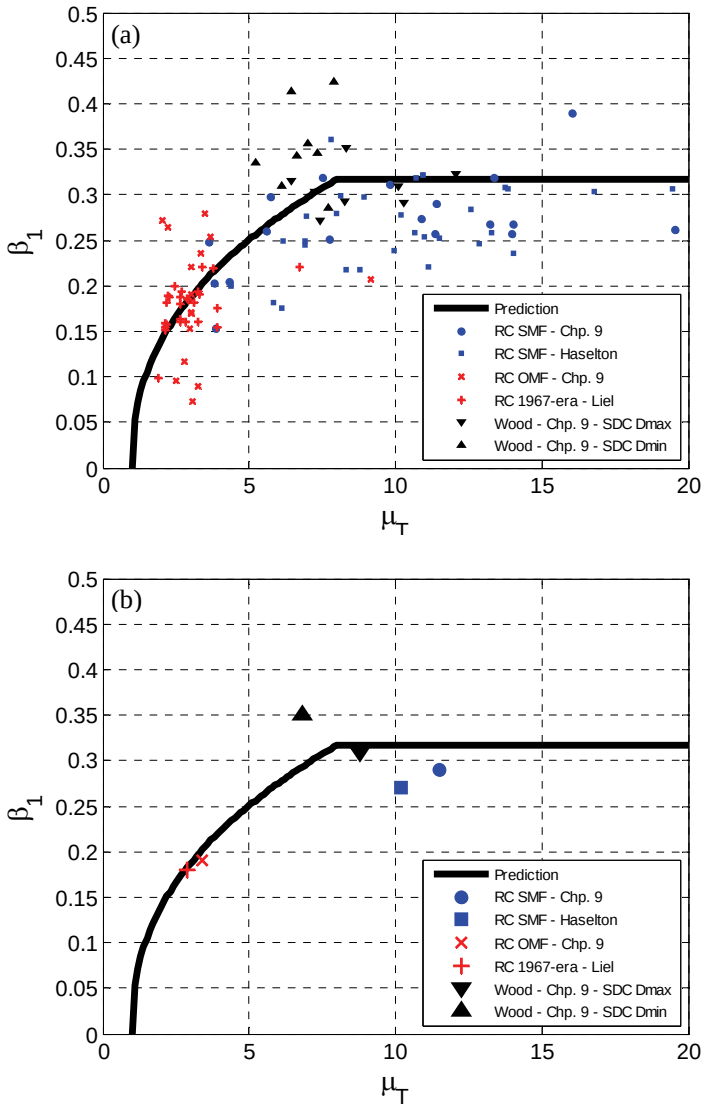

Figure B-8 Comparison of predicted and observed values of β_1, for all 118 buildings used to create the predictive equation. Figure (a) shows all the data, and Figure (b) shows the average values for the individual subsets of building types.

Table B-7 through Table B-9 present values of spectral shape factor, *SSF*, for various levels of building period-based ductility, μ_T, and various building periods, using Equation B-4. Table B-7 presents values for Seismic Design Categories B and C, Table B-8 presents values for SDC D, and Table B-9 presents values for SDC E.

To compute the adjusted collapse margin ratio, multiply the *SSF* value by the collapse margin ratio that was predicted using the Far-Field record set, as shown in Equation B-5:

$$ACMR = SSF * CMR \quad \text{(B-5)}$$

B.5 Application to Site Specific Performance Assessment

Simplified spectral shape adjustment factors can be modified for site-specific and building-specific collapse performance assessment. To compute the *SSF* for a site-specific collapse performance assessment, use Equation B-4 with the following values:

- β_1 should be computed using Equation B-3.
- $\overline{\varepsilon}_0$ (T) should not be based on Section B.3.2. Instead, $\overline{\varepsilon}_0$ (T) should be based directly on the dissagregation of the probabilistic seismic hazard analysis for the site of interest and for the ground motion hazard level of the median collapse capacity.
- $\varepsilon(T)_{,records}$ will differ depending on the ground motion set utilized in the performance assessment. If the site is within 10 km of an active fault capable of producing an event larger than magnitude M6.5, then the Near-Field ground motion record set should be used (Appendix A); otherwise, the Far-Field record set should be used. If the Far-Field record set is used, then $\varepsilon(T)_{,records}$ should be taken from Figure B-3 and Equation B-1. If the Near-Field record set is used, then $\varepsilon(T)_{,records}$ should be taken to equal $\varepsilon(T)_{,records,NF}$ from Figure B-9 and Equation B-6.

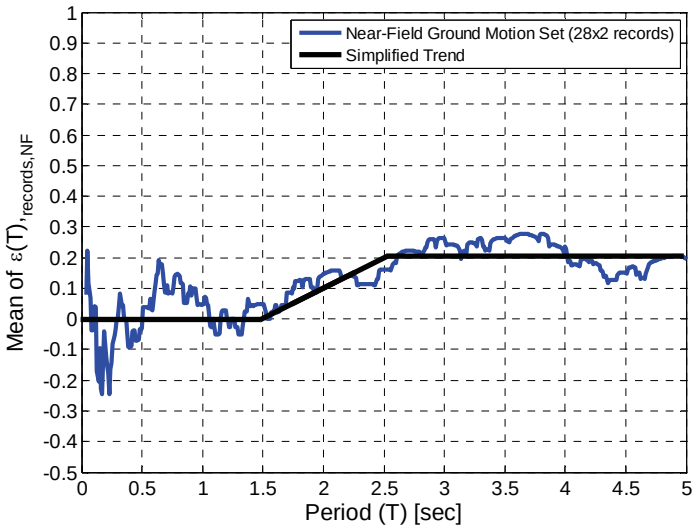

Figure B-9 Mean ε values for the Near-Field ground motion set, $\overline{\varepsilon}(\mathrm{T})_{,\mathrm{records,NF}}$.

The Near-Field set is nearly ε-neutral at all periods, but a slight simplified trend from Figure B-9 can be approximated using Equation B-6:

$$\overline{\varepsilon}(\mathrm{T})_{,\mathrm{records,NF}} = (0.2)(T - 1.5) \qquad \text{(B-6)}$$

where $0.0 \le \overline{\varepsilon}(\mathrm{T})_{,\mathrm{records,NF}} \le 0.2$.

Appendix C
Development of Index Archetype Configurations

This appendix illustrates how index archetype configurations are developed for reinforced concrete moment frame systems and wood light-frame shear wall systems.

Development of structural system archetypes considers both structural configuration issues and seismic behavioral effects described in Chapter 4. Consideration of structural configuration issues is discussed in this appendix. Examination of seismic behavioral effects is described in Appendix D. Index archetype configurations are subsequently used to develop index archetype designs, which are then used to develop index archetype models. Development and calibration of nonlinear index archetype models is described in Appendix E.

C.1 Development of Index Archetype Configurations for a Reinforced Concrete Moment Frame System

In this section, index archetype configurations are developed for a reinforced concrete special moment frame system conforming to design requirements contained in ASCE/SEI 7-05 *Minimum Design Loads for Buildings and Other Structures* (ASCE, 2006a), and ACI 318-05 *Building Code Requirements for Structural Concrete* (ACI, 2005). The index archetype configurations described here are used in the reinforced concrete moment frame system example of Section 9.2. When the Methodology is applied to a proposed new seismic-force-resisting system, index archetype configurations will be based on existing code requirements, as appropriate, and new design requirements developed specifically for the proposed system.

C.1.1 Establishing the Archetype Design Space

To establish the archetype design space, design parameters that significantly affect seismic performance are first identified, and then the bounds on each design parameter are established. The overall range of permissible configurations, structural design parameters, and other features that define the application limits for a seismic-force-resisting system are specified in the system design requirements and in existing code requirements, as applicable.

Parameters that were identified as having a critical impact on the collapse performance of reinforced concrete moment frame systems, along with related physical properties and associated design variables, are listed in Table C-1. This organizational approach is useful for deciding which of the many design variables should be the focus of further investigation in index archetype configurations.

Table C-1 Important Parameters, Related Physical Properties, and Design Variables for Reinforced Concrete Moment Frame Systems

Important Parameter	Related Physical Properties	Design Variables
Column and beam plastic rotation capacity	Axial load ratio	Building height, bay width, ratio of tributary areas for gravity and lateral loads
	Column aspect ratio	Building height, bay width, story heights, allowable reinforcement ratio
	Confinement ratio	Confinement ratio used in design
	Stirrup spacing	Stirrup spacing used in design
	Longitudinal bar diameter	Longitudinal bar diameter used in design
	Reinforcement ratios	Reinforcement ratio allowed in design
	Concrete strength	Concrete strength used in design
Element Strengths	All element strengths	Conservatism of engineer, dead and live loads used in design
	Beam strengths	Slab width (steel) assumed effective
	Column strengths	Ratio of factored to expected axial loads, level of conservatism in applying strong-column weak-beam provision
Number of stories in collapse mechanism	Strength/stiffness irregularities	Presence of strength or stiffness irregularity, ratio of first to upper story heights, how column heights are stepped down over height
Lateral stiffness of frame	Member sizes in frame	Member/joint/footing stiffness used in design
Gravity system strength/stiffness	Gravity system	Not considered in this assessment

Key design variables are those that are likely to have a significant impact on the collapse performance of the proposed system. Key design variables identified for reinforced concrete moment frame systems, along with their applicable ranges, are listed in Table C-2.

Table C-2 Key Design Variables and Ranges Considered in the Design Space for Reinforced Concrete Moment Frame Systems

Key Design Variable	Range Considered in Archetype Design Space
Structural System	
Special Reinforced Concrete Moment Frame (as per ASCE/SEI 7-05, ACI 318-05)	All designs meet code requirements
Seismic framing system	Perimeter and space frames
Configuration	
Building Height	1 to 20 stories
Bay Width	20 to 30 feet
First and upper story heights	15 and 13 feet
Element Design	
Confinement ratio and stirrup spacing	Conforming to ACI 318-05
Concrete compressive strength	5 to 7 ksi
Longitudinal bar diameter	#8 and #9 are commonly used
Strength/stiffness irregularities	As permitted by existing code
Loading	
Ratio of tributary areas for gravity and lateral loads	0.1 (perimeter frame) to 1.0 (space frame)
Design floor loads	175 psf
Lower and upper bounds on design floor load	150 to 200 psf
Design floor live load	Constant: 50 psf

The design variables and ranges identified in Table C-2 provide the basis for identifying a finite number of design variations for use in developing index archetype configurations.

Figure C-1 illustrates one example of how index archetype configurations might change for a design variable associated with the ratio of tributary areas for gravity and lateral loads (A_{grav}/A_{lat}). In the case of moment frame systems, this variable is primarily affected by whether the building is designed as a space frame or a perimeter frame system. Table C-2 identifies a range of 0.1 to 1.0 for this design variable, which is schematically shown in the figure.

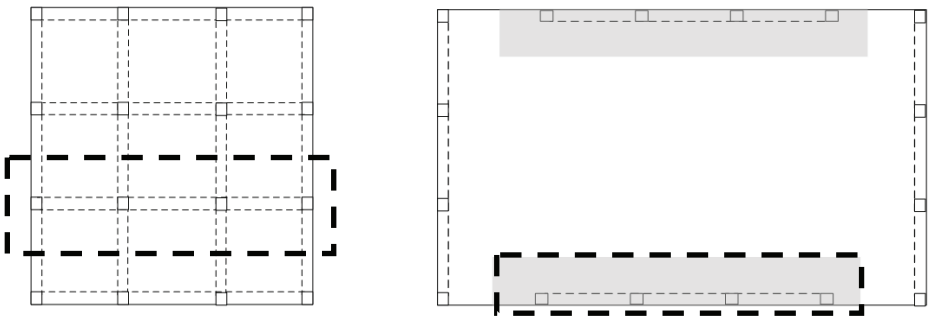

Figure C-1 Different index archetype configurations for varying ratios of tributary areas for gravity A_{grav} and lateral loads A_{lat}.

C.1.2 Identifying Index Archetype Configurations and Populating Performance Groups

Identification of a set of index archetype configurations requires consideration of performance group binning in accordance with Section 4.3.1. As a minimum, performance groups should consider the design ground motion intensities for the governing Seismic Design Category (maximum and minimum SDC), two fundamental period domains (long-period and short-period), variations in gravity load intensity (high and low gravity loads), and building configuration. In the case of reinforced concrete moment frames, "high gravity" systems are space frames and "low gravity" systems are perimeter frames, as shown in Figure C-1. This results in the need for index archetype configurations to populate at least eight performance groups, as described in Table 4-3:

- High gravity loads, maximum SDC, short-period archetypes
- High gravity loads, maximum SDC, long-period archetypes
- High gravity loads, minimum SDC, short-period archetypes
- High gravity loads, minimum SDC, long-period archetypes
- Low gravity loads, maximum SDC, short-period archetypes
- Low gravity loads, maximum SDC, long-period archetypes
- Low gravity loads, minimum SDC, short-period archetypes
- Low gravity loads, minimum SDC, long-period archetypes

Additional performance groups need to be defined where other design variables are important. For example, performance groups for reinforced concrete moment frame also include variation in bay width (column spacing) of 20 feet and 30 feet, respectively, which may be an important parameter for

system performance (Table 9-1). Each performance group must be robustly populated by buildings that have representative configurations and heights across the entire archetype design space. Each performance group is expected to contain at least three buildings, except in cases where that performance group represents an unusual rather than typical configuration of the structural system of interest.

Index archetype configurations must be conceived in such a way that index archetype models will capture important system behavior. For moment frames in general, three framing bays are considered to be the minimum number feasible for capturing variations in behavior related to interior and exterior columns and beam-column joints, strong-column weak-beam design provisions, and induced column axial loads due to overturning effects. As a result, the three-bay, variable story-height configuration shown in Figure C-2 was selected as the simplest model still capable of capturing important collapse performance behaviors for reinforced concrete moment frame systems.

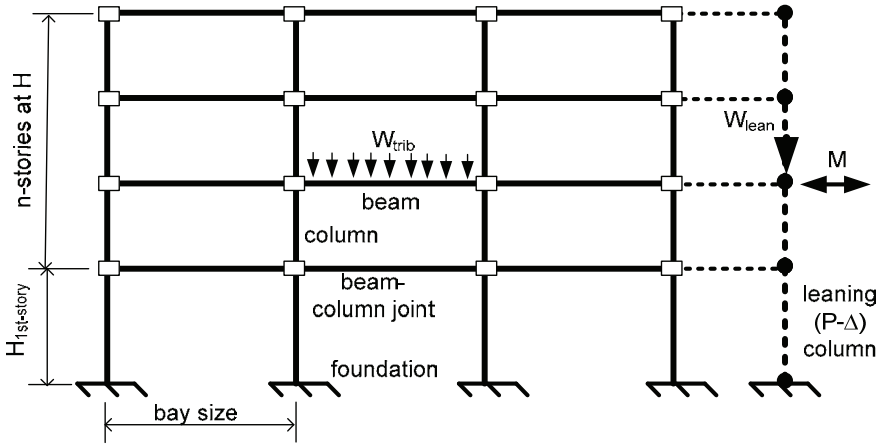

Figure C-2 Index archetype model for reinforced concrete moment frame systems.

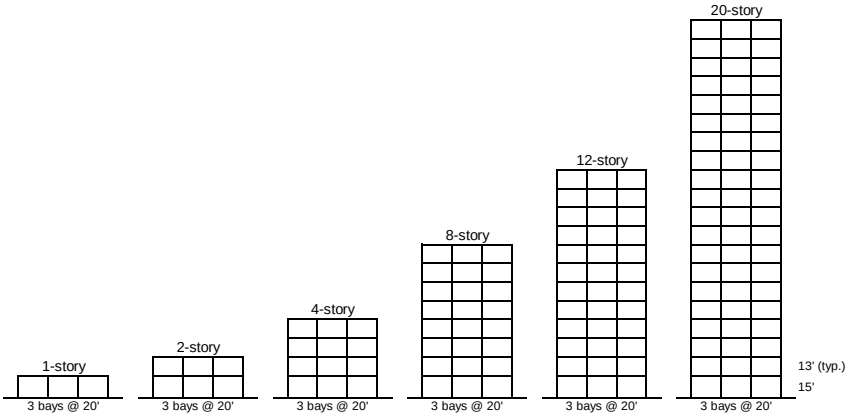
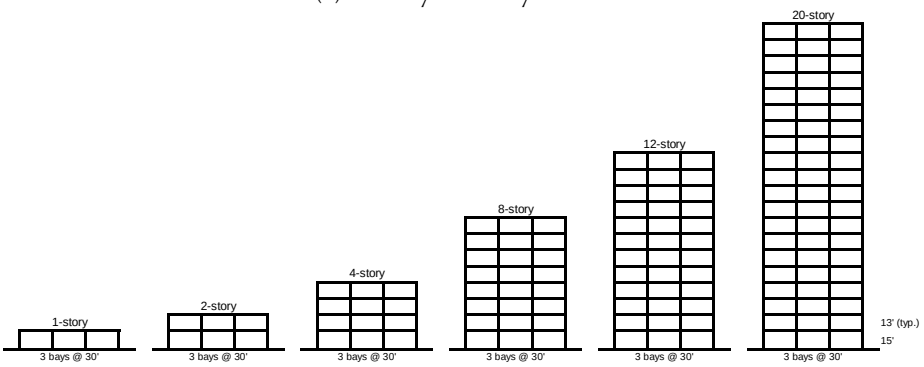
To develop a set of index archetype configurations, the range of parameters that will be commonly utilized in design and construction must be understood. As identified in Table C-2, building heights between one and twenty stories are expected, since most buildings taller than twenty stories would include a core wall in addition to moment frames. Considering typical office occupancies, story heights are expected to be relatively consistent, taken as 15 feet for the first story and 13 feet for the upper stories. Plan dimensions of 120 feet by 120 feet and 120 feet by 180 feet, along with bay widths ranging between 20 feet and 30 feet, are also expected to be typical for such buildings.

Figure C-3 illustrates two set of index archetype configurations representing the range of expected building heights for 20-foot and 30-foot configurations, respectively, that are used to populate reinforced-concrete moment frame performance groups. In this case, performance groups with short-period archetypes include 1-story and 2-story (and 3-story) buildings and performance groups with long-period archetypes include 4-story and taller buildings.



(a) Twenty-foot bay width



(b) Thirty-foot bay width

Figure C-3 Index archetype configurations for a reinforced concrete moment frame system.

Maximum and minimum seismic loads are defined by the range of possible design loads for Seismic Design Category D (SDC D_{max} and SDC D_{min}). High and low gravity load intensities are represented by the space frame or perimeter frame configurations.

Based on the information summarized in Table C-1 and Table C-2, and consideration of performance group binning and nonlinear analysis modeling, a matrix of index archetype configurations, such as the one described in Table C-3, can be developed. This matrix of index archetype configurations completely populates the performance groups expected to be most typical: 20-foot bay spacing of different heights, space and perimeter

frames, designed for the maximum seismic load intensity (SDC D_{max}). Taller buildings (4, 8, 12, and 20 stories) respond in the long-period range and are classified in separate performance groups from shorter short-period buildings (1, 2, and 3 stories). In order to verify that these performance groups control the assessment, a small number of additional archetype configurations are considered in other performance groups, including archetypes with a 30-foot bay width and archetypes designed for minimum seismic load intensity (SDC D_{min}).

Table C-3 Matrix of Index Archetype Configurations for a Reinforced Concrete Moment Frame System

Perform. Group No.	Archetype ID (Ch. 9)	No. of Stories	Period Domain	Bay Width	Gravity Loads	SDC

C.1.3 Preparing Index Archetype Designs and Index Archetype Models

Each of the index archetype configurations in Table C-3 are used to prepare index archetype designs, which are represented with index archetype models. In the examples of Chapter 9, index archetype designs for reinforced

concrete moment frames were prepared in accordance with the requirements of ASCE/SEI 7-05 and ACI 318-05. Complete adherence to design requirements is essential for adequately evaluating the performance of a class of buildings designed using the proposed system. Designs should address minimum design requirements, utilize nominal material properties, and not be overly conservative. Assumptions used in the development of index archetype designs for reinforced concrete moment frames are listed in Table C-4.

While index archetype designs are prepared using nominal material properties and other standard assumptions, index archetype models should be defined based on the expected behavior of the building. For modeling and assessment of the mean performance of reinforced concrete moment frame systems, this included the use of expected material properties, element stiffness assumptions based on test data, tributary slab contributions for beam strength and stiffness, and expected gravity loads. More details of modeling for reinforced concrete moment frame systems are described in Appendix D and Appendix E.

Table C-4 Index Archetype Design Assumptions for a Reinforced Concrete Moment Frame System

Design Parameter	Design Assumption
Assumed Stiffness	
Member stiffness assumed in design: Beams	$0.5EI_g$ (ASCE/SEI 41)
Member stiffness assumed in design: Columns	$0.7EI_g$ for all axial load levels (based on practitioner recommendation)
Slab consideration	Slab not included in stiffness/strength design of beams
Footing rotational stiffness assumed in design: 2-4 story	Effective stiffness of grade beam
Footing rotational stiffness assumed in design: 8-20 story	Basement assumed; exterior columns fixed at basement wall, interior columns consider stiffness of first floor beam and basement column
Joint stiffness assumed in design	Elastic joint stiffness
Expected Design Conservatisms	
Conservatism applied in element flexural and shear (capacity) strength design	1.15 times required strength
Conservatism applied in joint strength design	1.0 times required strength
Conservatism applied in strong-column weak-beam design	Use expected ratio of 1.3 instead of 1.2

C.2 Development of Index Archetype Configurations for a Wood Light-Frame Shear Wall System

In this section, index archetype configurations are developed for a wood light-frame shear wall system conforming to design requirements contained in ASCE/SEI 7-05. The system consists of wood light-frame bearing wall structures braced with wood structural panel shear walls. These archetypes are used in the wood light-frame bearing wall example of Section 9.4.

C.2.1 Establishing the Archetype Design Space

The following design variables were considered in the development of index archetype configurations for this system: (1) number of stories; (2) Maximum and minimum seismic intensity for the governing Seismic Design Category (SDC D in this case); (3) building occupancy and use; and (4) shear wall aspect ratio.

Wood light-frame buildings of upto three stories are common across most of the United States. Wood light-frame multi-family residential buildings of four to five stories represent a growing trend along the West Coast. The number of stories considered in the archetype design space ranges from one to five stories.

Minimum and maximum values of design spectral response acceleration, S_{DS}, used in this example are 0.375g and 1.00g, respectively. The minimum value of 0.375g is lower than 0.50g specified for SDC D in Table 5-1A, but is used in this illustrative example to make use of available designs. An S_{DS} of 1.00g represents the Maximum seismic intensity for regular, short-period SDC D structures. Design for wind loads is not considered.

The range of building occupancies considered includes residential and commercial occupancies, the latter including educational and institutional uses. The primary difference between residential and commercial buildings is the spacing between shear wall lines, which affects the tributary seismic mass. Residential buildings generally have more walls and closer spacing. A typical spacing of 25 feet between shear wall lines and a tributary width of 12.5 feet for seismic mass was used for residential occupancies. Commercial buildings are more likely to have open configurations with widely spaced shear walls at the perimeter. A typical spacing of 80 feet between shear wall lines and a tributary width of 40 feet for seismic mass was used for commercial occupancies.

Residential occupancies were further split into one- and two-family detached dwellings and multi-family dwellings, respectively. One- and two-family detached dwellings were assumed to be one- and two-stories tall, with typical

wood-frame floor weights (without topping slabs). Multi-family dwellings were assumed to be three- to five-stories tall, with floor weights including gypcrete topping slabs.

Shear wall aspect ratios included high aspect ratio shear walls (height/width ratios of 2.7 to 3.3) and low aspect ratio shear walls (height/width ratios of 1.5 or less). In accordance with ASCE/SEI 7-05, a capacity reduction was considered for high aspect ratio shear walls, resulting in the need for configurations with more dense nailing patterns.

C.2.2 Identifying Index Archetype Configurations and Populating Performance Groups

A set of 16 index archetype configurations are developed to investigate the effect of wall aspect ratio, height (one- to five-stories), and lateral loading intensity, as shown in Table C-5. These configurations are chosen recognizing the predominant use of high aspect ratio shear walls in residential buildings and low aspect ratio shear walls in commercial buildings. These structures are grouped into performance groups according to the design lateral load intensity (SDC D_{max} or D_{min}), wall aspect ratio (high or low) and period domain dominating the response (short- or long-period) (see Table 9-23). Other configurations were eliminated because they are not representative of wood light-frame construction. In particular, nominal gravity loads are considered in all the designs because light wood-frame archetype design and performance is not influenced by gravity loads. Likewise, there are few archetype configurations falling in the long-period domain because these are not representative.

C.2.3 Preparing Index Archetype Designs and Index Archetype Models

Each of the index archetype configurations in Table C-5 are used to prepare index archetype designs, which are represented with index archetype models. In this example, index archetype designs were prepared in accordance with the requirements of ASCE/SEI 7-05, considering only the contribution of wood structural panel sheathing, and ignoring the possible beneficial effects of gypsum wallboard that is likely to be present.

Designs were developed using a response modification coefficient, *R*, equal to 6. Index archetype designs, including number of piers, sheathing, and fasteners for *R*=6 are provided in Table C-6.

Table C-5 Index Archetype Configurations for Wood Light-Frame Shear Wall Systems

Model No.	No. of Stories	Seismic Design Coef. (S_{DS})	Tributary Width for Seismic Weight (ft)	Floor/Roof Tributary Seismic Weight (kips)	Shear Wall Aspect Ratio	Occupancy
1	1	1.0	40	41/0	Low	Commercial
2	1	1.0	12.5	13.65/0	High	1&2 Family
3	1	0.375	40	41/0	High	Commercial
4	1	0.375	12.5	13.65/0	High	1&2 Family

C.2.4 Other Considerations for Wood Light-Frame Shear Wall Systems

The following considerations were not addressed in this example, but are provided for the purpose of further illustrating the development of index archetype configurations.

A mix of shear wall aspect ratios could very likely occur within a given wood light-frame system. Careful thought should be given as to whether performance groups consisting of all high, all low, or mixed aspect ratio walls will be most representative or most critical. This could change with the system being considered.

It is becoming common practice to mix alternative bracing elements with conventional shear wall bracing in this type of construction. These elements could be designed to carry a small or large portion of the seismic story shear forces. Consideration should be given as to whether the seismic story shear carried by alternative bracing elements needs to be added as another variable in the index archetype configurations.

For wood light-frame systems in particular, wall finish materials are known to have a very significant impact on the overall collapse behavior of the system. The effects of wall finish materials should be considered in the context of the system being proposed. It may be appropriate to include a range of wall finish materials as another variable in the index archetype configurations.

Appendix D
Consideration of Behavioral Effects

This appendix illustrates how seismic behavioral effects are considered in the development of index archetype configurations for reinforced concrete moment frame systems conforming to design requirements contained in ASCE/SEI 7-05, *Minimum Design Loads for Buildings and Other Structures* (ASCE, 2006a), and ACI 318-05, *Building Code Requirements for Structural Concrete* (ACI, 2005).

Development of structural system archetypes considers both structural configuration issues and seismic behavioral effects described in Chapter 4. Consideration of structural configuration issues is discussed in Appendix C. Index archetype configurations are subsequently used to develop index archetype designs, which are then used to develop index archetype models. Development and calibration of nonlinear index archetype models for reinforced concrete moment frames is described in Appendix E.

D.1 Identification of Structural Failure Modes

Consideration of seismic behavioral effects includes identifying critical limit states, dominant deterioration modes and collapse mechanisms that are possible, and assessing the likelihood that they will occur. How a component or system behaves under seismic loading is often influenced by configuration decisions, so behavioral effects and configuration issues should be considered concurrently in the development of index archetype configurations. This process is illustrated in Figure D-1.

Once all possible failure modes have been identified for a given system, the list is narrowed to a subset of likely collapse mechanisms by ruling out failure modes that are unlikely to occur based on system design and detailing requirements, experimental data, engineering judgment, analytical models, or observations from past earthquakes. Remaining failure modes will be assessed through explicit simulation of failure modes through nonlinear analyses, or through evaluation of non-simulated failure modes using alternative limit state checks on demand quantities from nonlinear analyses. Index archetype configurations must address failure modes that will be explicitly simulated in nonlinear analysis models in Chapter 5.

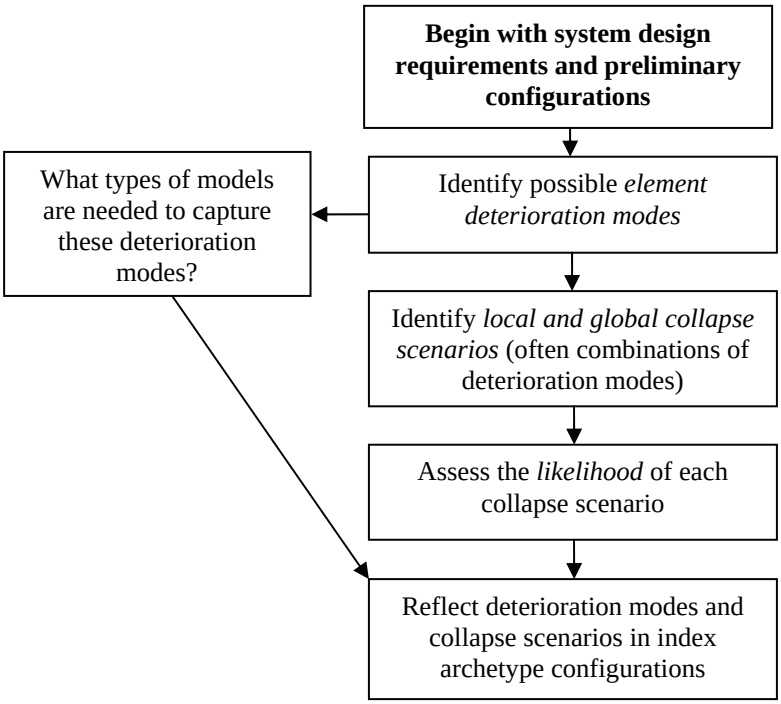

Figure D-1 Consideration of behavioral effects in developing index archetype configurations.

D.2 System Definition

Possible element deterioration and failure modes are influenced by the material properties, mechanical properties, and design requirements of the proposed seismic-force-resisting system.

Reinforced concrete moment frame systems in this example are assumed to meet design requirements for reinforced concrete moment frames specified in ASCE/SEI 7-05 and ACI 318-05. For *special* moment frames, these standards provide rigorous and specific design and detailing provisions intended to prevent certain failure modes from occurring, and to promote ductile failure modes in selected members. Special reinforced concrete moment frame requirements include, for example, an upper limit on longitudinal steel reinforcement ratio, seismic hoop detailing, confinement reinforcing in columns and beam-column joints, exclusion of lap splices from hinge regions, strong-column-weak-beam provisions, and other capacity design requirements. *Ordinary* moment frames are not subject to these provisions.

For a proposed seismic-force-resisting system, design and detailing requirements must be well-defined and specific before element deterioration modes and system collapse scenarios can be identified.

D.3 Element Deterioration Modes

In this example, failure modes have been identified for reinforced concrete moment frame components based on a review of experimental tests, available published information, and observations from past earthquakes. Potential deterioration modes for reinforced concrete moment frame components are listed in Table D-1 and shown in Figure D-2. They are classified into six groups (A to F) depending on the type of structural element and the physical behavior associated with deterioration, as shown in Figure D-3. For each mode, currently available nonlinear element models are rated for their ability to simulate the deterioration behavior.

Table D-1 Possible Deterioration Modes for Reinforced Concrete Moment Frame Components.

Deterioration Mode	Element	Behavior	Model Availability[1]		Description
			Simulation	Fragility	
A	Beam-column	Flexural	4	NR	Concrete spalling Reinforcing bar yielding Concrete core Reinforcing bar buckling (incl. Stirrup fracture) Reinforcing bar fracture
B	Beam-column	Axial compression	2	4	Concrete crushing, longitudinal bar yielding Stirrup-rupture, longitudinal bar buckling
C	Beam-column	Shear Shear +Axial	1	4	Concrete Shear Transverse tie pull-out of rupture Concrete Loss of aggregate interlock Possible loss of axial load-carrying capacity in columns
D	Joint	Shear	3	2	Panel shear failure
E	Reinforcing bar	Pull-out or Bond-slip	2	2	Reinforcing bar bond-slip or anchorage failure at joint Reinforcing bar lap-splice failure Reinforcing bar pull-out (in beams or at footing)
F	Slab connection	Shear	2	3	Punching shear or large shear eccentricity at slab column connection, in shear wall structures possible loss of connection between slab and wall Possible vertical collapse of slab

[1]Model availability ratings: 0 - nonexistent; 1 – low confidence; 5 – high confidence; NR – not required because behavior can be simulated.

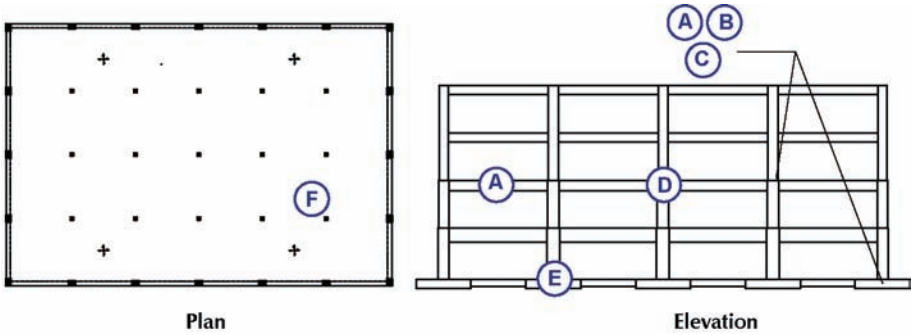

Figure D-2 Reinforced concrete frame plan and elevation views, showing location of possible deterioration modes.

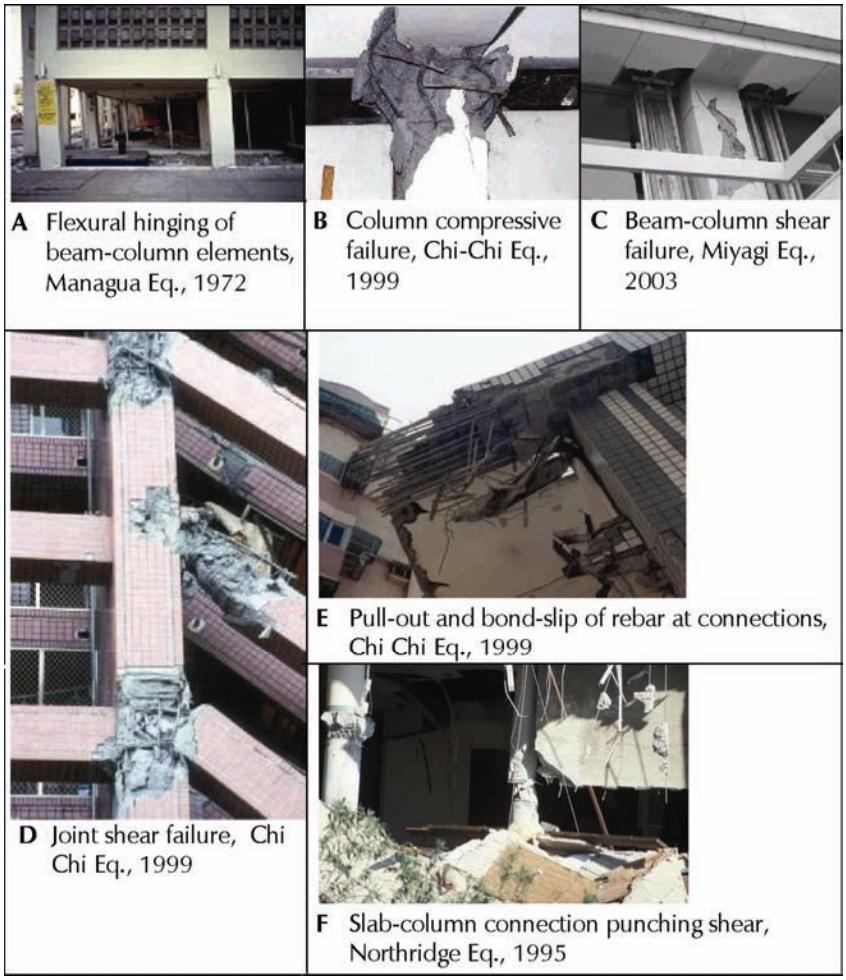

Figure D-3 Illustration and classification of possible deterioration modes for reinforced concrete moment frame components.[1]

[1] Photo sources: (A) nisee.berkeley.edu/thumbnail/6257_3021_0662/IMG0071.jpg (B) www.structures.ucsd.edu/Taiwaneq/buildi25.jpg (C) www.disaster.archi.tohoku.ac.jp/eng/topicse/030726htm/5-28.jpg (D) www.structures. ucsd.edu/Taiwaneq/ buildi21.jpg (E) www.structures.ucsd.edu/Taiwaneq/buildil9.jpg (F) www.nbmg.unr.edu/nesc/bobcox/ndx2.php

In this example, foundation failure modes have not been included because they are judged not critical for this system. Foundation failure modes should be considered if they are judged to have a potentially significant effect on the collapse performance of a proposed system.

D.3.1 Flexural Hinging of Beam and Columns

Deterioration mode 'A' consists of flexural hinging in beams and columns and associated concrete spalling, concrete core crushing, stirrup fracture, and reinforcing bar yielding, buckling, and fracture. Reinforcing bar yielding, concrete core crushing, and the associated strength and stiffness degradation can be simulated fairly accurately. In contrast, modeling of buckling and fracture of longitudinal reinforcement, or stirrup fracture is less accurate. These behaviors are important contributors to the deterioration of strength and stiffness in reinforced concrete frame elements at large deformations near collapse.

Fiber-type models capture the spread of plasticity along the length of the element and the constituent concrete models can be calibrated to adequately model the behavior associated with concrete deterioration from cracking to crushing (Haselton et al., 2007). However, currently available steel material models are not able to replicate the behavior of rebar as it buckles and fractures. Due to this limitation, current fiber models were judged inadequate for simulating collapse. While lumped plasticity models do not have the precision of fiber models, they can be calibrated to capture the deterioration associated with rebar buckling and stirrup fracture leading to loss of confinement (Haselton, 2006; Ibarra, 2003).

D.3.2 Compressive Failure of Columns

Deterioration mode 'B' corresponds to compressive failure of columns and is characterized by concrete crushing, buckling of longitudinal reinforcement, and yielding or fracture of transverse reinforcement. This deterioration mode occurs when compressive forces in the column exceed the compressive capacity. In earthquakes, this may occur due to overturning, which increases axial loads in some of the columns of a moment-resisting frame.

D.3.3 Shear Failure of Beam and Columns

Deterioration mode 'C' corresponds to shear failure of beam-columns, characterized by shear cracking in concrete and yielding and/or pull-out of transverse stirrups. This mode of deterioration is particularly dangerous for columns with significant axial load. Shear deterioration and increased

displacement demands can lead to subsequent vertical collapse of the column (Elwood and Moehle, 2005), and possibly progressive collapse of a structure.

Modeling the cyclic response of a reinforced concrete element experiencing shear deterioration is complex due to interactions between shear, moment, and axial force, as well as the overall brittle nature of the deterioration mode. Elwood (2004) and others have simulated deterioration in the lateral strength and stiffness of a column by adding a shear spring. To date, models for vertical collapse of columns following shear failure have been challenged by a lack of experimental data for columns experiencing vertical collapse.

Due to the brittle nature of this failure mode, special and intermediate moment frames in seismically active areas are required to utilize capacity design principles that ensure flexural hinging prior to shear failure (ACI, 2005). Capacity design requirements, however, do not apply to ordinary concrete moment frames. Shear failure, and the possible subsequent loss of gravity-load carrying capacity, is treated as a non-simulated collapse mode in evaluating ordinary moment frame systems, due to limitations in the ability to directly simulate these failure modes.

D.3.4 Joint Panel Shear Behavior

Deterioration Mode 'D' is associated with deterioration in shear strength and stiffness of the joint panel region. In reinforced concrete frame models, shear panels are modeled with an inelastic rotational spring inserted at the joint (Lowes et al., 2004; Altoontash, 2004). This joint modeling capability is available in the Open System for Earthquake Engineering Simulation (OpenSees, 2006) software framework and in most structural analysis software.

Several researchers have used a detailed approach that employs the modified compression field theory (Vecchio and Collins,1986; Stevens et al., 1991) to develop a monotonic backbone that relates the panel shear force to the shear deformation angle (Altoontash, 2004; Lowes et al., 2004). Modified compression field theory has been shown to work well for conforming joints, but is not as reliable for non-conforming joints with less confinement. Modeling of joint shear behavior is especially important for joints that are not protected by capacity design requirements (e.g., ordinary concrete moment frame systems).

D.3.5 Bond-Slip of Reinforcing Bars

Deterioration Mode 'E' corresponds to slip of the reinforcing bar relative to the surrounding concrete, including anchorage pull-out, bond slip, and splice

failure. The extent of slip, and the possible occurrence of bar pull-out, depends on the embedded length, bar diameter, concrete strength, and the number and magnitude of load cycles.

Slip without pull-out occurs when the embedment or splice length is sufficient to prevent the cut end of the rebar from moving relative to the surrounding concrete, even under cyclic loading. The effects of slip without pull-out include: (1) decreased pre-yield stiffness; (2) decreased post-yield stiffness; and (3) increased element plastic deformation capacity. These effects are included in the calibration of the plastic hinges for reinforced concrete moment frame models.

Slip with pull-out occurs when the rebar slips relative to the concrete over the full length of embedment. This occurs when the embedment or lap splice lengths are relatively short, as is typical of ordinary concrete moment frames. Slip with pull-out can lead to severe reduction in strength and stiffness, as well as a significant reduction in plastic rotation capacity. Models for pull-out are moderately well-developed and range from continuum finite element models (which attempt to model the interface between the rebar and concrete) to simple rotational spring models.

D.3.6 Punching Shear in Slab-Column Connections

Deterioration Mode 'F' corresponds to punching shear in slab-column connections or in wall-slab connections. Following punching shear failure, a slab may experience local collapse depending on the gravity load intensity and continuity of reinforcement in the area of the slab-column connection (Aslani 2005).

Punching shear deterioration can be modeled with a standard nonlinear lumped plasticity spring. The resulting vertical collapse is difficult to directly simulate, but this failure mode can be treated as a non-simulated collapse mode (Aslani and Miranda 2005).

D.4 Local and Global Collapse Scenarios

Collapse occurs when seismic loading causes element deterioration modes to combine in a way that forms a sidesway collapse mechanism or a vertical (local) collapse mechanism. For reinforced concrete frame systems, possible collapse scenarios and contributing element deterioration modes are identified and organized as shown in Tables D-2a and D2-b for sidesway and vertical collapse modes, respectively. These scenarios were established using engineering judgment based on examination of collapses in previous earthquakes, experimental test data, and analytical studies.

Table D-2a Collapse scenarios for Reinforced Concrete Moment Frames – Sidesway Collapse

Scenario	Element Deterioration Mode						Description
	A	B	C	D	E	F	
FS1	x						Beam and column flexural hinging, forming sidesway mechanism
FS2	x						Column hinging, forming soft-story mechanism
FS3	x		x				Beam or column flexural-shear failure, forming sidesway mechanism
FS4	x			x			Joint-shear failure, possibly with beam and/or column hinging
FS5	x				x		Reinforcing bar pull-out or splice failure in columns or beams, leading to sidesway mechanism

Table D-2b Collapse Scenarios For Reinforced Concrete Moment Frames – Vertical Collapse

Scenario	Element Deterioration Mode						Description
	A	B	C	D	E	F	
FV1			x				Column shear failure, leading to column axial collapse
FV2	x		x				Column flexure-shear failure, leading to column axial collapse
FV3						x	Punching shear failure, leading to slab collapse
FV4							Failure of floor diaphragm, leading to column instability
FV5		x					Crushing of column, leading to column axial collapse; possibly from overturning effects

D.5 Likelihood of Collapse Scenarios

Table D-3 includes the range of possible collapse scenarios for reinforced concrete frame structures. From this list, the scenarios which are most likely to occur for each type of moment frame defined in ACI 318-05 (ordinary, intermediate, and special) are identified.

Changes in detailing requirements for different reinforced concrete frame systems govern which collapse modes are likely to occur for that system. Design requirements for special concrete moment frames (ACI, 2005) are designed to promote ductile collapse modes and to prevent the formation of brittle collapse modes. These requirements serve to limit the likelihood of several possible collapse modes.

Ordinary moment frames are vulnerable to a wider range of possible collapse modes, due to less stringent design requirements. Several researchers (e.g. Aycardi et al., 1994; Kunnath et al., 1995; Filiatrault et al., 1998) have noted the tendency for soft story or column-hinging mechanisms to form in ordinary concrete moment frames. In addition, ordinary concrete moment frames might experience lap-splice failure, pull-out of reinforcing bars at beam-column joints, and column shear failures. The behavior of intermediate moment frames is anticipated to be somewhere between special and ordinary moment frames.

The likelihood of each collapse scenario for special, intermediate, and ordinary moment frames is shown in Table D-3. Depending on the proposed system and associated design requirements, there may be one or several collapse modes that are likely to occur.

Table D-3 Likelihood of Column Collapse Scenarios by Frame Type (H: High, M: Medium, L: Low)

System	Sidesway Collapse					Vertical Collapse				
	FS1	FS2	FS3	FS4	FS5	FV1	FV2	FV3	FV4	FV5
SMF	H	M	L	L	L	L	L	L	L	L-M
IMF	H	M-H	L	M	M	L	L	L	M	L-M
OMF	H	H	H	H	H	M	H	M	M	M-H

D.6 Collapse Simulation

For reinforced concrete moment frame systems, possible collapse modes are considered in the context of the three-bay variable-height archetype frame model described in Appendix C and Chapter 9. Index archetype configurations must account for all collapse scenarios that have been identified as likely to occur, and will be explicitly simulated in the nonlinear index archetype models. Critical limit states or failure modes that cannot be explicitly simulated in index archetype models are evaluated using the procedure for non-simulated collapse modes.

Appendix E

Nonlinear Modeling of Reinforced Concrete Moment Frame Systems

E.1 Purpose

This appendix describes the development of nonlinear index archetype models used for collapse assessment of reinforced concrete special moment frame and reinforced concrete ordinary moment frame example structures presented in Chapter 9. It includes an overview of critical modeling decisions and a description of the calibration procedures used for beam-column element models. Index archetype models represent index archetype configurations, which are developed with careful consideration of structural configuration issues (Appendix C) and seismic behavioral effects (Appendix D).

Although the information is specific to reinforced concrete moment frame systems, the example is illustrative of the issues and considerations typical of nonlinear collapse simulation for any structural system type. Similar procedures were used to create nonlinear models for the wood light-frame system presented in Chapter 9, and the steel special moment frame system presented in Chapter 10.

E.2 Structural Modeling Overview

Structural models should be capable of simulating the accrual of structural damage and the resulting sidesway collapse when a structure is subjected to severe ground shaking. Identification of key deterioration and collapse modes, as described in Appendix D, is an important precursor to the choice of the nonlinear analysis model.

The seismic-force-resisting system for reinforced concrete moment frames is represented by a two-dimensional, three-bay frame. The destabilizing P-delta effects are modeled using a leaning column. At the element level, frames are modeled with the following features illustrated in Figure E-1: beam-column elements with concentrated inelastic rotational hinges at each end and finite size beam-column joints that employ five concentrated inelastic springs to model joint panel shear distortion and bond slip at each

face of the joint. The collapse behavior is simulated using the Open System for Earthquake Engineering Simulation (OpenSees, 2006) software.

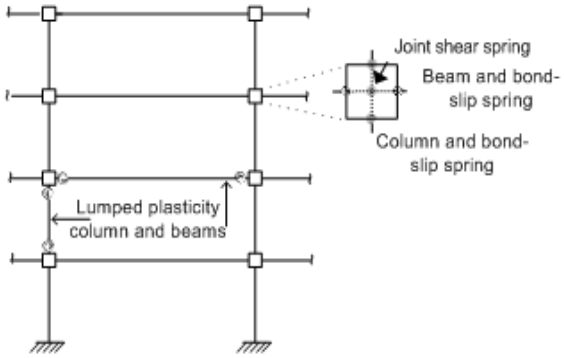

Figure E-1 Schematic diagram illustrating key elements of nonlinear frame model for reinforced concrete frame systems.

Although not shown in Figure E-1, the effect of foundation flexibility on the archetype models is incorporated using elastic, semi-rigid rotational springs at the base of the column. For shorter frame structures (fewer than 4 stories), the stiffness of the rotational springs is determined from assumed grade beam and soil stiffness. For taller buildings, the structure is assumed to have a basement, exterior columns are assumed to be fixed (connected to the basement wall), and the properties of the rotational spring attached to interior columns are computed based on the basement column and beam stiffnesses.

E.3 Beam-Column Element Model

Since the damage is likely to concentrate in the beams and columns of the reinforced moment frame structures, accurate modeling of the inelastic effects in beam and column elements is an essential component of collapse modeling of these structures. As shown in Figure E-1, the beam-column elements of the lateral resisting frame are modeled with lumped plasticity elements in the plastic hinge locations. Lumped plasticity elements are frequently used in structural analysis models, and their use here follows the precedent established in ASCE/SEI 41-06 *Seismic Rehabilitation of Existing Buildings* (ASCE, 2006b) and other guideline documents. When calibrated properly, they are capable of capturing degradation of strength and stiffness that is essential to collapse modeling. Their properties can also be easily modified in a sensitivity analysis to determine the effects of uncertainties in material modeling.

Researchers have also used a variety of other methods to simulate cyclic response of reinforced concrete beam-columns, including creating fiber models which can capture cracking behavior and the spread of plasticity throughout the element (see e.g., Filippou, 1999) The decision to use a

lumped-plasticity approach here was based on simplicity and an inherent limitation in the fiber element formulation which makes simulation of the strain softening associated with rebar buckling difficult. The choice of element model should be carefully evaluated for any given structural system, and with careful consideration of available simulation technologies.

In this section, the properties of the lumped plasticity elements used to model the example reinforced concrete special moment frame structures are illustrated, including descriptions of both the element model used and the process through which the key modeling parameters were calibrated. The calibration process described here demonstrates the level of detail and sophistication that is possible in studies of this type. Depending on the structural system and type of analytical model, a greater or lesser degree of detail may be required.

E.3.1 Element and Hysteretic Model

Lumped plasticity element models for the reinforced concrete special moment frame structures utilize a material model developed by Ibarra, Medina, and Krawinkler (2005), and implemented in OpenSees. This model is chosen because it is capable of capturing the important modes of deterioration that precipitate sidesway collapse of reinforced concrete frames, but one could imagine using another material model or software platform that also met these requirements.

Figure E-2 shows the tri-linear monotonic backbone curve and associated hysteretic rules of the model, which permit versatile modeling of cyclic behavior. For simulating structural collapse, the most important aspect of this model is the post-peak response, which enables modeling the strain softening behavior associated with concrete crushing, rebar buckling and fracture, and/or bond failure. The model also captures four basic modes of cyclic deterioration: (1) strength deterioration of the inelastic strain hardening branch; (2) strength deterioration of the post-peak strain softening branch; (3) accelerated reloading stiffness deterioration; and (4) unloading stiffness deterioration. Cyclic deterioration is based on an energy index that includes normalized energy dissipation capacity (λ) and an exponent term to describe how the rate of cyclic deterioration changes with accumulation of damage (c).

This element model requires the specification of seven parameters to control the monotonic and cyclic behavior of the model: M_y, θ_y, M_c/M_y, $\theta_{cap,pl}$, θ_{pc}, λ, and c. The post-yield and post-capping stiffnesses are quantified by M_c/M_y and θ_{pc}; K_s and K_c can be easily computed as:

$$K_s = K_e\left(\theta_y/\theta_{cap,pl}\right)\left(\left(M_c - M_y\right)/M_y\right) \quad \text{(E-1)}$$

$$K_c = -K_e\left(\theta_y/\theta_{pc}\right)\left(M_c/M_y\right). \quad \text{(E-2)}$$

Symbols are defined in Figure E-2 and in the list of symbols at the end of the document.

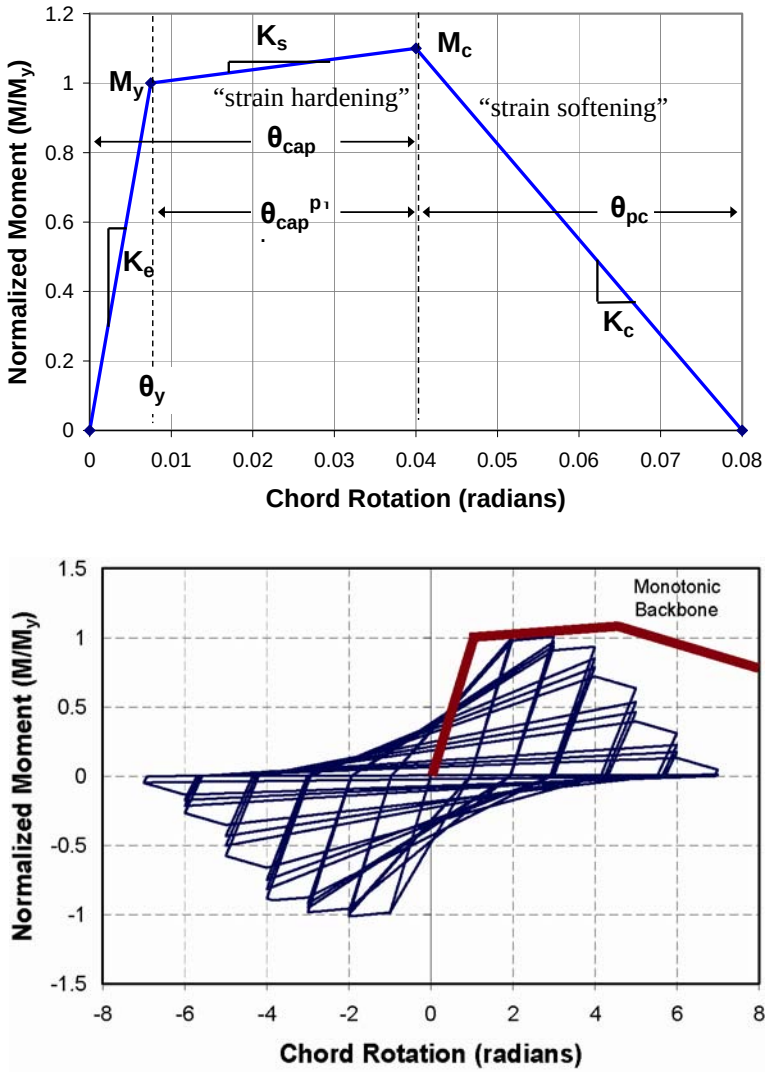

Figure E-2 Monotonic and cyclic behavior of component model used to model reinforced concrete beam-column elements.

In order to determine the appropriate values of each of these parameters, model parameters were carefully calibrated to 255 experimental tests of reinforced concrete columns. These calibrations were then used to develop empirical equations relating the design parameters of a beam-column to the modeling parameters needed for input in the lumped plasticity model. Calibrations are based on mean values. This type of calibration procedure

can be used in conjunction with any type of material model, provided that there is sufficient test data available.

E.3.2 Calibration of Parameters for the Reinforced Concrete Beam-Column Element Model

Experimental Database

Parameters of the material model are calibrated with data from the PEER Structural Performance Database (PEER, 2006a; Berry et al., 2004), assembled by Berry and Eberhard. This database includes the results of cyclic and monotonic tests of 306 rectangular columns and 177 circular columns. For each column test, the database reports the force-displacement time history, the column geometry and reinforcement information, the failure mode, and other relevant information. All data is converted to that of an equivalent cantilever, regardless of experimental setup.

From this database, rectangular columns failing in a flexural mode (220 tests) or in a combined flexure-shear mode (35 tests) were selected, for a total of 255 tests. These tests cover the typical range of column design parameters: $0.0 < v < 0.7$, $0.0 < P/P_b < 2.0$, $1.5 < L_s/H < 6.0$, $20 < f'_c\ (MPa) < 120$, $340 < f_y\ (MPa) < 520$, $0.015 < \rho < 0.043$, $0.1 < s/d < 0.6$, $0.002 < \rho_{sh} < 0.02$. These symbols are defined in the list of symbols at the end of this document.

Calibration Procedure

In order to calibrate the element model parameters, each column test in the database was modeled as a cantilever column in OpenSees, idealized using an elastic element and a zero-length Ibarra model plastic hinge at the column base. The properties of the plastic hinge are the subject of this calibration effort. This appendix provides only a brief description of the calibration process and the interested reader is referred to Haselton et al. (2007) for more details.

The calibration of the beam-column element model to the data from each experimental test was done systematically and, referring to Figure E-3, each test was calibrated according to the following standardized procedure. First, the yield shear force (1) was estimated visually from the experimental results. Then, the "yield" displacement (2) was calibrated as the point of a significant observed change in lateral stiffness, i.e., where rebar yielding or significant concrete crushing occurs. Calibration of this point often required judgment, since concrete response is nonlinear well before rebar yielding. In addition, displacement at 40% of the yield force (3) was calibrated to provide an estimate of initial stiffness. In step (4), the post-yield hardening stiffness was visually calibrated.

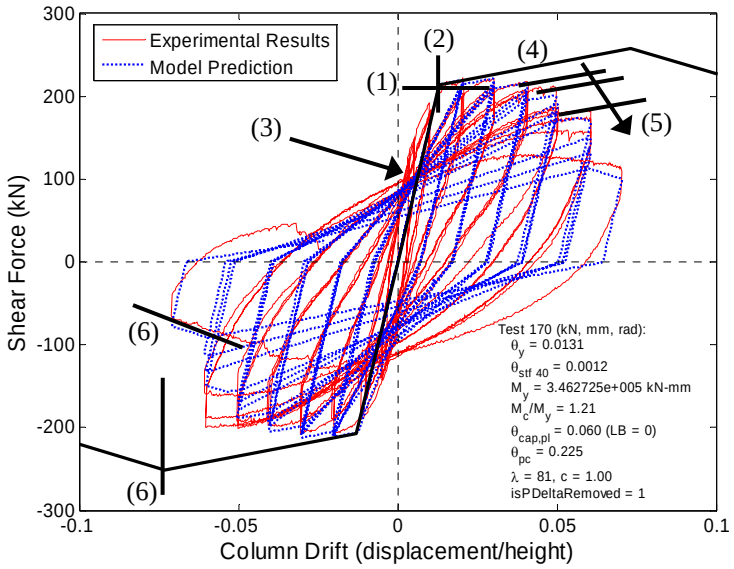

Figure E-3 Example of calibration procedure; calibration of reinforced concrete beam-column element to experimental test by Saatcioglu and Grira, specimen BG-6.

The next step (5) was to calibrate the normalized cyclic energy dissipation capacity, λ. This parameter is defined such that the total energy dissipated in a cycle is given by $E_t = \lambda M_y \theta_y$. The parameter c describes how energy dissipation changes in subsequent cycles (Ibarra et al., 2005). The element model allows cyclic deterioration coefficients λ and c to be calibrated independently for each of the four cyclic deterioration modes. However, based on a pilot study of 20 columns, c = 1.0 was found to be acceptable for columns failing in flexure and flexure-shear modes. The deterioration rate, λ, was set to be equal for the basic strength and post-capping strength deterioration modes, following recommendations by Ibarra (2003). Based on observations of the hysteretic response of the reinforced concrete columns, no accelerated stiffness deterioration was used. Unloading stiffness deterioration was neglected to avoid an error in the OpenSees implementation of the element model; in future, unloading stiffness deterioration should be employed, as it leads to better modeling of cyclic response. These simplifications reduce the calibration of cyclic energy dissipation capacity to one parameter (λ). When calibrating λ, the aim was to match the average deterioration for the full displacement history, but with a slightly higher emphasis on matching the deterioration rate of the later, more damaging, cycles.

The final step of the calibration process (6) involved quantification of the capping point and the post-capping deformation capacity. It has been shown (e.g., Haselton et al., 2007) that incorrect calibration of strength deterioration can have a significant impact on structural response prediction, and the

calibration procedure carefully distinguished between in-cycle and cyclic strength deterioration. The capping point and post-capping stiffness were only calibrated when a negative post-peak stiffness was clearly observed in the data, such that strength loss occurs within a single cycle (sometimes called "in-cycle strength deterioration"). Often the test specimen did not undergo sufficient deformations for a capping point to be observed. In such cases where the data do not reveal the capping point, a lower-bound value of the capping point was determined.

It should be noted that the hinge model is based on the definition of a monotonic backbone and cyclic deterioration rules. This calibration process relied primarily on cyclic tests with many cycles to calibrate both the monotonic backbone parameters and the cyclic deterioration rules. As a result, the monotonic backbone and the cyclic deterioration rules are interdependent, and the approximation of the monotonic backbone depends on cyclic deterioration rules assumed and, to some extent, the displacement pattern used in experimental tests. This approximation of the monotonic backbone from cyclic data is not ideal, but is necessary because sufficient data are not available to calibrate the monotonic and cyclic behavior separately.

A full table of calibrated model parameters for each of the 255 experimental tests used can be found in the extended report on this study (Haselton et al., 2007).

Interpretation of Calibration Results and Regression Analysis

Calibrated model parameters from the 255 column tests are used to create empirical equations that predict model parameters based on the column design parameters. The functional form used in regression analysis was carefully determined based on trends in the data and isolated effects of individual variables, previous research and existing equations, and judgment based on mechanics and expected behavior. The regression analysis was performed using the natural logarithm of the model parameter, and the logarithmic standard deviation quantifies the uncertainty. More details on how the data were dissected to create empirical regression equations to predict each model parameter is available in Haselton et al. (2007).

As noted previously, those test specimens in which post-capping behavior was not observed were calibrated with a lower-bound value for deformation capacity. In the regression analysis, this lower-bound calibration data were given special consideration. In order to take advantage of lower-bound data, without unnecessarily biasing the results, the deformation capacity equations presented here are based on all data, and the prediction uncertainties are

reported based on only the data with an observed capping point in order to avoid reporting the artificially high uncertainty associated with the lower-bound data. Note that this approach is still appropriate for elements with high deformation capacity because the lower-bound data underestimates the true deformation capacity.

Proposed Equations

Predictive equations were developed for each of the parameters of the element model for reinforced concrete columns. Each equation includes all statistically significant parameters, unless otherwise noted. The extended report on this study also includes more simplified equations (Haselton et al., 2007).

Effective Initial Stiffness (EI_y/EI_g and EI_{stf}/EI_g)

Due to nonlinearities in reinforced concrete behavior associated with cracking, the definition of the stiffness of a reinforced concrete element depends on the load and deformation level. In this work, two values of effective stiffness are defined: (1) the secant stiffness to the yield point of the component (termed EI_y or K_e) and (2) the secant stiffness to 40% of the yield force of the component (termed EI_{stf}). EI_{stf} is used as the initial stiffness in the creation of the structural models for reinforced concrete frames in Chapter 9, based on a study by Haselton et al. (2007). The component stiffness includes all modes of deformation including flexure, shear, and bond-slip.

The equation for secant stiffness to yield depends on both axial load ratio and shear span ratio of the column, and is given as follows:

$$\frac{EI_y}{EI_g} = -0.07 + 0.59\left[\frac{P}{A_g f_c^{'}}\right] + 0.07\left[\frac{L_s}{H}\right] \qquad \text{(E-3)}$$

where $0.2 \le \dfrac{EI_y}{EI_g} \le 0.6$

This equation represents the mean value of effective stiffness to yield. The prediction uncertainty, assuming the residuals are lognormally distributed, is given by the logarithmic standard deviation: $\sigma_{LN} = 0.28$. R^2, a measure of the extent to which the proposed equation explains the data, is 0.80. For this and all equations to follow, these values are reported below in Table E-1. The upper and lower limits on the stiffness were imposed because there is limited data for columns with very low axial loads and, at high levels of axial load,

the positive trend diminishes and the scatter in the data is large. The limits were chosen based on a visual inspection of data.

The effective initial stiffness, defined as the secant stiffness to 40% of the yield force of a reinforced concrete column, can be predicted as follows:

$$\frac{EI_{stf}}{EI_g} = -0.02 + 0.98\left[\frac{P}{A_g f_c^{'}}\right] + 0.09\left[\frac{L_s}{H}\right] \qquad \text{(E-4)}$$

where $0.35 \le \frac{EI_{stf}}{EI_g} \le 0.8$

For a typical column, Equation (E-4) predicts the initial stiffness to be approximately 1.7 times stiffer than the secant stiffness to yield (Equation (E-3)).

The effective stiffness of reinforced concrete columns has been the subject of much research; for comparison, selected studies are presented here. The guidelines in FEMA 356 *Prestandard and Commentary for Seismic Rehabilitation of Buildings* (FEMA, 2000) permit the use of standard simplified values based on the level of axial load for linear analysis: $0.5E_cI_g$ when $P/\left(A_g f'_c\right) < 0.3$, and $0.7E_cI_g$ when $P/\left(A_g f'_c\right) > 0.5$. More recently, Elwood and Eberhard (2006) proposed an equation for effective stiffness that includes all components of deformation (flexure, shear, and bond-slip), where the effective stiffness is defined as the secant stiffness to the yield point of the component. Their equation proposes $0.2E_cI_g$ when $P/\left(A_g f'_c\right) < 0.2$ and $0.7E_cI_g$ when $P/\left(A_g f'_c\right) > 0.5$, with a linear transition between these two extremes.

The equations proposed here for EI_y are similar to those recently proposed by Elwood and Eberhard (2006), but also includes an L_s/H term. Due to this additional term, the proposed Equation (E-3) has a lower prediction uncertainty of $\sigma_{LN} = 0.28$, as compared to the coefficient of variation of 0.35 reported by Elwood et al. The stiffness predictions in FEMA 356 are much higher than the values of EI_y predicted in this study, and slightly larger than the predicted values of EI_{stf}. Elwood and Eberhard (2006) found that most of this difference can be explained if it is assumed that the FEMA 356 values only include flexural deformation, and do not account for the bond-slip deformations, which can account for a significant proportion of an element's flexibility.

Flexural Strength (M_y)

Panagiotakos and Fardis (2001) have published equations to predict flexural strength. Their equation works well, so for this study their method is used to predict M_y. When comparing the calibrated values to flexural strength for the 255 columns to predictions by Panagiotakos and Fardis (2001) for these columns, the median ratio of $M_y / M_{y,(Fardis)}$ is 0.97, and the coefficient of variation is 0.36.

Plastic rotation capacity ($\theta_{cap,pl}$)

The following equation is proposed for predicting plastic rotation capacity, including all parameters that are statistically significant:

$$\theta_{cap,pl} = 0.12\left(1+0.55a_{sl}\right)\left(0.16\right)^{\nu}\left(0.02+40\rho_{sh}\right)^{0.43} \left(0.54\right)^{0.01c_{units}f_c'}\left(0.66\right)^{0.1s_n}\left(2.27\right)^{10.0\rho} \quad \text{(E-5)}$$

Possible correlations between ρ_{sh} and s_n were verified to be small to eliminate concerns regarding co-linearity in regression. This equation is based on all data, including the lower-bound data for plastic rotation capacity, as discussed previously. The shear-span ratio (L_s/H) is notably absent from the predictive equations for rotation capacity. The stepwise regression process consistently showed the shear-span ratio to be statistically insignificant. These findings differ from those of Panagiotakos and Fardis (2001).

The experimental data used in this study is limited to tests of columns with symmetrical arrangements of reinforcement and, as a result, Equation (E-5) applies only to columns with symmetric reinforcement. To eliminate the symmetric reinforcement limitation from the rotation capacity equation, it is proposed to multiply the rotation capacity obtained from these equations by the term proposed by Fardis and Biskini (2003), which accounts for the ratio between the areas of compressive and tensile steel.

It is also useful as verification to compare the predicted rotation capacity to the ultimate rotation capacity predicted by Fardis and Biskini based on their study of more than 700 reinforced concrete elements including beams, columns, and walls (Fardis and Biskini ,2003; Panagiotakos and Fardis, 2001). The equation based on these studies consistently predicts higher values, which is expected since Equation (E-5) predicts the capping point where the ultimate rotation capacity equation is based on the ultimate (20% strength loss) point. To make a more consistent comparison, the predictions of the ultimate rotation (at 20% strength loss) are combined with the calibrated values of post-capping slope (θ_{pc}) to back-calculate a prediction of

$\theta_{cap,pl}$ from the equation in Fardis and Biskini. This comparison shows that the proposed equation here predicts lower deformation capacity, with a mean ratio of 0.94 and a median ratio of 0.69. Based on this comparison, Equation (E-5) may still include some conservatism. This conservatism exists even though the predicted deformation capacities are already much higher than what is typically used; for example, values in ASCE/SEI 41 are typically less than one-half of those shown in Table E-2. Note: The recent supplement to ASCE/SEI 41 for concrete elements, particularly those with non-ductile detailing, has reduced some of the conservatism in ASCE/SEI provisions (Elwood et al., 2007).

Post-capping Rotation Capacity (θ_{pc})

Previous research on predicting post-capping rotation capacity has been limited, despite its important impact on predicting collapse capacity. The key parameters considered in the development of an equation for post-capping response are those that are known to most impact deformation capacity: axial load ratio (v), transverse steel ratio (ρ_{sh}), rebar buckling coefficient (s_n), stirrup spacing, and longitudinal steel ratio. The equation is based on only those tests where a post-capping slope was observed. The proposed equation for post-capping rotation capacity is as follows:

$$\theta_{pc} = (0.76)(0.031)^{v}(0.02 + 40\rho_{sh})^{1.02} \leq 0.10 \qquad \text{(E-6)}$$

The upper bound imposed on Equation (E-6) is due to lack of reliable data for elements with shallow post-capping slopes. The upper limit of 0.10 may be conservative for well-confined, conforming elements, but existing test data does not justify using a larger value.

Post-Yield Hardening Stiffness

Regression analysis shows that axial load ratio and concrete strength statistically impact the prediction of hardening stiffness (M_c/M_y). Even so, inclusion of both of the parameters scarcely improved the regression analysis, so a constant value of M_c/M_y is recommended. Equation (E-7) led to an acceptably low prediction uncertainty of σ_{LN} = 0.10.

$$M_c/M_y = 1.13 \qquad \text{(E-7)}$$

Cyclic Energy Dissipation Capacity

Based on the observed trends in the data, the following equation is proposed for the mean energy dissipation capacity, including all statistically significant predictors:

$$\lambda = (131.0)(0.18)^{\nu}(0.26)^{s/d}(0.57)^{V_p/V_n}(61.4)^{\rho_{sh,eff}} \quad \text{(E-8)}$$

As discussed previously, this value is calibrated for both types of strength deterioration and should be used with c = 1.0.

Discussion of Proposed Equations

The proposed equations can be evaluated to determine (a) how well they reflect the mean tendencies in the data, and (b) whether they provide suitably small prediction errors. Table E-1 reports the median ratio of predicted to observed values (from model calibrations) for each proposed equation. The regression analyses (e.g., Equations (E-3) – (E-8)) assumed the prediction uncertainty is lognormally distributed, so this median ratio should be close to 1.0; this ratio varies between 1.00 and 1.06 for the proposed equations, showing that the predictive equations have little bias.

Table E-1 Prediction Uncertainties and Bias in Proposed Equations

Equation	Median (predicted/ observed)	σ_{LN}	R^2
Effective Stiffness to Yield (E-1)	1.03	0.28	0.80
Effective Stiffness to 40% Yield (E-2)	1.02	0.33	0.59
Plastic Rotation Capacity (E-3)	1.02	0.54	0.60
Post-Capping Rotation Capacity (E-4)	1.00	0.72	0.51
Post-Yield Hardening Stiffness (E-5)	1.01	0.10	n/a
Cyclic Energy Dissipation Capacity (E-6)	1.06	0.47	0.51

Table E-1 also shows that the prediction uncertainty is large for many of the important parameters. For example, the prediction uncertainty (σ_{LN}) for plastic deformation capacity is 0.54. Previous research has shown that these large uncertainties in element deformation capacity cause similarly large uncertainties in collapse capacity (Ibarra, 2003; Goulet et al., 2006; Haselton et al., 2007). These large uncertainties are associated with wide variability in the physical phenomena and limitations in the available test data. With the availability of more test data it may be possible to reduce these uncertainties.

Due to its particularly large effect on collapse assessment, it is useful to also examine the prediction bias for selected subsets of the data for $\theta_{cap,pl}$ as given in Equation (E-5). For non-conforming elements (i.e., those with $\rho_{sh} <$ 0.003) the prediction is unbiased, with a median ratio of predicted to observed values of 1.02. The plastic rotation capacity equation tends to overpredict the plastic rotation capacity by approximately 12% for conforming elements ($\rho_{sh} > 0.006$), and underpredicts the plastic rotation

capacity by approximately 10% for elements with extremely high axial load (i.e., axial load ratios above 0.65). Considering the large uncertainty in the prediction of plastic rotation capacity and the small number of datapoints in some of the subsets, these computed biases seem reasonable. With more data, the prediction error and biases could be further reduced.

To illustrate the impact of column design variables on the model parameters predicted by Equation (E-3) through (E-8), modeling parameters obtained for an 8-story reinforced concrete special moment frame perimeter system are shown in Table E-2. When the proposed equations are used, a typical column at the base should be modeled with an effective stiffness to yield of 35% of EI_g, a post-yield hardening ratio of 1.13, a plastic rotation capacity of 0.085, a post-capping rotation capacity of 0.10 and λ equal to 154.

Table E-2 Predicted Model Parameters for an 8-Story Reinforced Concrete Special Moment Frame Perimeter System (Interior Column, 1st-Story Location)

Design Parameter	Value	EI_{stf}/EI_g	M_c/M_y	$\theta_{cap,pl}$	θ_{pc}	λ
All	Baseline[1]	0.35	1.13	0.085	0.100	154
v	0.0	0.35	1.13	0.095	0.100	170
	0.3	0.52		0.055	0.100	104
ρ_{sh}	0.002	0.35	1.13	0.042	0.059	154
	0.010			0.078	0.100	
	0.020			0.105	0.100	
L_s/h	2	0.35	1.13	0.085	0.100	154
	6	0.58				
s/d	0.1	0.35	1.13	0.085	0.100	163
	0.4					106
	0.6					80
ρ	0.01	0.35	1.13	0.080	0.100	154
	0.03			0.094		

[1]Baseline values: $v = 0.06$, $\rho_{sh} = 0.0121$, $L_s/h = 2.7$, $s/d = 0.14$, $\rho = 0.018$, $f'_c = 35$ MPa, $\alpha_{sl} = 1$, $s_n = 7.5$.

Table E-2 also illustrates how changes in each design parameter impact predicted model parameters. For example, suppose various design parameters were changed such that the column under consideration in the first row of Table E-2 has a different axial load ratio, amount of transverse reinforcement, or column reinforcement ratio; these changes would lead to modifications in the parameters used to model that column. Within the range of column parameters considered in Table E-2, the predicted plastic rotation

capacity varies from 0.042 to 0.105 radians. Axial load ratio (v) and the lateral confinement ratio (ρ_{sh}) have the largest effect on the predicted value of $\theta_{cap,pl}$, while concrete strength (f'_c), rebar buckling coefficient (s_n), and longitudinal reinforcement ratio (ρ) have less dominant effects (f'_c and s_n are not shown here). Table E-2 also shows the effects of the design parameters on initial stiffness, hardening stiffness ratio, post-capping stiffness, and cyclic deterioration parameters.

Summary and Limitations

The calibration process provided a comprehensive set of equations capable of predicting the parameters of a lumped plasticity element model for a reinforced concrete beam-column, with the empirical predictive equations having the ability to capture the effects of design aspects such as detailing and level of axial load. These equations are proposed for use with the element model developed by Ibarra et al. (2003, 2005), and can be used to model cyclic and in-cycle strength and stiffness degradation to capture element behavior up to the point of structural collapse. Even so, these equations are general and can be used with slight modifications with most lumped plasticity models currently used in research.

The predictive empirical equations proposed here provide a critical link between column design parameters and element modeling parameters, facilitating the creation of nonlinear structural models of reinforced concrete frame elements. The empirical equations predict the mean value of each parameter, so the prediction uncertainty associated with each equation is also quantified and reported. This provides an indication of the uncertainty in the prediction of model parameters, and can be used in sensitivity analyses and propagation of structural modeling uncertainties.

As with any study, there are limitations in terms of the applicability of these equations, which are discussed briefly here.

The equations developed here are based on a comprehensive database assembled by Berry et al. (Berry et al., 2004; PEER, 2006a). Even so, the range of column parameters included in the database is limited, and the derived equations may not be applicable outside the range of column parameters considered.

The equations are also limited more generally by the number of test specimens available that have an observed capping point. There are only a small number of experimental tests with clearly observable negative post-capping stiffness. For model calibration and understanding of element behavior, it is important that future testing continue to deformation levels

large enough to clearly show the negative post-capping stiffness. In addition, there is very limited data that show post-peak cyclic deterioration behavior. With additional data, it may be possible to further remove some of the conservatism still in the proposed equations and reduce the prediction uncertainties. A further limitation is associated with the testing protocols; virtually all of the available test data are based on a cyclic loading protocol with many cycles and 2-3 cycles per deformation level. This type of loading may not be representative of the type of earthquake loading that typically causes structural collapse, which would generally only contain a few large displacement cycles before collapse occurs. Tests conducted under a variety of loading histories will lead to a better understanding of how load history impacts cyclic behavior, and provide a basis for better development and calibration of the element model cyclic rules.

In addition to the above mentioned issues, it is also important to remember that the empirical equations developed in this work are all based on laboratory test data where the test specimen was constructed in a controlled environment, and thus indicative of a high quality of construction. Actual buildings are constructed in a less controlled environment, so we expect the elements of actual buildings to have a lower level of performance than that predicted using the equations presented here. This work does not attempt to quantify this difference in performance coming from construction quality.

E.4 Joint Modeling

Nonlinear models of reinforced concrete structures employ a two-dimensional joint model developed and implemented by Lowes et al. (2004). This model accounts for the finite joint size, and includes rotational springs and systems of constraints for direct modeling of the shear panel and bond-slip behavior. Figure E-4 shows a schematic diagram of this model.

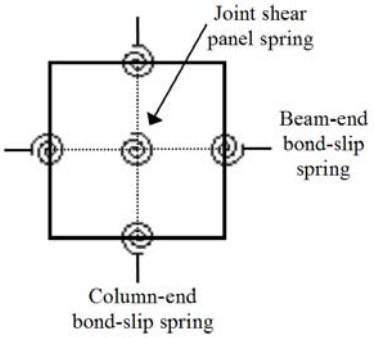

Figure E-4 Schematic diagram of joint model.

The joint model and parameters are based on a careful review of previous research. This approach is different than the detailed calibration study presented earlier to determine the parameters for beam-column elements.

E.4.1 Shear Panel Spring

Current building code provisions require that the joint shear capacity be based on capacity design principles for special moment frames, so if properly implemented, the joint shear demand should never exceed the capacity. A review of available research finds that the joint shear capacity designs provisions are conservative, and should be able to prohibit joint shear failure in all properly designed reinforced concrete special moment frame structures. For example, Brown and Lowes (2006) reviewed results of 45 experimental tests of conforming joints, finding that not one of these conforming joints exhibited damage requiring joint replacement. As a result of observations like these, the joint shear modeling is not judged to be a critical part of the overall behavior of the frame; damage in the joint shear panel will increase the flexibility of the frame, but the joint shear panel is not a dominant damage/failure mode (see also Appendix D).

For reinforced concrete special moment frame structures, joint models are developed to accurately reflect system stiffness. For simplicity, joints are modeled as elastic elements with the cracked stiffness based on simple mechanics (Umemura and Aoyama, 1969). Reinforced concrete ordinary moment frame structures are modeled to account for the deterioration that may occur in the joints of those structures. For readers interested in a more detailed approach, the modified compression field theory (MCFT) (Vecchio and Collins, 1986; Stevens et al., 1991; Altoontash, 2004, Lowes et al., 2004; and Lowes and Altoontash, 2003) is often used to develop panel shear models.

E.4.2 Bond-Slip Spring Model

The effect of bond-slip in joints and column footings is to decrease the pre-yield and post-yield stiffnesses and increase the plastic rotation capacity of reinforced concrete elements. In this study, bond-slip deformations are directly included in the plastic hinge calibration and thus do not need to be separately defined.

By lumping the effects of bond-slip in the plastic hinge model, it is inherently assumed that the bond-slip component of deformation is linear from zero to the yield load. This is a simplification, and a quadrilinear model could instead be used to capture the nonlinear bond-slip behavior prior to rebar yielding.

Appendix F

Collapse Evaluation of Individual Buildings

F.1 Introduction

Although developed as a tool to establish seismic performance factors for generic seismic-force-resisting systems, the Methodology could be readily adapted for collapse assessment of an individual building system. As such, it could be used to demonstrate adequate collapse performance for a new building designed using performance-based design methods (as permitted by ASCE/SEI 7-05), or for collapse safety evaluation of an existing building. This appendix describes an adaptation of the Methodology for use in collapse evaluation of an individual building system.

F.2 Feasibility

Buildings designed or evaluated using performance-based methods are often large or important structures. Such projects typically utilize detailed models for analysis of the building, and peer review is often required. In this way, they are already set up to utilize many aspects of the Methodology.

In contrast to index archetype models, analytical models for individual buildings might have more elements based on the actual configuration and specific geometry of the building. Collapse evaluation can be performed using two-dimensional or three-dimensional models of the building. Depending on the needs of the project, individual building models may, or may not include a high level of sophistication in modeling nonlinear behavior.

F.3 Approach

The Methodology is based on the concept of collapse level ground motions, defined as the level of ground motions that cause median collapse (i.e., one-half of the records in the set cause collapse). For a building to meet the collapse performance objectives of this Methodology, the median collapse capacity must be an acceptable ratio above the Maximum Considered Earthquake (MCE) ground motion demand level (i.e., the adjusted collapse margin ratio, *ACMR*, must exceed acceptable values).

By starting with an acceptable collapse probability for MCE ground motions, and working backwards through the Methodology, values of the spectral shape factor, *SSF*, and collapse margin ratio, *CMR*, can be calculated to determine the ground motion intensity corresponding to median collapse. The Methodology can be "reverse engineered" to determine the level of ground motions for which not more than one-half of the records should cause collapse.

By scaling the record set to this level, trial designs for a subject new building can be evaluated. If the analytical model of the trial design survives one-half or more of the records without collapse, then the building has a collapse probability that is equal to (or less than) the acceptable collapse probability for MCE ground motions, and meets the collapse performance objectives of the Methodology.

Similarly, an existing building can be evaluated for records scaled to the intensity corresponding to median collapse. If the analytical model of the existing building survives one-half or more of the records, then the existing building meets the collapse performance objectives of the Methodology. If different seismic criteria are needed, as is often the case with existing buildings, the process can begin with any probability of collapse deemed acceptable for the project.

F.4 Collapse Evaluation of Individual Building Systems

The process for collapse evaluation of an individual building system is summarized in the following steps.

F.4.1 Step One: Develop Nonlinear Model(s)

Development of a representative model (or models) of the building must incorporate the nonlinear behavioral characteristics of building-specific components.

- **Two-Dimensional Versus Three-Dimensional Models.** It is likely that the project has developed a three-dimensional (3-D) model of the building (for design), which could be used for collapse evaluation. Two-dimensional (2-D) models could be used, but such models would need to address response in both horizontal directions (e.g., two 2-D models) and account for torsion and potential coupling of bi-directional response.
- **Gravity System.** Since the construction of the building is known, elements of the gravity system can be incorporated into the building-specific model. Whether or not they are directly simulated, potential

collapse modes of the gravity system must be included in the collapse assessment process for an individual building. This is necessary because displacement compatibility requirements do not prohibit gravity system collapse from becoming a controlling behavior mode; they only address compatibility of displacements at the MCE ground motion level, not at collapse level ground motions. P-delta effects must consider the full weight of the building.

Inclusion of gravity system collapse modes is a departure from the formal application of the Methodology, which does not account for gravity system collapse. Accounting for collapse modes of the gravity system is typically accomplished by using limit state criteria for non-simulated collapse modes. Practically speaking, there is little experimental data on which to base limit state criteria for many gravity system collapse modes. In these cases, a peer review team could assist in determining appropriate criteria for use in the collapse assessment.

- **Nonlinear Elements.** Model(s) should incorporate nonlinear properties for all elements of a seismic force-resisting system (and gravity system) that cannot be shown to remain fully elastic in a near-collapse condition.

F.4.2 Step Two: Define Limit States and Acceptance Criteria

- **Limit States.** Accurately simulating sidesway collapse requires sophisticated modeling of element degradation and strain softening. Depending on the availability of component test data, and ability to develop high-fidelity representations of individual building components, use of non-simulated collapse limit states (Chapter 5) can be considered in lieu of direct simulation of collapse.
- **Acceptable Collapse Probability.** The maximum acceptable probability of collapse should be determined. An acceptable collapse probability of 10% is consistent with the collapse performance objectives of this Methodology.

F.4.3 Step Three: Determine Total System Uncertainty and Acceptable Collapse Margin Ratio

Total System Uncertainty (β_{TOT}). The value of total system collapse uncertainty, β_{TOT}, is determined in accordance with Section 7.3, based on quality of the design requirements, quality of the test data used to develop nonlinear properties, and quality of the nonlinear model.

The quality of design requirements (Chapter 3) could be "Superior" for buildings generally conforming to materials and detailing requirements of ASCE/SEI 7-05. In the case of an existing building, a judgment

would need to be rendered on the quality of the code under which the building was originally constructed. The quality of test data (Chapter 3) could range from "Good" to "Fair" depending on the extent to which available test data accurately capture degrading behavior of existing building components. For an individual building, the extent to which a model captures the full range of the "design space" would be considered "High," because the building configuration is a known quantity. In this case, when determining model quality in accordance with Chapter 5, the first row in Table 5-3 should be used.

- **Acceptable Value of Adjusted Collapse Margin Ratio (e.g., $ACMR_{10\%}$).** The acceptable value of the adjusted collapse margin ratio should be determined. Based on an acceptable collapse probability of 10%, $ACMR_{10\%}$ is consistent with the collapse performance objectives of this Methodology.

F.4.4 Step Four: Perform Nonlinear Static Analysis (NSA)

- **Nonlinear Static Analysis.** A nonlinear static (pushover) analysis is performed to check nonlinear behavior of the model, and to verify that all elements assumed to be essentially elastic have not yielded at the point that a collapse mechanism develops in the structure. Pushover analyses should be completed in both horizontal directions.
- **Structure Period-Based Ductility, μ_T.** The period-based ductility, μ_T, is determined from pushover analysis results, for both horizontal directions, in accordance with Chapter 6 and including non-simulated limit states as appropriate.
- **Spectral Shape Factor, *SSF*.** The spectral shape factor, *SSF*, for both horizontal directions, is determined based on the period-based ductility, μ_T, the building Seismic Design Category, and the fundamental period, *T*, in the direction of interest, in accordance with Section 7.2.2.

F.4.5 Step Five: Select Record Set and Scale Records

- **Record Set Selection.** If the building is located within 10 km of an active fault, then the Near-Field record set should be selected for collapse evaluation, otherwise the Far-Field record set should be used.
- **Record Set Scaling.** Both components of each record in the record set should be scaled up to the required collapse level intensity at which one-half or more of the records must not cause collapse.

  To scale the records to this level, all normalized records are multiplied by the same scale factor, *SF*. The scaling factor, *SF*, should be computed

for both horizontal directions and the average value used to scale both components of each record.

$$SF = \frac{ACMR_{10\%}}{C_{3D}\, SSF}\left(\frac{S_{MT}}{S_{NRT}}\right) \qquad \text{(G-1)}$$

where:

SF = record (and component) scale factor in the direction of interest, required for collapse evaluation of an individual building system.

$ACMR_{10\%}$ = acceptable value of the adjusted collapse margin ratio from Section 7.4, corresponding to an acceptable collapse probability of 10%.

SSF = spectral shape factor in the direction of interest, as defined in Chapter 7.

C_{3D} = three-dimensional analysis coefficient, taken as 1.2 for three-dimensional analysis, and 1.0 for two-dimensional analysis.

S_{MT} = MCE, 5% damped, spectral response acceleration at the fundamental period, T, of the building in the direction of interest, as defined in Section 11.4.3 of ASCE/SEI 7-05, including Site Class.

S_{NRT} = median value of normalized record set, 5% damped, spectral response acceleration at the fundamental period, T, of the building in the direction of interest.

T = the fundamental period of the building in the direction of interest, based on the limits of Section 12.8.2 of ASCE/SEI 7-05, computed in accordance with Equation 5-5 in Chapter 5.

F.4.6 Step Six: Perform Nonlinear Dynamic Analysis (NDA) and Evaluate Performance

- **Nonlinear Dynamic Analysis.** A nonlinear dynamic analysis of the model(s) is performed separately for each scaled record of the record set. The response is classified as either "collapse" or "non-collapse," based on sidesway collapse of the analytical model or through the use of non-simulated collapse component acceptance criteria. Ground motion record pairs should be applied to two-dimensional and three-dimensional models in accordance with Chapter 6.
- **Collapse Evaluation.** If less than one-half of the records cause collapse, then the trial design (or the existing building) meets the collapse performance objective, and the building has an acceptably low probability of collapse for MCE ground motions. If one-half or more of

the records cause collapse, then the design does not meet the collapse performance objective, and re-design and re-evaluation are required.

Symbols

A = force normalized by effective seismic weight, W, corresponding to arbitrary post-yield displacement, D, of the isolation system in the horizontal direction under consideration, used to define bi-linear spring properties of isolators

A_g = gross cross-sectional area of an element

a_{sl} = indicator variable (0 or 1) to signify possibility of longitudinal rebar slip past the column end, where a_{sl} = 1 if slip is possible (Panagiotakos, 2001)

A_y = force normalized by effective seismic weight, W, corresponding to idealized yield displacement, D_y, of the isolation system in the horizontal direction under consideration, used to define bi-linear spring properties of isolators

$ACMR$ = adjusted collapse margin ratio

$ACMR_{10\%}$ = acceptable value of the adjusted collapse margin ratio ($ACMR$), on average, for the performance group of interest

$ACMR_{20\%}$ = acceptable value of the adjusted collapse margin ratio ($ACMR$) for an individual archetype of the performance group of interest

b = element width

B_{1E} = numerical coefficient as set forth in Table 18.6-1 of ASCE/SEI 7-05 for the effective damping equal to $\beta_I + \beta_{V1}$ and period equal to T

c = cyclic deterioration calibration term (exponent); describes the change in the *rate* of cyclic deterioration as the energy dissipation capacity is exhausted

C_{3D} = 3-dimensional analysis coefficient, 1.2 for 3-dimensional analysis (and 1.0 for 2-dimensional analysis)

C_d = deflection amplification factor (current values given in Table 12.2-1 of ASCE/SEI 7-05)

C_s = seismic response coefficient as determined in Section 12.8.1.1 of ASCE/SEI 7-05)

C_t = approximate period coefficient as determined in Table 12.8-2 of ASCE/SEI 7-05)

C_u = upper-limit period coefficient as determined in Table 12.8-1 of ASCE/SEI 7-05)

c_{units} = a units conversion variable that equals 1.0 when f'_c is in MPa units and 6.9 for ksi units

CI = confidence interval

CMR = collapse margin ratio

C_0 = coefficient relating fundamental-mode (SDOF) displacement to roof (MDOF) displacement of an index archetype model, as defined in Section 6.3

d = column depth

D = effect of dead load for use in load combinations of Section 12.4 of ASCE/SEI 7-05

D = arbitrary post-yield displacement, in inches, of the isolation system in the horizontal direction under consideration used to define bi-linear spring properties of isolators (Chapter 10)

D_M = maximum displacement, in inches, at the center of rigidity of the isolation system in the direction under consideration, as prescribed by Eq. 17.5-3 of ASCE/SEI 7-05

D_{TM} = total maximum displacement, in inches, of the isolation system in the direction under consideration considering both translational and torsional displacement, as prescribed by Eq. 17.5-6 of ASCE/SEI 7-05

D_y = idealized yield displacement, in inches, of the isolation system in the horizontal direction under consideration used to define bi-linear spring properties of isolators

EI_g = gross cross-sectional moment of inertia

EI_{stf} = effective cross-sectional moment of inertia such that the secant stiffness is defined to 40% of the yield moment/force of the component

EI_y = effective cross-sectional moment of inertia that provides a secant stiffness through the yield point

E_t = total energy dissipation capacity

EXP = exponential

F_a = short-period site coefficient (at 0.2-second period) as given in Section 11.4.3 of ASCE/SEI 7-05

F_c = maximum strength (at capping point)

F_r = residual strength

F_v = long-period site coefficient (at 1.0-second period) as given in Section 11.4.3 of ASCE/SEI 7-05

F_x = nonlinear static (pushover) analysis force at level x

F_y = yield strength of material

f'_c = compressive strength of unconfined concrete, based on standard cylinder test

f_y = yield stress of longitudinal reinforcement (Appendix E).

g = constant acceleration due to gravity

H = foundation loads due to lateral earth pressure, ground water pressure, or pressure of bulk materials, Chapter 2 of ASCE/SEI 7-05

h = element height

h_n = height in feet above the base to the highest level of the structure (ASCE/SEI 7-05)

h_r = height above the base to the roof level of the archetype building

I = the importance factor in Section 11.5.1 of ASCE/SEI 7-05

K = residual strength present in material model, defined as a ratio of M_y

K_c = post-capping stiffness, i.e., stiffness beyond $\theta_{cap,pl}$

K_e = effective elastic secant stiffness to the yield point

K_{pc} = post-capping tangent stiffness

k_{eff} = effective stiffness of the isolation system, in kips/in., at displacement, D, in the horizontal direction under consideration

k_{Mmin} = minimum effective stiffness, in kips/in., of the isolation system at the maximum displacement in the horizontal direction under consideration, as prescribed by Eq. 17.8-6 of ASCE/SEI 7-05

K_s = hardening stiffness, i.e., stiffness between θ_y and $\theta_{cap,pl}$

L = effect of live load for use in load combinations of Section 12.4 of ASCE/SEI 7-05

L_s = shear span, distance between column end and point of inflection

LN = natural logarithm

M_c = moment capacity at the capping point; used for prediction of hardening stiffness

M_y = yield moment for Ibarra material model (nominal moment capacity of the column)

$M_{y\ (Fardis)}$ = yield moment as calculated based on predictive equations (Panagiotakos and Fardis, 2001)

M_p = plastic moment capacity of element

m_x = mass of index archetype model at level x

N = number of levels (stories) in an index archetype model

NMi = normalization factor of the i^{th} record of the set of interest

$NTH_{1,i}$ = normalized i^{th} record, horizontal component 1

$NTH_{2,i}$ = normalized i^{th} record, horizontal component 2

P = perimeter frame system (Chapter 9)

P = axial load

P_b = axial load at the balanced condition

PGV_{PEER} = peak ground velocity of the i^{th} record based on the geometric mean of the two horizontal components considering different record orientations, based on the PEER-NGA database

Q_E = the effect of horizontal seismic force from total design base shear, V, for use in load combinations of Section 12.4 of ASCE/SEI 7-05

R = response modification coefficient (current values given in Table 12.2-1 of ASCE/SEI 7-05)

R_{eff} = effective R factor which accounts for the additional strength caused by the minimum base shear requirement

R_I = numerical coefficient related to the type of seismic force-resisting system above the isolation system (i.e., three-eights of the R value given in Table 12.2.-1 of ASCE/SEI 7-05, not to exceed 2.0, need not be taken as less than 1.0)

RC = reinforced concrete

s = spacing of transverse reinforcement in the column hinge region

S = snow load, Chapter 2 of ASCE/SEI 7-05

S = space frame system (Chapter 9)

S_1 = mapped MCE, 5-percent damped, spectral response acceleration parameter at a period of 1 second as defined in Section 11.4.1 of ASCE/SEI 7-05

S_{CT} = random variable representing collapse level earthquake, 5-percent damped, spectral response acceleration at the fundamental period, T, of the building (Site Class D)

$S_{CT(SC)}$ = collapse level earthquake, 5-percent damped, spectral response acceleration at the fundamental period, T, of the building (Site Class D) obtained from simulated collapse failure modes.

$S_{CT(NSC)}$ = collapse level earthquake, 5-percent damped, spectral response acceleration at the fundamental period, T, of the building (Site Class D) obtained from non-simulated collapse failure modes.

$\hat{S}_{CT}$ = median value of collapse level earthquake, 5-percent damped, spectral response acceleration at the fundamental period, T, of the building (Site Class D)

S_{CT1} = collapse level earthquake, 5-percent damped, spectral response acceleration at the fundamental period, T_1, of the building (Site Class D)

S_{DS} = design, 5-percent damped, spectral response acceleration parameter at short periods as defined in Section 11.4.4 of ASCE/SEI 7-05

S_{D1} = design, 5-percent damped, spectral response acceleration parameter at a period of 1 second as defined in Section 11.4.4 of ASCE/SEI 7-05

S_{max} = maximum lateral force of the fully-yielded seismic force-resisting system normalized by the effective seismic weight of the building, W

S_{MS} = the MCE, 5-percent damped, spectral response acceleration parameter at short periods adjusted for site class effects as defined in Section 11.4.3 of ASCE/SEI 7-05

S_{MT} = MCE, 5-percent damped, spectral response acceleration at the fundamental period, T, of the building, as defined in Section 11.4.3 of ASCE/SEI 7-05 (Site Class D)

S_{M1} = the MCE, 5-percent damped, spectral response acceleration parameter at a period of 1 second adjusted for site class effects as defined in Section 11.4.3 of ASCE/SEI 7-05 (Site Class D)

s_n = rebar buckling coefficient, $(s/d_b)(f_y/100)^{0.5}$, where f_y is in MPa (similar to a term proposed by Dhakal and Maekawa (2002))

$\hat{S}_{NRT}$ = median value of normalized record set, 5-percent damped, spectral response acceleration at the fundamental period, *T*, of the building

S_S = mapped MCE, 5-percent damped, spectral response acceleration parameter at short periods as defined in Section 11.4.1 of ASCE/SEI 7-05

S_T = median value of normalized record set, 5-percent damped, spectral response acceleration at the fundamental period, *T*, for record set scaled to an arbitrary intensity. This parameter is also the anchor point for individual ground motion records of the record set at this intensity

S_a = spectra acceleration, g

$S_a(T)$ = the spectral acceleration at the period, *T*

SCWB = ratio of flexure strengths of column and beams framing into a joint, computed as per ACI 318-05 (ACI 2005)

SD_{CT} = median value of collapse level earthquake, 5-percent damped, spectral response displacement at the fundamental period, *T*, of the building corresponding to spectral response acceleration, $\hat{S}_{CT}$

SD_{MT} = MCE, 5-percent damped, spectral response displacement at the fundamental period, *T*, of the building, corresponding to spectral response acceleration, S_{MT}

SF = record (and component) scale factor required for collapse evaluation of an individual building

SMF = special moment frame

SSF = spectral shape factor

SSF_i = spectral shape factor of *i*th index archetype analysis model

T = the fundamental period of the building, in seconds, based on the limits of Section 12.8.2 of the ASCE/SEI 7-05 and the approximate fundamental period, T_a

T_1 = the fundamental period of the building, as determined by eigenvalue analysis of the structural model (seconds)

T_a = the approximate fundamental period of the building, in seconds, as determined in Section 12.8.2.1 of ASCE/SEI 7-05

T_{eff} = effective period of isolation system, in seconds, at displacement, D, in the horizontal direction under consideration.

$TH_{1,i}$ = record i, horizontal component 1, PEER database

$TH_{2,i}$ = record i, horizontal component 2, PEER database

T_L = long-period transition period of the building, in seconds, as defined in Section 11.4.5 of ASCE/SEI 7-05

T_M = effective period, in seconds, of the seismically isolated structure at the maximum displacement in the direction under consideration, as prescribed by Eq. 17.5-4 of ASCE/SEI 7-05

T_s = short-period transition period of the building, in seconds, equal to S_{D1}/S_{DS}, as defined by Section 11.3 of ASCE/SEI 7-05

V = total design lateral force or shear at base (ASCE/SEI 7-05)

V_c = shear capacity of concrete, as per ACI 318-05

V_E = lateral force that would be developed in the seismic force-resisting system if the system remained entirely elastic for design earthquake ground motions (FEMA, 2004b)

V_{max} = maximum lateral force of the fully-yielded seismic force-resisting system (same as V_Y parameter, FEMA, 2004b)

V_{mpr} = capacity shear demand, caused by fully plastic moments at each end of the element, and including 25% overstrength, as per ACI 318-05 (ACI 2005)

V_n = nominal shear capacity including contributions from concrete and steel, as per the ACI 318-05

V_s = total lateral seismic design force or shear on elements above the isolation system, as prescribed by Eq. 17.5-8 of ASCE/SEI 7-05

V_u = shear demand

W = effective seismic weight of the structure above the isolation interface, as defined in Section 17.5.3.4 of ASCE/SEI 7-05

W = effective seismic weight of the building as defined in Section 12.7.2 of ASCE/SEI 7-05

w_x = portion of W that is located at or assigned to Level x

x = parameter of Equation (12.8-7) given in Table 12.8-2 of ASCE/SEI 7-05

β_0 = regression coefficient from the equation $LN[S_{CT1}] = \beta_0 + \beta_1 \varepsilon$

β_1 = regression coefficient from the equation $LN[S_{CT1}] = \beta_0 + \beta_1 \varepsilon$

β_{DR} = design requirements-related collapse uncertainty

β_{eff} = effective damping of the isolation system, percent of critical damping, at displacement, D, in the horizontal direction under consideration.

β_F = uncertainty associated with ductile fracture of steel reduced beam sections, logarithmic standard deviation

β_I = component of effective damping of the structure due to the inherent dissipation of energy by elements of the structure, at or just below the effective yield displacement of the seismic force-resisting system, Section 18.6.2.1 of ASCE/SEI 7-05

β_M = effective damping, percent of critical, of the isolation system at the maximum displacement in the direction under consideration, as prescribed by Eq. 17.8-8 of ASCE/SEI 7-05

β_{MDL} = modeling-related collapse uncertainty

β_{RTR} = record-to-record collapse uncertainty

β_{TD} = test data-related collapse uncertainty

β_{TOT} = total system collapse uncertainty

β_{V1} = component of effective damping of the fundamental mode of vibration of the structure in the direction of interest due to viscous dissipation of energy by the damping system, at or just below the effective yield displacement of the seismic force-resisting system, Section 16.6.2.3 of ASCE/SEI 7-05

δ = roof drift of the seismic force-resisting system for design earthquake ground motions (FEMA, 2004b)

δ_c = displacement associated with maximum strength, F_c (at the capping point)

δ_E = roof drift of the seismic force-resisting system if the system remained entirely elastic for design earthquake ground motions (FEMA, 2004b)

δ_u = roof displacement used to approximate the ultimate displacement capacity of the seismic force-resisting system, as derived from pushover analysis

δ_p = pre-capping plastic deformation capacity

$\delta_{y,eff}$ = effective roof displacement used to approximate full yield of the seismic force-resisting system, as derived from pushover analysis

ε = number of standard deviations between observed spectral value and the median prediction from an attenuation function

$\varepsilon(T)$ = the epsilon value of a ground motion, evaluated at period, T

$\varepsilon(T)_{,\text{records}}$ = the mean epsilon value of the Far-Field ground motion set, evaluated at period, T

$\overline{\varepsilon}_0(T)$ = the expected ε value for the site and hazard-level of interest

ϕ = strength reduction factor

$\phi_{1,x}$ = ordinate of the fundamental mode in the direction of interest at level x

$\phi_{1,r}$ = ordinate of the fundamental mode in the direction of interest at the roof

λ = normalized energy dissipation capacity; defined such that $E_t = \lambda M_y \theta_y$ (Ibarra et al. 2005)

λ_{DR} = random variable representing design requirements-related collapse uncertainty

λ_{MDL} = random variable representing modeling-related collapse uncertainty

λ_{RTR} = random variable representing record-to-record collapse uncertainty

λ_{TD} = random variable representing test data-related collapse uncertainty

μ_T = period-based ductility of an index archetype model

ν = axial load ratio ($P/A_g f'_c$)

θ_{cap} = total chord rotation at capping, sum of elastic and plastic deformations (radians)

$\theta_{cap,pl}$ (or θ_p) = plastic chord rotation from yield to cap (radians)

θ_p = plastic hinge rotation (radians)

θ_{pc} = post-capping plastic rotation capacity, from the cap to point of zero strength (radians)

$\hat{\theta}_p$ = median value of plastic hinge rotation at which ductile fracture in steel RBS is initiated (radians)

θ_y = chord rotation at yielding, taken as the sum of flexural, shear and bond-slip components; yielding is defined as the point of significant stiffness change, i.e., steel yielding or concrete crushing (radians)

ρ = redundancy factor based on the extent of structural redundancy present in a building as defined in Section 12.3.4 of ASCE/SEI 7-05

ρ (or ρ_{tot}) = ratio of total area of longitudinal reinforcement (for columns) or ratio of tensile longitudinal reinforcement (for beams)

ρ' = ratio compressive longitudinal reinforcement (for beams)

ρ_{sh} = area ratio of transverse reinforcement in column hinge region

$\rho_{sh,eff}$ = effective ratio of transverse reinforcement in column hinge region ($\rho_{sh} f_{y,w}/f'_c$)

σ_{LN} = logarithmic standard deviation for the prediction uncertainty

Ω = calculated overstrength of an index archetype analysis model

Ω_O = overstrength factor appropriate for use in the load combinations of Section 12.4 of ASCE/SEI 7-05 (current values of Ω_O are given in Table 12.2-1 of ASCE/SEI 7-05)

Glossary

Definitions

Archetype: A prototypical representation of a seismic-force-resisting system.

Archetype Design Space: The overall range of permissible configurations, structural design parameters, and other features that define the application limits for a seismic-force-resisting system.

Base: The level at which the horizontal seismic ground motions are considered to be imparted to the structure (ASCE/SEI 7-05).

Base Shear: Total design lateral force or shear at the base (ASCE/SEI 7-05).

Building: Any structure whose intended use includes shelter of human occupants (ASCE/SEI 7-05).

Collapse Level Earthquake Ground Motions: The level of earthquake ground motions that cause collapse of the seismic force-resisting system of interest.

Component: A part or element of an architectural, electrical, mechanical or structural system (ASCE/SEI 7-05).

Damping Device: A flexible structural element of the damping system that dissipates energy due to relative motion of each end of the device (ASCE/SEI 7-05).

Damping System: The collection of structural elements that includes all individual damping devices, all structural elements or bracing required to transfer forces from damping devices to the base of the structure, and the structural elements required to transfer forces from damping devices to the seismic force-resisting system (ASCE/SEI 7-05).

Design Earthquake Ground Motions: The earthquake ground motions that are two-thirds of the corresponding MCE ground motions (ASCE/SEI 7-05).

Design Requirements-Related Uncertainty: Collapse uncertainty associated with the quality of the design requirements of the system of interest.

Displacement Restraint System: A collection of structural elements that limits lateral displacement of seismically isolated structures due to the maximum considered earthquake (Chapter 17, ASCE/SEI 7-05).

Effective Damping: The value of equivalent viscous damping corresponding to energy dissipated during cyclic response of the isolation system (Chapter 17, ASCE/SEI 7-05).

Effective Stiffness: The value of the lateral force in the isolation system, or element thereof, divided by the corresponding lateral displacement (Chapter 17, ASCE/SEI 7-05).

Importance Factor: A factor assigned to each structure according to its Occupancy Category, as prescribed in Section 11.5.1 of ASCE/SEI 7-05.

Incremental Dynamic Analysis: Series of nonlinear response history analyses using an input ground motion that is incrementally scaled to increasing intensities until collapse is detected in the analysis.

Index Archetype Configuration: A prototypical representation of a seismic-force-resisting system configuration that embodies key features and behaviors related to collapse performance when subjected to earthquake ground motions.

Index Archetype Design: An index archetype configuration that has been proportioned and detailed using the design requirements of the system of interest.

Index Archetype Model: An idealized mathematical representation of an index archetype design used to simulate collapse using nonlinear static and dynamic analyses.

Isolation Interface: The boundary between the upper portion of the structure, which is isolated, and the lower portion of the structure, which moves rigidly with the ground (Chapter 17, ASCE/SEI 7-05).

Isolation System: The collection of structural elements that includes all individual isolator units, all structural elements that transfer force between elements of the isolation system, and all connections to other structural elements. The isolation system also includes the wind-restraint system, energy-dissipation devices, and/or the displacement restraint system, if such systems and devices are used to meet the design requirements of Chapter 17 (ASCE/SEI 7-05).

Isolator Unit: A horizontally flexible and vertically stiff structural element of the isolation system that permits large lateral deformations under design seismic loads. An isolator unit is permitted to be used either as

part of, or in addition to, the weight-supporting system of the structure (Chapter 17, ASCE/SEI 7-05).

Maximum Considered Earthquake (MCE) Ground Motions: The most severe earthquake effects considered, as defined by Section 11.4 of ASCE/SEI 7-05.

Modeling Uncertainty: Collapse uncertainty associated with the quality of the index archetype models.

Nonbuilding Structure: A structure, other than a building, constructed of a type included in Chapter 15 of ASCE/SEI 7-05.

Non-Simulated Collapse: Structural collapse caused by collapse modes that are not represented in the analytical model. Non-simulated collapse occurs when a component limit state is exceeded, as defined by component fragility functions.

Occupancy: The purpose for which a building or other structure, or part thereof, is used or intended to be used (ASCE/SEI 7-05).

Occupancy Category: A classification assigned to a structure based on occupancy as defined in Table 1-1 of ASCE/SEI 7-05.

Performance Group: A subset of the archetype design space containing a group of index archetype configurations that share a set of common features or behavioral characteristics, binned for statistical evaluation of collapse performance.

Record-to-Record Uncertainty: Collapse uncertainty due to variability in response to different ground motions.

Record-to-Record Variability: Variation in the response of a structure under multiple input ground motions that are scaled to a consistent ground motion intensity.

Seismic Design Category: A classification assigned to a structure based on Occupancy Category and the severity of design earthquake ground motions at the site, as defined in Section 11.4 of ASCE/SEI 7-05.

Seismic Force-Resisting System: That part of the structural system that is considered to provide the required resistance to seismic forces prescribed in ASCE/SEI 7-05.

Sidesway Collapse: Structural collapse due to excessive story drift associated with loss of lateral strength and stiffness due to material and geometric nonlinearities.

Simulated Collapse: Structural collapse caused by collapse modes that are directly represented in the analytical model.

Site Class: A classification assigned to a site based on the types of soils present and their engineering properties, as defined in Chapter 20 of ASCE/SEI 7-05.

Structure: That which is built or constructed and limited to buildings and nonbuilding structures, as defined in ASCE/SEI 7-05.

Test Data-Related Uncertainty: Collapse uncertainty associated with the quality of the test data for the system of interest.

Total Maximum Displacement: The maximum considered earthquake lateral displacement, including additional displacement due to actual and accidental torsion, required for verification of the stability of the isolation system or elements thereof, design of structure separations, and vertical load testing of isolator unit prototypes (Chapter 17, ASCE/SEI 7-05).

Vertical Collapse: Structural collapse due to the loss of vertical-load-carrying capacity of a critical component.

Which Spectral Acceleration Are You Using?

Jack W. Baker,[a] **M.EERI, and C. Allin Cornell,**[a] **M.EERI**

Analysis of the seismic risk to a structure requires assessment of both the rate of occurrence of future earthquake ground motions (hazard) and the effect of these ground motions on the structure (response). These two pieces are often linked using an intensity measure such as spectral acceleration. However, earth scientists typically use the geometric mean of the spectral accelerations of the two horizontal components of ground motion as the intensity measure for *hazard* analysis, while structural engineers often use spectral acceleration of a single horizontal component as the intensity measure for *response* analysis. This inconsistency in definitions is typically not recognized when the two assessments are combined, resulting in unconservative conclusions about the seismic risk to the structure. The source and impact of the problem is examined in this paper, and several potential resolutions are proposed. This discussion is directly applicable to probabilistic analyses, but also has implications for deterministic seismic evaluations. [DOI: 10.1193/1.2191540]

INTRODUCTION

Calculation of the risk to a structure from future earthquakes requires assessment of both the probability of occurrence of future earthquakes (hazard) and the resulting response of the structure due to earthquakes (response). The analysis of hazard is typically performed by earth scientists (e.g., seismologists or geotechnical engineering scientists), while the analysis of response is typically performed by structural engineers. The results from these two specialists must then be combined, and this is often done by utilizing an intensity measure (IM) (Banon et al. 2001, Cornell et al. 2002, Moehle and Deierlein 2004). Earth scientists provide the probability of occurrence of varying levels of the IM (through hazard maps or site-specific analysis), and structural engineers estimate the effect of an earthquake with given levels of the IM (using dynamic analysis or by associating the IM with the forces or displacements applied in a static analysis).

Spectral acceleration, *Sa*, is the most commonly used intensity measure in practice today for analysis of buildings. This value represents the maximum acceleration that a ground motion will cause in a linear oscillator with a specified natural period and damping level. (In fact, the true measure is pseudospectral acceleration, which is equal to spectral displacement times the square of the natural frequency, but the difference is often negligible and the name is often shortened to simply "spectral acceleration.") But *Sa* is often defined differently by earth scientists and structural engineers. The difference originates from the fact that earthquake ground motions at a point occur in more than

[a] Department of Civil and Environmental Engineering, Stanford University, Stanford, CA 94305-4020

Earthquake Spectra, Volume 22, No. 2, pages 293–312, May 2006; © 2006, Earthquake Engineering Research Institute

one direction. While structural engineers often use the *Sa* caused by a ground motion along a single axis in the horizontal plane, earth scientists often compute *Sa* for two perpendicular horizontal components of a ground motion, and then work with the geometric mean of the *Sa*'s of the two components. Both definitions of *Sa* are valid. However, the difference in definitions is often not recognized when the two pieces are linked, because both are called "spectral acceleration." Failure to use a common definition may introduce an error in the results.

In this paper, the differences in these two definitions are examined, along with the reasons why earth scientists and structural engineers choose their respective definitions. Examples of the use of these definitions are presented, along with the potential impact of failing to recognize the discrepancy. Several procedures for addressing the problem are examined, and the relative advantages and disadvantages of each are considered. Analysis is sometimes performed for each axis of a structure independently, and other times an entire 3-D structural model is analyzed at once. Both of these cases are considered, and consistent procedures for each are described. These procedures should be helpful for analysts performing seismic risk assessments of structures.

SPECTRAL ACCELERATION: TWO DEFINITIONS

TREATMENT OF SPECTRAL ACCELERATION BY EARTH SCIENTISTS

The earth scientist's concern with spectral acceleration is in predicting the distribution of spectral acceleration at a site, given an earthquake with a specified magnitude, distance, faulting style, local soil classification, etc. This prediction is made in the form of an attenuation model. Many attenuation models are empirically developed using analysis of recorded ground motions (see Abrahamson and Silva 1997, Boore et al. 1997, Campbell 1997, Sadigh et al. 1997, and Spudich et al. 1999, among many others). There is scatter in this recorded data (due to path effects, variation in stress drop, and other factors that are not captured by the attenuation model), which must be dealt with during development of the attenuation model.

The observed variability in spectral acceleration is well represented by a lognormal distribution (Abrahamson 1988, 2000). Thus, attenuation models work with the mean and standard deviation of the logarithm of *Sa*, which can be represented by a Gaussian distribution. The broad variability of the distribution hinders estimation of the mean value of $\ln Sa$ needed for the attenuation law. The log *Sa*'s of two perpendicular components of the ground motion are thus averaged, reducing the variance and allowing the mean value of $\ln Sa$ to be estimated with greater confidence. For example, in Figure 1 it is seen that arbitrary-component spectra vary more about the estimated mean than their geometric mean does.

The exponential of the mean of the logarithms of two numbers is termed the "geometric mean" because it is the square root of their product (this is also the same as the SRSS spectral values referred to in section 9.5.7.2.2 of ASCE 2002). For conciseness, we will refer to the geometric mean of spectral acceleration of two components as $Sa_{g.m.}$, and the spectral acceleration of an arbitrary component will be referred to as Sa_{arb}. The logarithms of these values will be referred to as $\ln Sa_{g.m.}$ and $\ln Sa_{arb}$, respectively. The

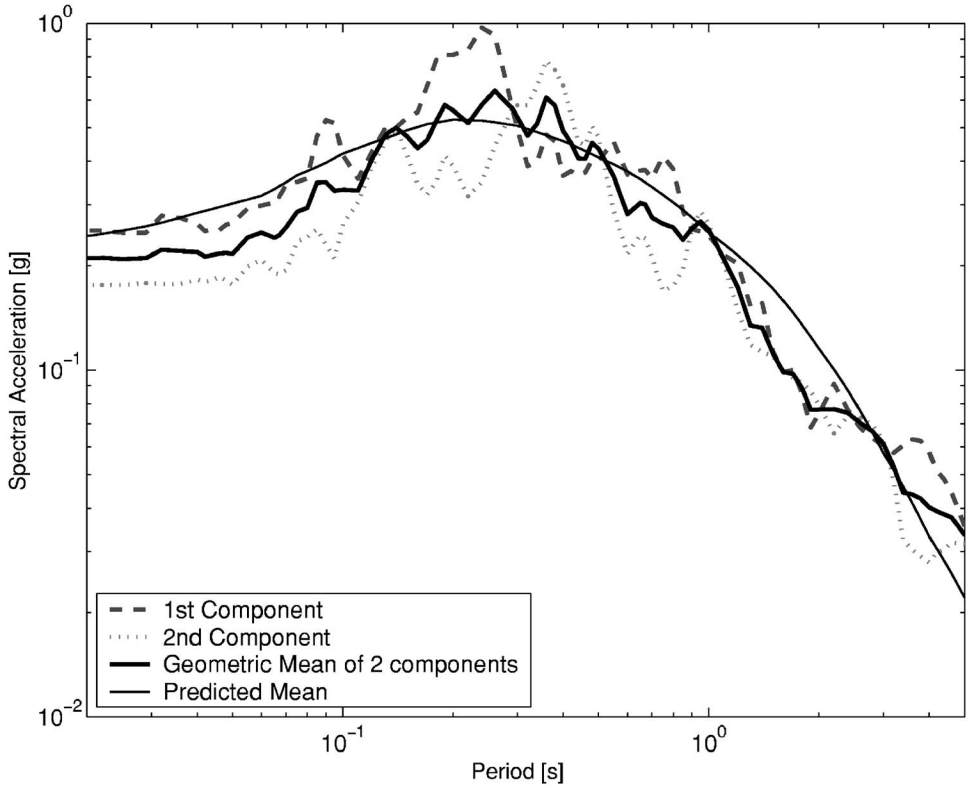

Figure 1. Response spectra from the magnitude 6.2 Chalfant Valley earthquake recorded at Bishop LADWP, 9.2 km from the fault rupture. Response spectra for the two horizontal components of the ground motion, the geometric mean of the response spectra, and the predicted mean for the given magnitude and distance using the prediction of Abrahamson and Silva (1997).

terms *Sa* and ln *Sa* will be used to refer to spectral acceleration and its logarithm, without specification as to which definition is used. And the standard deviation of ln *Sa* will be referred to as the "dispersion" of *Sa*, following common practice elsewhere. It is noted again that these values are functions of the period and damping level specified, but this is not stated explicitly in the notation because consideration of a particular period and damping are not needed for this discussion.

Attenuation models typically provide a predicted mean and standard deviation for the conditional random variable ln $Sa_{g.m.}$, given an earthquake magnitude, distance, etc. These estimates for ln $Sa_{g.m.}$ can be made directly from the data, because the averaging of the two components transformed the observed data into values of $Sa_{g.m.}$. For a given earthquake, the mean of the conditional random variable ln Sa_{arb} is equal to the mean of ln $Sa_{g.m.}$. But the standard deviation of ln Sa_{arb} is greater than that of ln $Sa_{g.m.}$ by a factor that could be as large as $\sqrt{2}$ if the two components were uncorrelated (because the

standard deviation of the mean of 2 uncorrelated random variables with common standard deviation σ is equal to $\sigma/\sqrt{2}$). Calculating the standard deviation of $\ln Sa_{arb}$ thus takes an additional step of going back to the non-averaged data and examining the standard deviation there. Some researchers (e.g., Boore et al. 1997, Spudich et al. 1999) have taken this step, but many others have not because it was not recognized as important. However, the difference in standard deviations is in fact relevant for ground motion hazard analysis, as will be seen in the next section.

Deterministic Ground Motion Hazard Analysis

The effect of the standard deviation of $\ln Sa$ is easily seen in deterministic seismic hazard analysis. Often in a deterministic hazard analysis, a target spectral acceleration for a "Maximum Considered Event" is computed by specifying a scenario event (magnitude and distance), and then computing the value of $\ln Sa$, at a given period and damping level, that is one standard deviation greater than the mean prediction for that event (Reiter 1990, Anderson 1997). But the value of the standard deviation depends upon whether $Sa_{g.m.}$ or Sa_{arb} is being used as the IM. Because of its greater dispersion (logarithmic standard deviation), the target value of Sa_{arb} will thus be larger than that for $Sa_{g.m.}$. So the target spectral acceleration depends on the definition of Sa being used, even though both definitions have the same mean value of $\ln Sa$. For a "mean plus one sigma" ground motion, Sa_{arb} will thus be larger than that for $Sa_{g.m.}$ by a factor of $\exp(\sigma_{\ln Sa_{arb}} - \sigma_{\ln Sa_{g.m.}})$. For example, using the model of Boore et al. (1997, Boore 2005), this difference is $\exp(0.047)$ at a period of 0.8 seconds with 5% damping, implying that if Sa_{arb} is to be used as the IM, the target spectral acceleration would be about 5% larger than if $Sa_{g.m.}$ is used.

Another method used in deterministic hazard maps is to take as the hazard value 150% of the median spectral acceleration value for a characteristic event (ASCE 2002). One of the justifications for the 150% rule is that this will capture a reasonable fraction of the Sa values that could result from occurrence of this characteristic event. However, the fraction captured will vary based on which of the two definitions is used. Consider Sa at a period of 0.8 seconds. Per the Boore et al. (1997, Boore 2005) attenuation relationship used above, Sa_{arb} has a 23% chance of exceeding 150% of the median Sa value given the event, while $Sa_{g.m.}$ has a 21% chance of exceeding 150% of the median Sa given the event. Thus the level of conservatism resulting from this rule varies slightly depending on the Sa definition used. Spectral acceleration is merely a tool used to simplify the analysis problem; therefore the factor of safety should not vary based on the definition used. In principle the 150% rule for $Sa_{g.m.}$ should be a "156% rule" for Sa_{arb}, in order to provide the same level of conservatism.

Probabilistic Ground Motion Hazard Analysis

The variation in standard deviation is also seen in probabilistic seismic hazard analysis. In Figure 2, hazard curves for the two definitions of Sa are shown for a hypothetical site 8 kilometers away from a recurring magnitude 6.5 earthquake (this simple hazard environment is representative of sites near a single large fault). Again the attenuation model of Boore et al. (1997, Boore 2005) is used, because it provides dispersions for

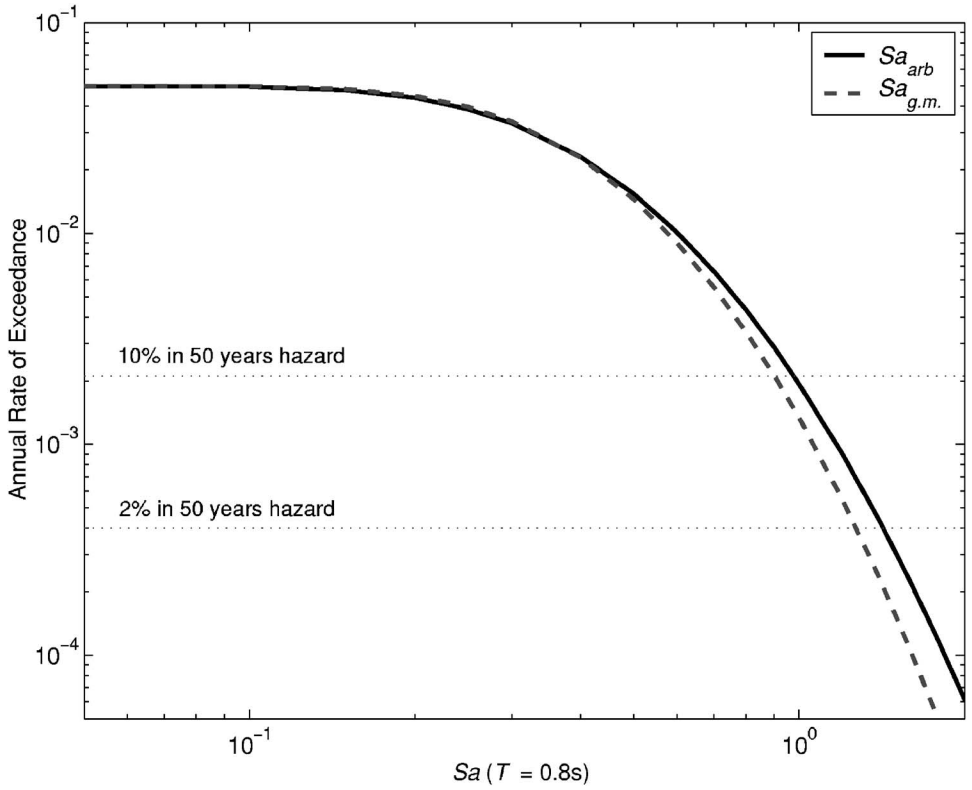

Figure 2. Ground motion hazard from a recurring magnitude 6.5 earthquake at a distance of 8 km, for Sa_{arb} and $Sa_{g.m.}$ at a period of 0.8 seconds with 5% damping.

both Sa_{arb} and $Sa_{g.m.}$. We see that the hazard curve for Sa_{arb} is greater than $Sa_{g.m.}$ due to the larger dispersion in Sa_{arb}. This is because ground motion hazard, especially at long return periods, is driven by ground motions that are larger than average. So even though Sa_{arb} and $Sa_{g.m.}$ have the same median value for each magnitude/distance considered, the larger-than-average values for Sa_{arb} will be greater than those for $Sa_{g.m.}$. This is the same effect as is seen in the deterministic hazard analysis case. (It is also true that the smaller-than-average values will be smaller for Sa_{arb} than for $Sa_{g.m.}$, but these events make a relatively smaller contribution to hazard, so the larger-than-average and smaller-than-average events are not offsetting.) For this site the Sa_{arb} with a 2% probability of exceedance in 50 years is 12% larger than the corresponding $Sa_{g.m.}$. The hazard for sites near multiple faults is simply a weighted sum of hazard curves similar to that shown in Figure 2, so we expect hazard curves at all sites to show this pattern.

The conclusion to be drawn from these examples is that the ground motion hazard is dependent on the definition of spectral acceleration. Even though $Sa_{g.m.}$ and Sa_{arb} have the same median value (for a given magnitude, distance, etc.), the difference in dispersion will cause a difference in ground motion hazard.

This result is important, because it means that ground motion hazard cannot be used interchangeably for both Sa_{arb} and $Sa_{g.m.}$. This brings to light a problem with the U.S. Geological Survey maps of spectral acceleration hazard (Frankel et al. 2002). The maps are produced using results from several attenuation models, some of which emphasize the dispersion in Sa_{arb}, and some of which provide only dispersion for $Sa_{g.m.}$. The U.S. Geological Survey has used the dispersions emphasized by the models' authors, resulting in a mix of both definitions being used. Thus the current maps are not strictly interpretable as the ground motion hazard for either Sa_{arb}, or $Sa_{g.m.}$. This will be addressed in future revisions to the maps, in light of the new recognition of the importance of this issue (Frankel 2004).

TREATMENT OF SPECTRAL ACCELERATION BY STRUCTURAL ENGINEERS

Structural engineers also utilize spectral acceleration as a basis for analysis of structural response. Let us first consider analysis of a single two-dimensional frame of a structure—a common situation in practice. In this case, only a single horizontal component of earthquake ground motion is needed for analysis. Therefore, spectral acceleration is computed only for the selected component at a period equal to the elastic first-mode period of the structure, and that is used as the intensity measure. In most cases, no distinction is made between the two components of a ground motion, so using a single component in this case is equivalent to using Sa_{arb} as the intensity measure. To compute $Sa_{g.m.}$ using both horizontal components of the ground motion, but then use only one of the components, the stronger or the weaker, for analysis would only introduce unnecessary scatter into the relationship between the IM and structural response.

This increased scatter resulting from prediction with $Sa_{g.m.}$ is illustrated in Figure 3. Prediction of response of a structure is made using both Sa_{arb} and $Sa_{g.m.}$. A model of an older seven-story reinforced concrete frame, described by Jalayer (2003), is used for analysis. Sixty unscaled recorded ground motions were used to perform nonlinear dynamic analysis. Figure 3 shows that the prediction of the mean log maximum interstory drift ratio, denoted as ln θ, is very similar for both intensity measures, but use of $Sa_{g.m.}$ as the IM results in increased dispersion of θ relative to the use of Sa_{arb}, as was anticipated above. The larger dispersion implies that there is greater uncertainty in the estimate of median response (i.e., if $Sa_{g.m.}$ is used as the IM, a greater number of analyses would need to be performed to achieve the same confidence in the mean ln θ). Thus the use of Sa_{arb} as the IM is preferable for the structural engineer in order to minimize the number of nonlinear dynamic analyses performed.

Many examples of the use of *Sa* as an intensity measure exist in the literature. For example, modal analysis (Chopra 2001), the SAC/FEMA methodology (SAC 2000a, b, c), and incremental dynamic analysis (Vamvatsikos and Cornell 2002) all use *Sa* as a predictor of structural response in some cases. In virtually every application of these procedures, Sa_{arb} (as opposed to $Sa_{g.m.}$) is used as the intensity measure for analysis of a single frame of a structure.

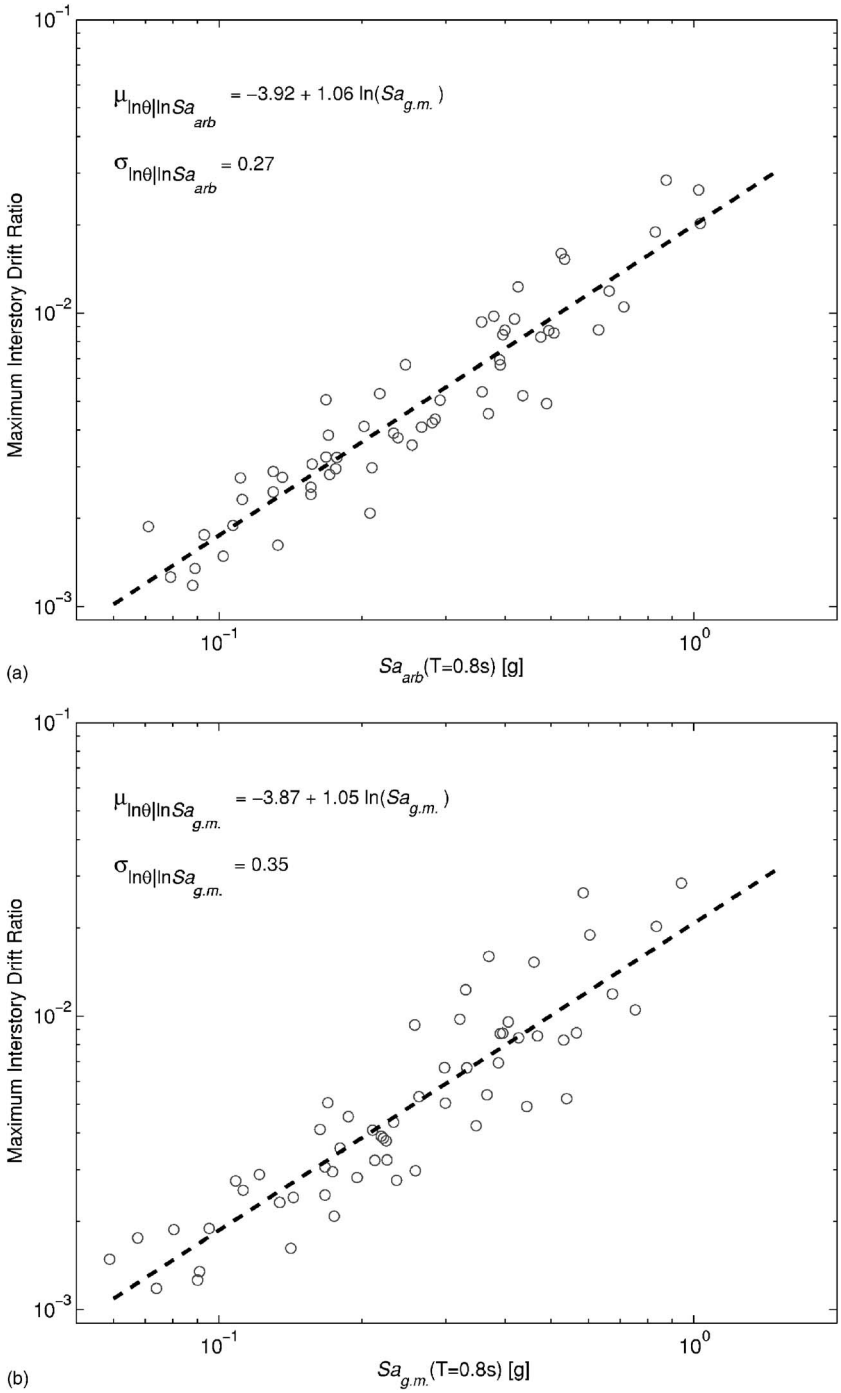

Figure 3. Prediction of the response of a single frame of a structure using (a) the spectral acceleration of the ground motion component used (Sa_{arb}), and (b) the spectral acceleration of the average of both components ($Sa_{g.m.}$).

INCORRECT INTEGRATION OF HAZARD AND RESPONSE

Spectral acceleration hazard is coupled with response analysis during performance-based analysis procedures (e.g., Cornell and Krawinkler 2000, Cornell et al. 2002). In past application of these procedures, frequently the ground motion hazard analysis has been unwittingly performed with $Sa_{g.m.}$ (to utilize existing attenuation models), and the response analysis has performed with Sa_{arb} (to minimize dispersion in the response prediction), resulting in the inconsistency discussed in this paper. Examples where the authors know only too intimately that a hazard analysis based on $Sa_{g.m.}$ was inadvertently coupled with a response analysis based on Sa_{arb} include Baker and Cornell (2004), Jalayer and Cornell (2003), Yun et al. (2002), and Shome and Cornell (1999). In the work of others it is seldom clear because the question was not discussed, but it can be suspected that if the hazard analysis were based on the USGS hazard maps or popular attenuation laws such as Abrahamson and Silva (1997) and Sadigh et al. (1997), where the only reported dispersion is that for $Sa_{g.m.}$, then an inconsistency is likely to exist.

In addition, other design and analysis procedures (e.g., ASCE 2000, 2002), utilize the U.S. Geological Survey maps of spectral acceleration hazard (Frankel et al. 2002) to attain target *Sa* values at which the performance of the structure should be checked. Although in this case there is no explicit statement of the reliability of a structure analyzed in this manner, *Sa* is still used as a link between hazard and response. Thus it is preferable to define *Sa* consistently in both the hazard and response. Possibilities for a consistent treatment of the problem are discussed in the following section.

VALID METHODS OF COMBINING HAZARD AND RESPONSE

For performance-based analysis procedures, it is necessary that the median and dispersion of response at a given IM level be consistent with the IM definition used for hazard analysis. This can be achieved in several ways, the choice of which may depend in part on the situation and available information. Three proposed solutions for use in analyzing a structure along a single axis are outlined below. The common characteristic of each method is that the IM used for hazard analysis and the IM used for response analysis are consistently defined.

1. CALCULATE THE GROUND MOTION HAZARD FOR Sa_{arb}

With this method, the structural response analysis described above is unchanged, but the ground motion hazard analysis is performed for the consistent intensity measure, Sa_{arb}. This allows for the estimation of structural response with less dispersion than when $Sa_{g.m.}$ is used (e.g., see Figure 3). And once more attenuation models are developed with dispersion for Sa_{arb}, the hazard analysis is no more difficult than hazard analysis for $Sa_{g.m.}$. The disadvantage is that few current attenuation models provide the dispersion for Sa_{arb}, meaning that many models, and the resulting hazard analysis, cannot be used without modification.

2. PREDICT STRUCTURAL RESPONSE USING $Sa_{g.m.}$

With this method, the ground motion hazard is unchanged from current $Sa_{g.m.}$-based practice. Instead, the response analysis is modified, using $Sa_{g.m.}$ as the IM rather than Sa_{arb}. To do this, one would compute the IM of a record as the geometric mean of Sa of the two components of the ground motion, even though only one component will be used for analysis. This method has the advantage of not requiring new attenuation laws or hazard analysis. Unfortunately, it will introduce additional dispersion into the response prediction, as was seen in Figure 3, and hence will be less efficient as an IM.

3. PERFORM HAZARD ANALYSIS WITH $Sa_{g.m.}$, RESPONSE ANALYSIS WITH Sa_{arb}, AND INFLATE THE RESPONSE DISPERSION

This method takes advantage of the fact that the median structural response for a given Sa level is the same whether $Sa_{g.m.}$ or Sa_{arb} is used. Only the dispersion is increased if $Sa_{g.m.}$ is used, as was seen in Figure 3. Structural response is thus performed using Sa_{arb} (as per standard practice) to obtain the median response. Then the dispersion in response is inflated to reflect that which would have been seen if $Sa_{g.m.}$ had been used as the intensity measure instead. An estimate of the amount by which the dispersion should be increased can be obtained using a first-order approximation. For this procedure, we assume the following model for the relationship between spectral acceleration and response:

$$\ln \theta = a + b \ln Sa_{arb} + \epsilon_{arb} \tag{1}$$

$$\ln \theta = a + b \ln Sa_{g.m.} + \epsilon_{g.m.} \tag{2}$$

where θ is the structural response value of interest, a and b are coefficients to be estimated from the data using least-squares regression, and ϵ's are zero-mean random variables (note that a and b have the same expected value in Equations 1 and 2, as is demonstrated in the Appendix—Equations 3 and 11—and as is supported by the empirical estimates in Figure 3). The model is seen to fit well in Figure 3, as in many other cases (at least locally). We are interested in estimating the standard deviation of $\ln \theta$ given $Sa_{g.m.}$, in the case where we know only the standard deviation of $\ln \theta$ given $\ln Sa_{arb}$. From Equation 13, we can find the ratio of the two conditional standard deviations. For the example data set here, $\rho_{\ln Sa_x, \ln Sa_y} = 0.797$ and $\rho_{\ln \theta_x, \ln Sa_x} = 0.942$, implying a ratio between standard deviations of 1.34. Thus the predicted conditional standard deviation for the example problem would be $1.34^{*}0.27 = 0.36$, approximately matching the standard deviation in 2b (0.35).

The SAC procedure (SAC 2000a, b, c) uses the model of structural response adopted in Equation 1, but with $b = 1$. So an analysis using the SAC procedure would be a natural candidate for this method. One would simply perform analysis using Sa_{arb} as before, but inflate the dispersion in structural response using Equation 13 before continuing with the SAC methodology.

In the short term, this third method is attractive because it leaves existing hazard and response procedures unmodified, and instead makes a correction before the two analyses

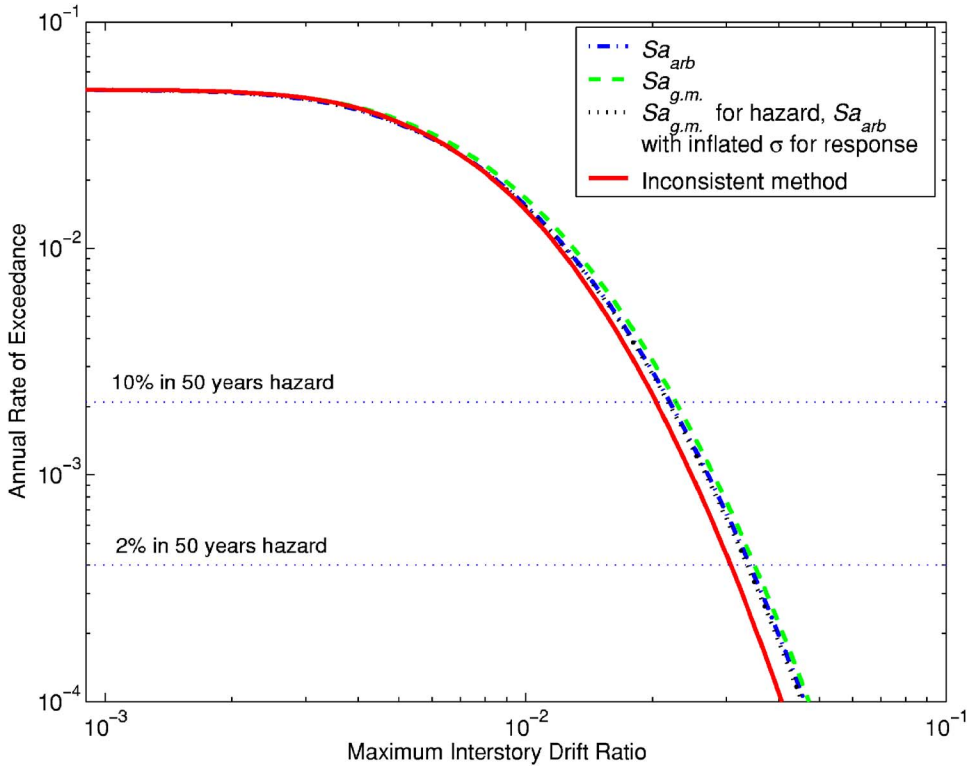

Figure 4. Drift hazard as computed using the three methods proposed above and the inconsistent method.

are combined. However, in the long term one of the two more direct methods using a consistent IM for both hazard and response would be more expeditious.

RESULTS FROM THE PROPOSED METHODS

All three of the methods described should result in the same answer for the probability of exceedance of a given limit state in the structure, aside from the inherent variability in the answer resulting from the statistically uncertain estimates of hazard and response (Baker and Cornell 2003). Additional methods can also be conceived using alternative intensity measures, but the above methods are expected to be the simplest and most similar to current practices.

To illustrate the results of the proposed methods, a drift hazard analysis is performed using the three proposed methods and the previous inconsistent method. This analysis combines the ground motion hazard from Figure 2 with the structural response analysis from Figure 3 to determine the rate of exceeding a given response level in the structure. The procedure for computing this drift hazard curve is described by Bazzurro et al. (1998). The results are displayed in Figure 4. It is seen that the three proposed methods

produce comparable results, while the inconsistent method results are unconservative (e.g., the drift level exceeded with a 2% probability in 50 years is underestimated by approximately 10%). While the magnitude of the error is not overwhelmingly large, it nonetheless represents an easily correctible systematic flaw in the procedure.

In many applications today, the drift hazard curve is not computed. Rather, the ground motion hazard is used to specify a target spectral acceleration to use in analyzing structural response (i.e., the spectral acceleration associated with a 2% probability of exceedance in 50 years). An inconsistent approach will cause a comparable bias in these calculations as well.

ANALYSIS OF 3-D STRUCTURAL MODELS: COMBINING HAZARD AND RESPONSE

When analyzing a 3-D structural model, both horizontal components of the ground motion are used, so the above procedures using a single component are not necessarily applicable. In this case, as before, the concern is that the intensity measures used in the hazard analysis and response analysis should be consistent. Fortunately, the preferred method for analysis in this case is also a method that is apparently often used in practice. Several potential procedures are discussed here:

1. USE $Sa_{g.m.}$ AS THE INTENSITY MEASURE

In this case, ground motion hazard analysis is performed for $Sa_{g.m.}$, as is standard practice today. The intensity measure used for structural response is also $Sa_{g.m.}$, computed for the two components of ground motion used in the analysis. This method is in use today (e.g., Stewart et al. 2001) and appears to be the most straightforward for 3-D structures. For this reason, it is currently recommended by the authors when a scalar intensity measure is used (see below). The preferred choice of an IM in the case where the two axes of the structure have different fundamental periods has not been extensively examined. In the absence of further research, one obvious possibility is to use $Sa_{g.m.}$ at an intermediate period (e.g., the geometric mean of the two periods).

2. USE Sa_{arb} AS THE INTENSITY MEASURE

When using Sa_{arb} as an intensity measure in this case, it is necessary to specify the component of the ground motion being measured, as there are now two horizontal components used in the analysis, each with a differing value of Sa. If the objective is only a scalar drift hazard curve (e.g., there is only a single response parameter of interest), then the practitioner may obtain the most efficient estimate by performing the regression analysis shown in Figure 3 one time for each candidate IM (e.g., for Sa_{arb} oriented along the "x-x" axis of the structure, for Sa_{arb} oriented along the "y-y" axis of the structure, and for $Sa_{g.m.}$). Because all three IM choices should lead to the same answer (in the limit with a very large sample of dynamic analyses), the engineer is free to choose the IM that results in the most efficient estimation. That is, the IM that results in the smallest standard deviation of response prediction. In some cases, the optimal IM will be apparent a priori: if the response parameter of interest is a drift in the x-x axis, then it is likely that

the optimal IM is Sa_{arb} oriented along the *x*-*x* axis. In other cases, for example, when assessing the axial force in a corner-column of a structure or when there is significant torsion in the structure, the optimal IM may be less obvious.

In some cases it is necessary to select a common IM for estimation of more than one response parameter simultaneously. For example, in loss estimation procedures associated with performance-based engineering it is often desirable to know the probability distribution of a set of story drifts and floor accelerations *simultaneously*. In this case, it may again be useful to consider several candidate IMs and examine the trade-offs in efficiency. For instance, Sa_{arb} oriented along the *x*-*x* axis is likely to estimate the responses along the *x*-*x* axis efficiently but the responses along the *y*-*y* axis less efficiently and vice versa for Sa_{arb} along the *y*-*y* axis. Choosing an IM in this case will depend upon the relative importance of the various response parameters of interest, and an understanding of which IM is most efficient for predicting the important response parameters. Note that the results for the less-important response parameters will not be incorrect, but only estimated with less statistical precision.

The above procedure appears to be valid in the case where no record-scaling is used as part of the response predictions. If the records are scaled before performing the structural analysis, the scaling procedure must be carefully considered. Previous studies of the implications of scaling a single component of ground motion may not be applicable to scaling of two components. The authors are particularly concerned about the choice of a scale factor for the orthogonal component of a ground motion when a selected component has been scaled by a specified factor. This problem is currently under investigation.

3. USE A VECTOR INTENSITY MEASURE REPRESENTING THE TWO COMPONENTS INDIVIDUALLY

This approach uses a two-parameter intensity measure, consisting of the spectral accelerations in both the *x*-*x* and *y*-*y* directions. Vector-valued ground motion hazard analysis (Bazzurro and Cornell 2002) is used to compute the joint hazard for the spectral acceleration values of the two components of ground motion. Response prediction can then be an explicit function of the two components independently. This approach should reduce the dispersion in structural response and may be useful in some situations (e.g., the two axes of the structure have differing periods, or Sa_{arb} along a given axis is not effective at estimating responses along the opposite axis). However, this method is not ready for widespread adoption until use of vector ground motion hazard analysis becomes more common.

APPLICATION TO CURRENT PRACTICE

The approaches described above rationally combine the uncertainty in both ground motion hazard and structural response, but they differ from current U.S. building code–based design practice (i.e., ASCE 2002). When dynamic time-history analyses are utilized in practice today, a suite of ground motions (typically three or seven) is scaled to a target response spectrum (obtained using the deterministic or probabilistic hazard analysis methods described above). These motions are then used to analyze a structure, and

evaluation is based on either the maximum structural response (if fewer than seven motions are used) or the average response (if at least seven motions are used). But again, the definition of spectral acceleration is not stated explicitly. An inconsistent basis (e.g., $Sa_{g.m.}$ spectra and Sa_{arb} scaling) is to be discouraged. As shown above, the use of $Sa_{g.m.}$ for two-dimensional analysis will result in lower target spectra than when Sa_{arb} is used, but higher variation among the structural response. If fewer than seven records are used, then the higher variation of structural response values will be implicitly (but not accurately) captured by the current rule because the maximum response value is likely to be larger. If, however, seven records are used and the average structural response is taken, then there is no penalty paid for the higher variation of structural response that results from using $Sa_{g.m.}$ rather than Sa_{arb}. Therefore, consistent use of $Sa_{g.m.}$ would be somewhat unconservatively biased with seven or more records under the current rule. The ideal solution to this inconsistency would be to incorporate the structural response uncertainty explicitly (as is done explicitly in, e.g., SAC [2000a, b, c] and Banon et al. [2001]). Short of this, the code should require that target response spectrum be based on Sa_{arb} when at least seven records are used for two-dimensional analysis, so that the analysis will include the extra variability in the ground motion intensity. In this case structural engineers should explicitly request that the hazard analysis and the scaled ground motion records be based on the Sa_{arb} definition of Sa. For three-dimensional analysis, $Sa_{g.m.}$ is probably the natural choice for the reasons outlined in the previous section.

CONCLUSIONS

Although intensity measure–based analysis procedures have proven to be useful methods for linking the analyses of earth scientists and structural engineers, care is needed to make sure that the link does not introduce errors into the analysis. Two definitions of "spectral acceleration" are commonly used by analysts, and the distinction between the definitions is not always made clear. Because of this, a systematic error has been introduced into the results from many risk analyses, typically resulting in unconservative conclusions. For an example site and structure located in Los Angeles, the error resulted in a 12% underestimation of the spectral acceleration value exceeded with a 2% probability in 50 years, and a 10% underestimation of the structure's maximum interstory drift ratio exceeded with a 2% probability in 50 years.

This problem is, however, merely one of communication, and not a fundamental flaw with the intensity measure approach. It is not difficult to use intensity measures in ways that produce correct results. For analysis of a single frame of a structure, the authors see three paths to the correct answer: (1) use Sa_{arb} for both parts of the analysis; (2) use $Sa_{g.m.}$ for both parts of the analysis; and (3) perform hazard analysis with $Sa_{g.m.}$, and structural response analysis with Sa_{arb}, but inflate the dispersion in the structural response prediction to represent the dispersion that would have been seen if $Sa_{g.m.}$ had been used. If a three-dimensional model of a structure is to be analyzed, the most straightforward method is to use $Sa_{g.m.}$ as the intensity measure for both the ground motion hazard and the structural response. In the absence of a single standard procedure,

both earth scientists and structural analysts are encouraged to explicitly state which *Sa* definition they are using for evaluation, in the interest of transparency.

The methods described above will all produce valid estimates of the annual frequency of exceeding a given structural response level. In the future it would be desirable to have attenuation models that estimate the dispersion of both $Sa_{g.m.}$ and Sa_{arb}, in order to allow flexibility in the definition of the spectral acceleration used for analysis. Finally, vector-based methods of hazard and response analysis should improve upon the current situation in the future.

APPENDIX: SLOPES AND STANDARD DEVIATIONS OF REGRESSION PREDICTIONS

This appendix explores in more detail the prediction of structural response as a function of either spectral acceleration of an arbitrary component or an average component. Consider a set of earthquake ground motions consisting of two components. We will refer to these two components as the "X" and "Y" components for clarity (the common assumption of no preferential orientation of motion is made here, which is typically valid when near-fault directivity effects are not present). Now consider the probabilistic distribution of the spectral acceleration values of these ground motion components. Logarithms of spectral acceleration and structural response are used, to take advantage of the linear relationships in the logarithmic domain often observed between these variables (e.g., Figure 3 and 5).

The ln *Sa* values of the *x* and *y* components have means, denoted as $\mu_{\ln Sa_x}$ and $\mu_{\ln Sa_y}$, and standard deviations, denoted as $\sigma_{\ln Sa_x}$ and $\sigma_{\ln Sa_y}$. Because there is no preferential direction to these motions, $\mu_{\ln Sa_x}=\mu_{\ln Sa_y}$ and $\sigma_{\ln Sa_x}=\sigma_{\ln Sa_y}$ (although our *estimates* of these values for a particular data set might not be exactly equal, the underlying *true values* are assumed to be). We can compute a correlation coefficient between the two components, denoted as $\rho_{\ln Sa_x,\ln Sa_y}$. The dependence between $\ln Sa_x$ and $\ln Sa_y$ is purely linear due to the lack of preferential orientation, as can be seen, for example, in Figure 5. We make the further mild assumption that the conditional variances of $\ln Sa_y$ given $\ln Sa_x$ and $\ln Sa_x$ given $\ln Sa_y$ are constant.

Consider now the analysis of a structural frame, oriented along the *x* axis of the ground motions. We perform nonlinear dynamic analysis with the *x* component of each ground motion to calculate a set of structural response values. The logarithmic response values have a mean, $\mu_{\ln \theta_x}$, and a standard deviation, $\sigma_{\ln \theta_x}$. There is a relationship between $\ln Sa_x$ (log spectral acceleration in the *x* direction) and $\ln \theta_x$ (log response of the structure, oriented in the *x* direction) that can be represented by a linear correlation, and

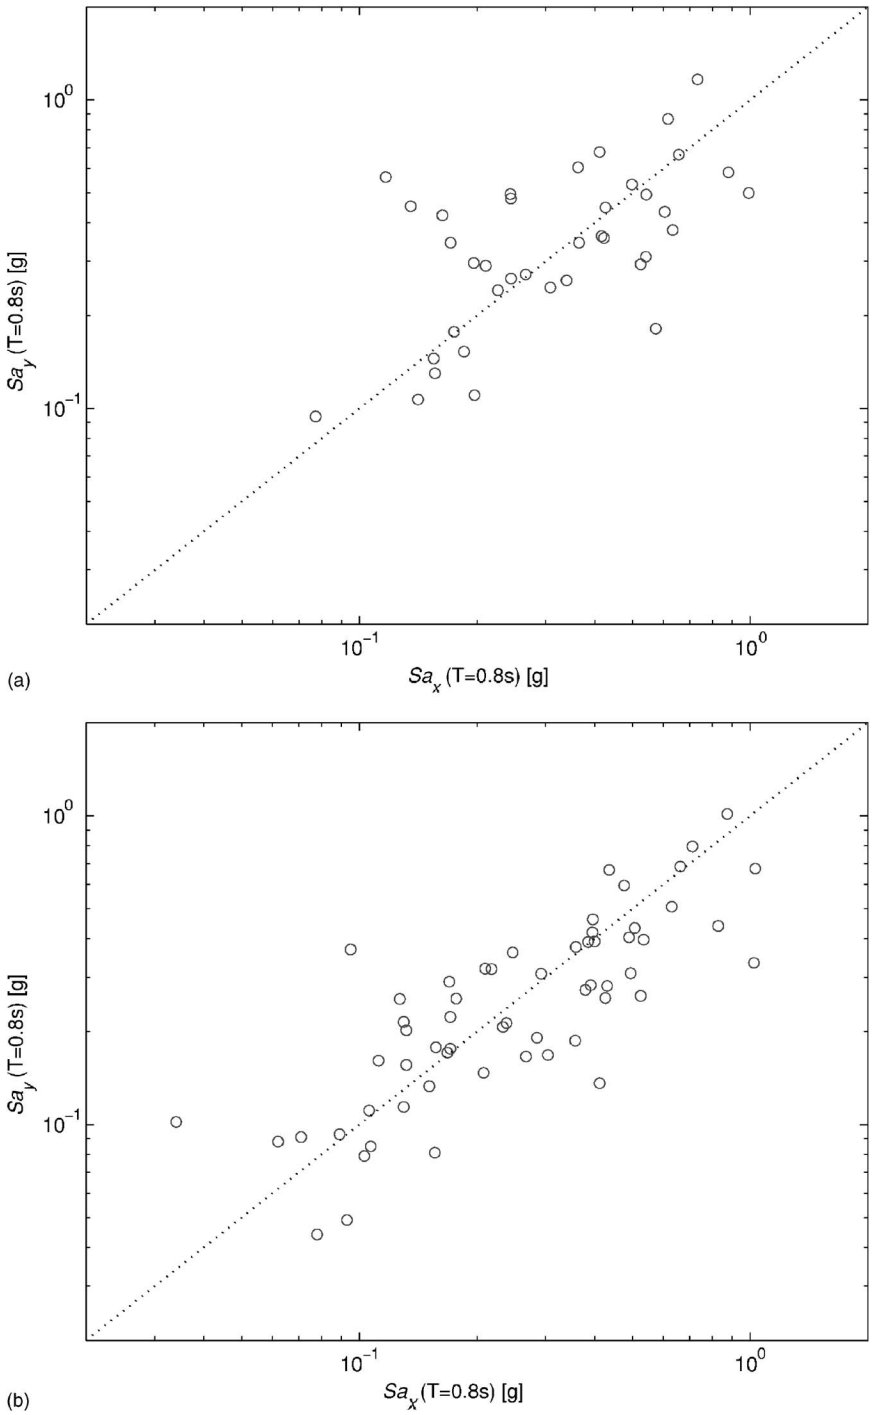

Figure 5. Samples of $(\ln Sa_x, \ln Sa_y)$ pairs from (a) a set of ground motions with magnitude ≈6.5 and distance ≈8 km, and (b) a set of ground motions with a wider range of magnitudes and distances, used to perform the structural analyses displayed in Figure 3.

measured with a correlation coefficient denoted as $\rho_{\ln \theta_x, \ln Sa_x}$. This linear relationship is represented by, for instance, the regression line shown in Figure 3a. But sometimes the relationship between ground motion intensity and structural response is represented as a function of the geometric mean of the *Sa*'s of the two components, as in Figure 3b. We can represent this relationship with the correlation coefficient denoted as $\rho_{\ln \theta_x, \ln Sa_{g.m.}}$. We make the assumption that the dependence between $\ln \theta_x$ and $\ln Sa$ is purely linear and the conditional variance of $\ln \theta_x$ given $\ln Sa$ is constant (for both $\ln Sa_x$ and $\ln Sa_{g.m.}$). We are interested in the relationship between the slopes and standard deviations of prediction errors resulting from prediction using these two predictors $\ln Sa_x$ and $\ln Sa_{g.m.}$.

First, recalling that $\ln Sa_{g.m.}$ is the average of $\ln Sa_x$ and $\ln Sa_y$, we note that the spectral acceleration of the *y* component has no direct physical effect on the response of the frame oriented in the *x* direction (indeed, the *y* component of the ground motion is not even used in analysis). By itself, the parameter $\ln Sa_y$ does have, however, an indirect ability to predict θ_x simply due to its correlation with the predictor $\ln Sa_x$. Therefore, while $\ln \theta_x$ and $\ln Sa_y$ are statistically correlated, it is true that *given* $\ln Sa_x$, $\ln Sa_y$ provides no *additional* information about the distribution of $\ln \theta_x$. That is, $\ln \theta_x$ and $\ln Sa_y$ are conditionally independent given $\ln Sa_x$.

Using the above information, we can calculate conditional means and variances, using best linear predictors. For example, the mean value of $\ln \theta_x$ given $\ln Sa_x$ is

$$\mu_{\ln \theta_x | \ln Sa_x = x} = \left(\mu_{\ln \theta_x} - \frac{\rho_{\ln \theta_x, \ln Sa_x} \sigma_{\ln \theta_x} \mu_{\ln Sa_x}}{\sigma_{\ln Sa_x}} \right) + \left(\frac{\rho_{\ln \theta_x, \ln Sa_x} \sigma_{\ln \theta_x}}{\sigma_{\ln Sa_x}} \right) x \equiv a + bx \quad (3)$$

It can be shown that *a* and *b* are the expected values of the coefficients estimated from linear least squares regression of $\ln \theta_x$ on $\ln Sa_x$. The conditional variance of $\ln \theta_x$ given $\ln Sa_x$ is

$$\sigma^2_{\ln \theta_x | \ln Sa_x} = \sigma^2_{\ln \theta_x} (1 - \rho^2_{\ln \theta_x, \ln Sa_x}) \quad (4)$$

We are interested in computing the conditional mean and variance of $\ln \theta_x$ given $\ln Sa_{g.m.}$ for comparison, but several intermediate results are needed first. The marginal mean and variance of $\ln Sa_{g.m.}$ are

$$\mu_{\ln Sa_{g.m.}} = E[1/2(\ln Sa_x + \ln Sa_y)] = \mu_{\ln Sa_x} \quad (5)$$

$$\sigma^2_{\ln Sa_{g.m.}} = \mathrm{Var}[1/2(\ln Sa_x + \ln Sa_y)] = 1/4(\sigma^2_{\ln Sa_x} + \sigma^2_{\ln Sa_y} + \rho_{\ln Sa_x, \ln Sa_y} \sigma_{\ln Sa_x} \sigma_{\ln Sa_y})$$

$$= \sigma^2_{\ln Sa_x} \frac{1 + \rho_{\ln Sa_x, \ln Sa_y}}{2} \quad (6)$$

The conditional variance of $\ln Sa_x$ given $\ln Sa_y$ is

$$\begin{aligned}\sigma^2_{\ln\theta_x|\ln Sa_y} &= \mathrm{E}[\mathrm{Var}[\ln\theta_x|\ln Sa_x,\ln Sa_y]|\ln Sa_y] + \mathrm{Var}[\mathrm{E}[\ln\theta_x|\ln Sa_x,\ln Sa_y]|\ln Sa_y] \\ &= \mathrm{E}[\sigma^2_{\ln\theta_x}(1-\rho^2_{\ln\theta_x,\ln Sa_x})|\ln Sa_y] \\ &\quad + \mathrm{Var}\left[\mu_{\ln\theta_x} + \rho_{\ln\theta_x,\ln Sa_x}\sigma_{\ln\theta_x}\left(\frac{\ln Sa_x - \mu_{\ln Sa_x}}{\sigma_{\ln Sa_x}}\right)\middle|\ln Sa_y\right] \\ &= \sigma^2_{\ln\theta_x}(1-\rho^2_{\ln\theta_x,\ln Sa_x}) + \rho^2_{\ln\theta_x,\ln Sa_x}\frac{\sigma^2_{\ln\theta_x}}{\sigma^2_{\ln Sa_x}}\mathrm{Var}[\ln Sa_x|\ln Sa_y] \\ &= \sigma^2_{\ln\theta_x}(1-\rho^2_{\ln\theta_x,\ln Sa_x}\rho^2_{\ln Sa_x,\ln Sa_y}) \end{aligned} \quad (7)$$

This implies that the correlation coefficient between $\ln\theta_x$ and $\ln Sa_y$ is $\rho_{\ln\theta_x,\ln Sa_x}\rho_{\ln Sa_x,\ln Sa_y}$, showing that it is weaker than the correlation between $\ln\theta_x$ and $\ln Sa_x$, and only as strong as the correlation $\ln Sa_y$ has with $\ln Sa_x$ permits. This simple product form is a result. Next we compute the covariance between $\ln\theta_x$ and $\ln Sa_{g.m.}$:

$$\begin{aligned}\mathrm{Cov}[\ln\theta_x,\ln Sa_{g.m.}] &= 1/2\mathrm{Cov}[\ln\theta_x,\ln Sa_x] + 1/2\mathrm{Cov}[\ln\theta_x,\ln Sa_y] \\ &= 1/2(\rho_{\ln\theta_x,\ln Sa_x}\sigma_{\ln\theta_x}\sigma_{\ln Sa_x} + \rho_{\ln\theta_x,\ln Sa_x}\rho_{\ln Sa_x,\ln Sa_y}\sigma_{\ln\theta_x}\sigma_{\ln Sa_y}) \\ &= 1/2\rho_{\ln\theta_x,\ln Sa_x}\sigma_{\ln\theta_x}\sigma_{\ln Sa_x}(1+\rho_{\ln Sa_x,\ln Sa_y}) \end{aligned} \quad (8)$$

Finally, using the results of Equations 6 and 8, we compute the correlation coefficient between $\ln\theta_x$ and $\ln Sa_{g.m.}$:

$$\rho_{\ln\theta_x,\ln Sa_{g.m.}} = \frac{\mathrm{Cov}[\ln\theta_x|\ln Sa_{g.m.}]}{\sigma_{\ln\theta_x}\sigma_{\ln Sa_{g.m.}}} = \rho_{\ln\theta_x,\ln Sa_x}\sqrt{\frac{1+\rho_{\ln Sa_x,\ln Sa_y}}{2}} \quad (9)$$

We are now ready to find the conditional mean of $\ln\theta_x$ given $\ln Sa_{g.m.}$:

$$\mu_{\ln\theta_x|\ln Sa_{g.m.}=z} = \mu_{\ln\theta_x} + \rho_{\ln\theta_x,\ln Sa_{g.m.}}\sigma_{\ln\theta x}\left(\frac{z-\mu_{\ln Sa_{g.m.}}}{\sigma_{\ln Sa_{g.m.}}}\right) \quad (10)$$

Substituting from Equations 5, 6, and 9 gives

$$\mu_{\ln\theta_x|\ln Sa_{g.m.}=z} = \left(\mu_{\ln\theta_x} - \frac{\rho_{\ln\theta_x,\ln Sa_x}\sigma_{\ln\theta_x}\mu_{\ln Sa_x}}{\sigma_{\ln Sa_x}}\right) + \left(\frac{\rho_{\ln\theta_x,\ln Sa_x}\sigma_{\ln\theta_x}}{\sigma_{\ln Sa_x}}\right)z = a + bz \quad (11)$$

where a and b are the same as in Equation 3. Therefore, *the expected slope and intercept of a regression analysis will be the same regardless of whether* $\ln Sa_{g.m.}$ or $\ln Sa_x$. *is used to predict* $\ln\theta_x$. Now consider the conditional variance of $\ln\theta_x$ given $\ln Sa_{g.m.}$:

$$\sigma^2_{\ln\theta_x|\ln Sa_{g.m.}} = \sigma^2_{\ln\theta_x}\left(1-\rho^2_{\ln\theta_x,\ln Sa_{g.m.}}\right) = \sigma^2_{\ln\theta_x}\left(1-\rho^2_{\ln\theta_x,\ln Sa_x}\frac{1+\rho_{\ln Sa_x,\ln Sa_y}}{2}\right) \quad (12)$$

Therefore, the conditional standard deviation of $\ln\theta_x$ given $\ln Sa_{g.m.}$ is greater than the conditional standard deviation given $\ln Sa_x$ by a factor equal to

$$\frac{\sigma_{\ln\theta_x|\ln Sa_{g.m.}}}{\sigma_{\ln\theta_x|\ln Sa_x}} = \sqrt{1+\frac{1-\rho_{\ln Sa_x,\ln Sa_y}}{2}\left(\frac{\rho^2_{\ln\theta_x,\ln Sa_x}}{1-\rho^2_{\ln\theta_x,\ln Sa_x}}\right)} \quad (13)$$

Noting that correlation coefficients always lie on the interval $[-1,1]$, we see that the ratio in Equation 13 is always greater than or equal to 1, and increases with decreasing $\rho_{\ln Sa_x,\ln Sa_y}$ or increasing $\rho_{\ln\theta_x,\ln Sa_x}$. The term $\rho_{\ln Sa_x,\ln Sa_y}$ is dependent on the record set in use, but typically falls between 0.8 and 0.9, depending on the range of magnitudes and distances of the records (letting the magnitude and distance vary in the record set increases the correlation between components relative to a recordset selected from a narrow range of magnitude and distance values, as is seen in Figure 5).

Note that this result only holds under the conditions described above. The most critical assumption is that response in the x direction is unaffected by ground motion input in the y direction. This may not be the case in, for example, torsionally coupled structures. In addition, the assumption of linear dependence between $\ln\theta_x$ and $\ln Sa$ may not always hold. In these cases, the simple inflation factor is not applicable.

Three-Dimensional Simulation of a Magnitude 7.75 Earthquake on the San Andreas Fault

Kim B. Olsen, Ralph J. Archuleta,* Joseph R. Matarese

Simulation of 2 minutes of long-period ground motion in the Los Angeles area with the use of a three-dimensional finite-difference method on a parallel supercomputer provides an estimate of the seismic hazard from a magnitude 7.75 earthquake along the 170-kilometer section of the San Andreas fault between Tejon Pass and San Bernardino. Maximum ground velocities are predicted to occur near the fault (2.5 meters per second) and in the Los Angeles basin (1.4 meters per second) where large amplitude surface waves prolong shaking for more than 60 seconds. Simulated spectral amplitudes for some regions within the Los Angeles basin are up to 10 times larger than those at sites outside the basin at similar distances from the San Andreas fault.

The damage in Mexico City from the Michoacan earthquake (19 September 1985) and in the Marina district of San Francisco from the Loma Prieta earthquake (19 October 1989) has clearly illustrated the risks for population centers located in basins at a significant distance from the causative fault. The sediments filling the basins, which have low elastic moduli, amplify the seismic waves relative to the surrounding bedrock. In addition, the edges of the basins can generate large-amplitude waves that can prolong the shaking in the basins. Moderate-sized events, such as the magnitude (**M**) 6.7 Northridge earthquake (17 January 1994), the **M** 6.0 Whittier Narrows earthquake (1 October 1987), and the **M** 6.6 San Fernando earthquake (9 February 1971), have emphasized the seismic hazard from faults on the Los Angeles (LA) fault system (*1–5*). Nonetheless, the San Andreas fault (SAF) remains potentially the most hazardous for the LA area because it has produced large earthquakes in historical time (*2, 6, 7*).

To determine the amount of shaking that could occur in the LA area, we simulated a **M** 7.75 earthquake on the section of the SAF closest to LA. We considered a propagating rupture for 170 km from Tejon Pass to San Bernardino (Fig. 1A). This part of the SAF, which consists of two segments, the Mojave and part of the San Bernardino Mountains segment (*2*), is believed to have produced the **M** 7.5 earthquake on 12 December 1812 (*6, 8*). The average recurrence time between large earthquakes with surface rupture on the Mojave segment is 150^{+123}_{-71} years and on the San Bernardino segment it is 146^{+91}_{-60} years (*2*). Mean conditional probabilities of 26 ± 11% (**M** 7.53) and 28 ± 13% (**M** 7.30) have been determined for earthquakes on the Mojave and San Bernardino segments, respectively, to occur before the year 2024 (*2*). Because both segments have similar recurrence intervals and conditional probabilities, and may have ruptured together in earlier events (*6*), it is reasonable to consider a scenario where this section of the SAF ruptures again in a single earthquake.

To estimate the ground shaking from such an earthquake (*9*) we incorporated the three-dimensional (3D) structure of the medium through which the seismic waves will travel from the SAF to LA. The geology of this region is varied: Igneous and metamorphic basement rocks crop out extensively in the Mojave Desert and San Gabriel Mountains (*10*) whereas sedimentary rocks fill the deep basins in LA and the San Fernando Valley (*11*). The seismic energy will thus propagate for at least 35 km through igneous and metamorphic rocks before impinging on the sedimentary basins of greater LA (Fig. 1B). Were it not for the basins beneath the San Fernando Valley and LA (including the San Gabriel Valley) (Fig. 1B), the model would consist of horizontal layers where the material parameters varied only with depth (*12*). However, with their irregular geometry and different material properties, these sedimentary basins affect the ground motion by amplifying seismic waves, prolonging their duration, and generating waves at the basin edges (*3, 13, 14*).

To approximate a **M** 7.75 earthquake on the SAF, we simulated a rupture on a fault plane 16.5 km deep and 170 km long that extends from Quail Lake (10 km southeast of Gorman) to Mill Creek (11 km northeast of Redlands). The fault plane had a constant strike (118°) that followed the strike of the SAF with a slight deviation (maximum of 6 km) at the northwestern end of the Mojave segment (Fig. 1A). The rupture initiated at a point 2 km from the northwestern end of the fault segment, at 10 km depth, and dextrally offset the two sides of the fault by 4.82 m everywhere (*15*) (Table 1). The earthquake rupture lasted 68 s before terminating at Mill Creek. The shear (S) waves that continuously radiated from the rupture impinged on the basins about 20 s after the earthquake started. Some areas of the LA basin continued to vibrate for more than 60 s because of the continual stimulation from waves arriving from different parts of the fault, waves generated at the basin edges, and resonances in the basin.

Numerical model for the earthquake rupture and 3D wave propagation. We subdivided a large volume (230 km by 140.4 km by 46 km) of southern California into 23,209,875 cubes 0.4 km on a side with a gridpoint at each vertex. Each gridpoint was assigned a compressional wave velocity, an S wave velocity, and a density (*16*). The 3D structure did not include the basins beneath the Upper Santa Ana Valley, the San Bernardino Valley, or the Ventura area (*14, 17*) because there was no discretized 3D model for their elastic and material properties. Therefore the amplitude and duration of the simulated ground motion is probably underestimated in these areas (*14, 18*).

We kinematically simulated the earthquake as a constant slip that radially propagated outward with a velocity 85% of the local S wave velocity. The slip rate function is Gaussian with a dominant period of 4.5 s. This function was later deconvolved from the synthetic records to obtain a slip rate with uniform spectral response to displacement for frequencies up to 0.4 Hz that is constant everywhere on the fault (*3*). This formulation allows the seismic moment and synthetics to be scaled by a single value of slip. The effective rise time is about 3 s everywhere on the fault (*19*).

The source was implemented in the finite-difference grid by adding $-M_{ij}(t)/V$ to $S_{ij}(t)$, where $M_{ij}(t)$ is the ij'th component of the moment tensor for the earthquake, V is

Modeling parameters are listed in Table 1.

the cell volume, and $S_{ij}(t)$ is the ij'th component of the stress tensor on the fault at time t (Table 2).

We use a staggered-grid finite-difference scheme to solve the 3D elastic equations of motion (*20*); the accuracy is fourth order in space and second order in time. The numerical implementation of the 3D scheme is described in (*21*). To eliminate artificial reflections from the boundaries of the grid, we implemented absorbing boundary conditions coupled with a buffer zone of strong attenuation (*22*). In the following, we removed these zones and present the simulation results within the area (174 km by 114.8 km) (Fig. 1A) that encompasses the population centers of the LA area.

Finite-difference modeling of elastic waves in large-scale 3D models, such as the one used in the SAF simulation, consumes vast quantities of computational resources. The earth model and the calculated stress and velocity fields require gigabytes of physical memory and gigaflops of CPU for tens of hours to simulate the total duration of ground motion within a reasonable period of time. Such computational requirements are beyond the resources of workstations and most supercomputers with shared-memory configurations. To carry out our simulation we used grid-decomposition techniques on the massively parallel processors of the nCUBE 2 at the Earth Resources Laboratory of the Massachusetts Institute of Technology.

Gridpoints along 28°	352*
Gridpoints along vertical	116
Timesteps	4800
Simulation time (s)	120

*Figures show 436 gridpoints along the 118° azimuth and 288 gridpoints along the 28° azimuth.

Figure 2 illustrates how we subdivide the 3D volume of the model over eight parallel processors (Fig. 2). Each processor is responsible for performing stress and velocity calculations for its portion of the grid, as well as dealing with boundary conditions at the external edges of each volume. At the internal edges, where neighboring portions of the earth volume are contained on separate nodes, the processors must exchange stress and velocity information to propagate the waves correctly. On the nCUBE 2, this communication time represents a negligible part of the total run time. In other words, the same simulation can be performed twice as fast on twice as many processors as long as the internal edges represent a small part of the model held by each processor.

For the SAF simulation we used all 512 processors available on the nCUBE 2. With grid dimensions of 576 by 352 by 116 points, the most memory-efficient decomposition involved assigning subgrids of 36 by 44 by 29 points to the individual processors. In keeping with the fourth order finite-difference scheme, a two-point-thick padding layer was added to the outside of each subgrid to bring the total subgrid dimensions to 40 by 48 by 33 points. To store 12 arrays (three elastic coefficients, three components of velocity, and six components of stress) of this size required just over 2.9 megabytes of the 4 megabytes of physical memory on each processor. The remaining memory was consumed by the program logic and additional variables as well as the operating system kernel. Using a grid decomposition code based upon the portable Message Passing Interface standard, the finite-difference simulation took 17 s per timestep or nearly 23 hours to complete the 120 s of simulated ground motion. More than a gigabyte of disk space was used to store the time history of the ground motion at the surface.

Simulated ground motion and seismic hazard in LA. To illustrate the development of the ground motion as the rupture propagated along the SAF we show snapshots of long-period ground velocity (Fig. 3) over the 19,975 km^2 area (Fig. 1A). By 20 s, the S waves had entered San Fernando Val-

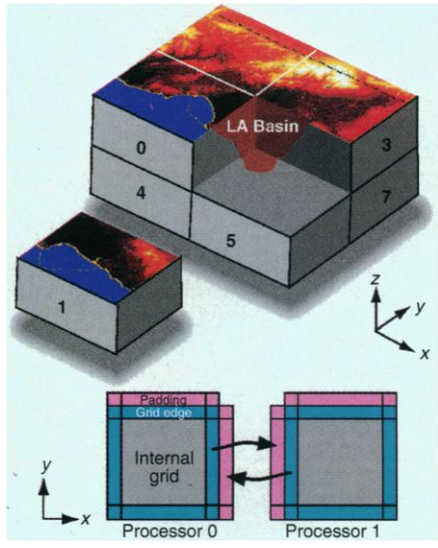

Fig. 2. Grid decomposition of the SAF rupture model on the nCUBE 2. (**Top**) The model is decomposed into a number of subgrids, labeled 0 through 7. The actual model was divided into 512 subgrids, corresponding to the number of processors used in the simulation. (**Bottom**) Illustration of the communication between neighboring subgrids. The fourth-order finite-difference scheme requires that a two-point-thick padding layer be added to the outside of each subgrid in order to propagate the waves correctly. This padding layer always contains the most recently updated wavefield parameters exchanged from the edge of the neighboring subgrid (arrows).

ley. By 30 s, when the rupture had propagated about halfway along the SAF, the S waves had entered the main LA basin. The area near the northern intersection of Interstates 5 and 405 showed intense ground motion. The high intensity was produced because resonance in the deep part of the San Fernando Valley basin radiated secondary waves as seen by the faint circular wavefronts centered on this area (R, Fig. 3 at 40 s). At 40 s, the ground motion in the LA basin had intensified: the San Gabriel Valley, just southeast of the intersection of Interstates 10 and 605, and the area just south of downtown LA show large amplitude ground motions. At 50 s the entire LA basin was excited by large amplitude surface waves. The rupture was almost complete by 60 s, at which time the wavefronts in the basin slowly began changing direction from southeast parallel to the long axis of the LA basin to the southwest. At 70 s, large amplitude waves were generated by reflections from the steep northeast sides of the basin; the peaks and troughs of the waves were aligned with the long axis of the basin and propagated west into the offshore area. This pattern persisted but diminished through 100 s where only faint shadows mimicked the larger amplitudes that existed 30 s before.

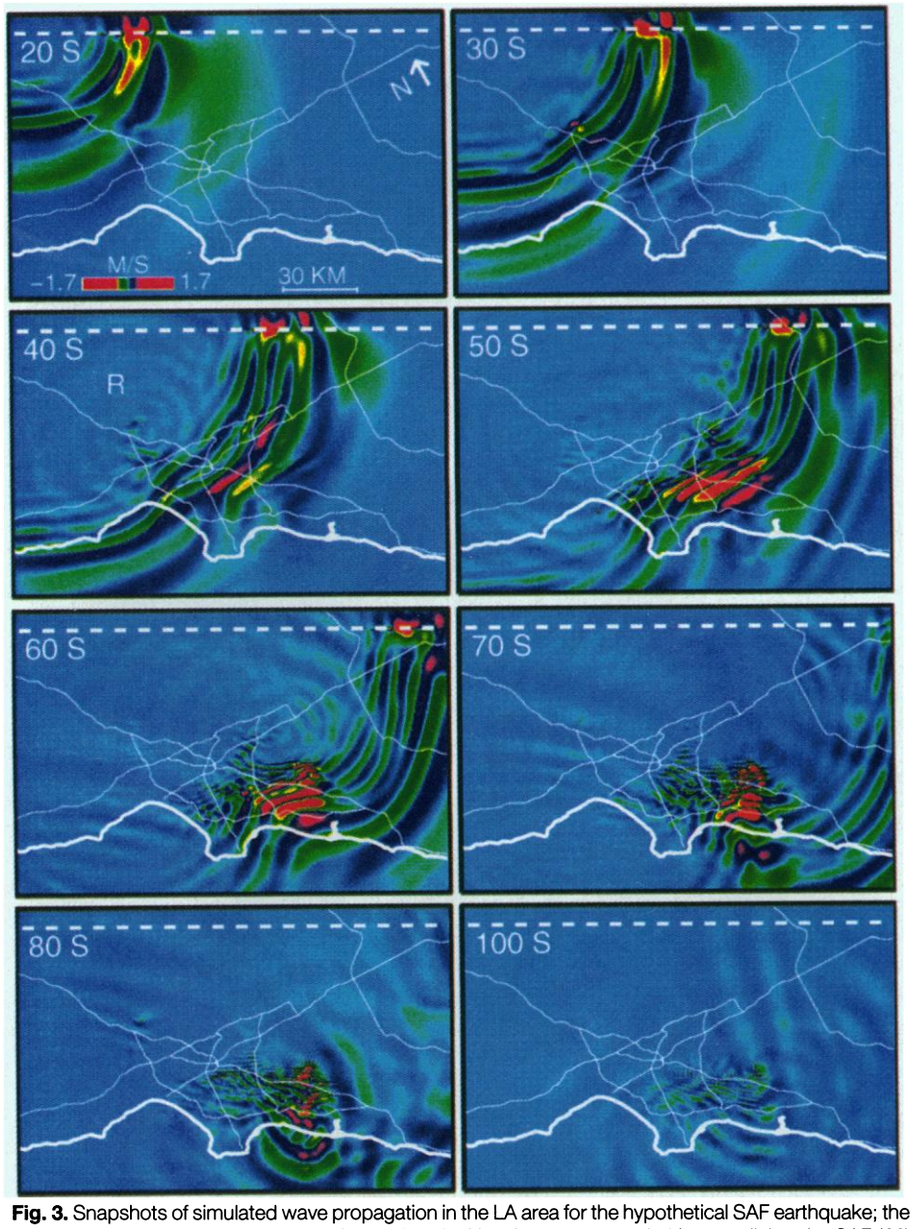

Fig. 3. Snapshots of simulated wave propagation in the LA area for the hypothetical SAF earthquake; the snapshots depict the horizontal (118°) particle velocities that represent shaking parallel to the SAF (*23*) from 20 s to 100 s after the origin time of the rupture. Red depicts large amplitudes of both positive and negative polarity. R depicts an area of local resonance above the deepest part of the San Fernando Valley basin. The particle motion is scaled by a constant for all snapshots. Lines labeled as in Fig. 1A.

To encapsulate many of these effects we show a suite of seismograms and the S wave velocity structure (Fig. 4, A and B) from the Ventura basin to the mountains east of San Clemente (B-B′, Fig. 1A). By visually correlating the suite of seismograms with the S wave velocity structure, the effect of the basin on the amplitude and duration of shaking is evident. The basin affected all three components of motion (Fig. 4C) but primarily the component parallel (118°) to the axis of the trough (*23*). To examine the frequency content of the shaking, we compared the Fourier spectral amplitudes of particle velocity for the 118° component for three sites (Fig. 4D): (i) over the deepest part of the basin, (ii) above the edge of the basin, and (iii) outside the basin (Fig. 1A). The maximum spectral amplitude for the edge site was a factor of two larger than for the site over the deepest part of the basin. The edge site had its spectral maximum at a higher frequency (0.25 Hz) compared to the site above the central basin where the first broad peak occurred around 0.16 Hz—approximately the fundamental resonant frequency of the LA basin (*24*). The spectral amplitude for a site at the edge of the basin was 10 times the spectral amplitude for a site outside the basin even though both are at the same distance from the SAF (*25*).

Contours of the peak particle velocity over the area reveal effects due to rupture and structure (Fig. 5). The 118° component was largest near the SAF and in the LA basin. The high amplitudes near the fault were expected; the amplitudes (>0.5 m/s) in the LA basin ~60 km from the fault were not. The 0.25 m/s contour basically outlines the San Gabriel Valley and LA basins. Moreover, there is a large area with amplitudes larger than 0.75 m/s corresponding to the deeper parts of the LA basin.

The large lobe with peak velocity greater than 0.75 m/s for the 28° component (Fig. 5) reflects the directivity of the rupture (*4*, *26*) and the radiation pattern from the source (*23*) that combine to produce the maximum slip velocity 2.5 m/s. The 28° component shows that in the simulation those areas in the forward direction of the rupture were as severely shaken as LA. Most of the area with peak velocity greater than 0.75 m/s was confined to the less populated San Gabriel Mountains. However, the southeastern part of the 0.75 m/s lobe cov-

Table 3. Comparison of maximum peak particle velocities (m/s) near the SAF and in the LA basin for three components of wave motion.

Location	118°	28°	Vertical
Near SAF	2.01	2.51	0.91
LA basin	1.37	0.70	0.54

ered the region in the populated Upper Santa Ana Valley (including cities such as Ontario, Pomona, and Upland) and the San Bernardino Valley (including cities such as San Bernardino and Redlands). Because the SAF passes just to the northwest of these areas, the severity of the shaking increases because of proximity to the fault (*25*) and rupture directivity. The amplitude of the waves attenuated with distance from the SAF except for the amplification resulting from the LA basin where amplitudes on the 28° component also exceeded 0.5 m/s.

The smallest peak particle velocities were for the vertical component as expected for strike-slip motion on a vertical fault. However, like the horizontal components, the LA basin amplifies the vertical motion relative to the surrounding area. The net result is that the total ground motion in the LA region in the simulation was much larger than would be predicted by a 1D model (*3*, *13*, *14*). We illustrate this point by mapping the total cumulative kinetic energy (*27*) that takes into account the amplitude and duration of shaking for all three components of motion (Fig. 6). A large swath within 30 km of the SAF experienced significant shaking. The cumulative kinetic energy decreased with distance from the fault except for the basins, especially the LA basin—where, for frequencies up to 0.4 Hz, the cumulative kinetic energy was equivalent to that near the fault. The expected attenuation with distance of the amplitude of the seismic waves (*25*) was counteracted by the basin geometry and velocity structure.

The simulated ground motion should be considered in the context of three factors: (i) Because of computational limitations, the maximum frequency was 0.4 Hz. Observed ground motions contain higher frequencies that will increase the amplitudes of the particle velocities especially near the SAF where anelastic material attenuation has less effect than for distances far from the fault (*25*). The component of motion perpendicular to the strike (28°), is 25% larger than the parallel component near the fault (Table 3). This 28° component is amplified by directivity of the rupture and almost always has the maximum particle velocity (*4*, *26*). However, the observed near-fault peak velocities were generally associated with pulses dominated by frequencies 1.0 Hz or less (*4*, *26*) so that the lower frequency of 0.4 Hz may not be a critical factor. The structures most affected by the computed ground motion would be those that have their lowest mode response with frequencies less than 0.4 Hz (periods ≥2.5 s); almost all one- and two-story structures have their peak response at much higher frequencies (*28*). (ii) The minimum S wave velocity is 1.0 km/s, again due to computational limitations. In engineering terms this means that all of the ground motion is for rock rather than soil (*29*). Inclusion of the lower velocity sediments would increase the ground motion amplitudes (*30*). The omission of higher frequencies and lower near-surface velocities in the simulation define our results as a lower bound for the expected ground motion for the SAF rupture scenario. (iii) Our kinematic rupture model is smooth in that the slip and slip rate are constant everywhere on the fault and rupture velocity is a fixed percentage of the S wave velocity. The slip and the slip rate have plausible values (*15*) but could certainly be allowed to vary spatially; such variation would affect signal duration more than amplitude (*9*). In real, large earthquakes rupture velocity varies significantly over long fault length. A variable rupture velocity would decrease the coherency of the waves leaving the fault and mitigate the effects of directivity. Whether this would increase or decrease the ground motion in LA is unknown.

Our simulation of a **M** 7.75 earthquake on the SAF predicted long-period peak par-

(**A**) Simulated velocity seismograms for the 118° horizontal component: site 1 is within the basin, site 2 is along the basin edge, and site 3 is outside the basin. (**B**) Vertical cross section along B-B′; the contours on the map depict the S-wave velocity at a contour interval of 0.5 km/s. (**C**) Three component velocity seismograms at site 2. L depicts Love waves and LL depicts Love waves reflected at the basin edge. (**D**) Fourier spectral amplitude for the 118° horizontal component at sites 1, 2, and 3 (see Fig. 1A).

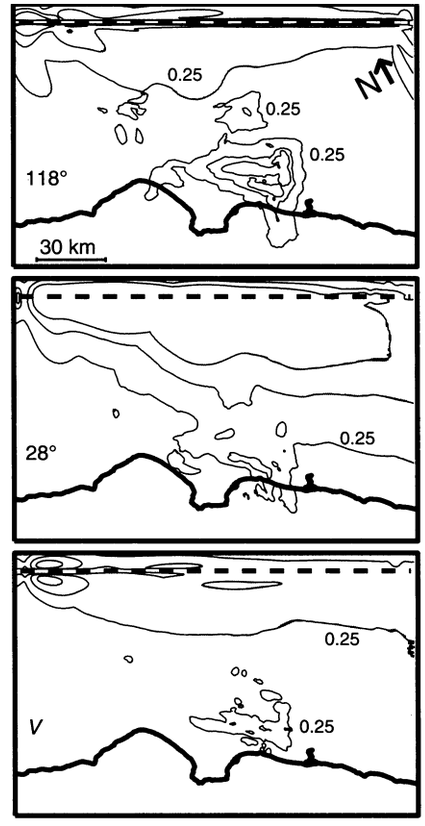

Fig. 5. Contour maps of simulated peak velocities along the 118°, 28°, and vertical components for the hypothetical SAF earthquake. Contour interval is 0.25 m/s with the 0.25 m/s contour labeled. Lines labeled as in Fig. 1A.

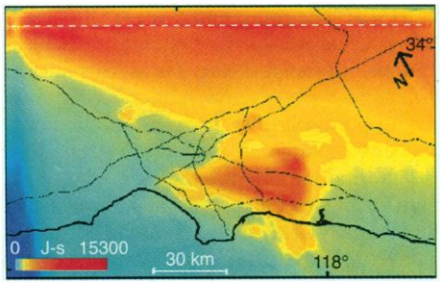

Fig. 6. Map of simulated total cumulative kinetic energies for the hypothetical SAF earthquake. Note that the color scale is logarithmic in units of Joules-seconds (J-s). Lines labeled as in Fig. 1A.

ticle velocities greater than 1.0 m/s at some areas in LA and greater than 0.75 m/s over a large central area even though the main trough of the basin is about 60 km from the fault (Fig. 5). These peak velocities are similar to those observed near the fault for some damaging earthquakes (*4*, *26*) and larger than particle velocities from simulated **M** 6.75 earthquakes on faults in LA (*3*). While these simulated long-period waves have large amplitudes, the threat they pose to existing structures is unknown.

15. With an average slip of 4.82 m, we calculate a seismic moment of 4.75×10^{20} Nm, giving a **M** 7.75 for the earthquake. The slip of 4.82 m is within the range of characteristic slip (4.5 ± 1.5 m) for earthquakes on the Mojave segment but is slightly larger than the characteristic slip (3.5 ± 1.0 m) on the San Bernardino segment (*2*). Similarly the stress drop σ for a long strike-slip fault with width, W, is given by $\sigma = (2/\pi)\mu(s/W)$ [L. Knopoff, *Geophys. J.* **1**, 44 (1958)] from which we estimate a stress drop of 69 bars—a value consistent with average earthquakes (H. Kanamori and D. Anderson, *Bull. Seismol. Soc. Am.* **65**, 1073 (1975).

19. A propagating rupture is analogous to a double zipper. The first zipper, moving at the velocity of the rupture, unlocks the two sides of the fault. A second zipper arrives later to lock the two sides of the fault. In the time between the two zippers, the two sides of the fault move relative to each other. The total amount of relative movement before the second zipper locks the two sides is the offset or slip. The time it takes for the slip to occur is the rise time. The slip divided by the rise time is slip rate, that is how fast the slip occurs on the fault.

23. The movement of the ground is three dimensional and can be completely described by examining it on three perpendicular axes. The natural choices are along the vertical and two horizontal directions. We have chosen the headings of 118° and 28°, parallel and perpendicular to the San Andreas, respectively, for positive horizontal ground velocity.
24. Y. Hisada *et al.*, in *Proc. Fourth Int. Conf. Seismic Zonation,* Stanford, CA (1991), vol. II, p. 245; A. Edelman and F. Vernon, unpublished report.
25. The amplitude of seismic waves can be attenuated by many different mechanisms, but the primary mechanisms are geometrical spreading and intrinsic attenuation. Geometrical spreading of the wavefront attenuates the amplitude as a direct result of conservation of energy. As the wavefront expands with distance from the source, the energy is spread over a greater surface area resulting in a smaller energy per unit area and accordingly a smaller amplitude. A simple approximation to geometrical spreading for body waves is: $A \propto 1/R$, where A is the amplitude of the wave and R is the distance between the source and the observer. For surface waves (Love and Rayleigh) the geometrical attenuation is approximately: $A \propto 1/\sqrt{R}$ so that surface waves decay more slowly than body waves. Intrinsic attenuation is the irreversible loss of wave energy due to internal friction as the waves propagate through the medium. The amplitude decay due to internal friction can be approximated by : $A \propto \exp(-\pi ft/Q)$ where f is frequency, t is the time it takes for a wave to travel from the source to the observer, and Q is a measure of the energy loss due to internal friction. We have omitted intrinsic attenuation in our simulation. However, comparison of observed seismic data from the 17 January 1994 **M** 6.7 Northridge event to an elastic simulation of the earthquake (*3*) suggests that intrinsic attenuation has limited effects on ground motion for frequencies less than 0.4 Hz, as used in this study.
26. The rupture directivity is an effect that modifies the energy in seismic waves depending on the angle between the observation point and the direction of rupture propagation [A. Ben-Menahem, *Bull. Seismol. Soc. Am.* **51**, 401 (1961)]. Directivity increases the energy in the direction the rupture propagates and decreases the energy in the back direction. A seismic pulse in the forward direction increases in amplitude and contracts in time; a seismic pulse in the back direction decreases in amplitude and expands in time. The directivity effect combined with the radiation pattern of S waves leads to large velocity pulses (on the order of 1.0 m/s) in the forward direction of earthquake ruptures [R. Archuleta and S. Hartzell, *Bull. Seismol. Soc. Am.* **71**, 939 (1981); R. Archuleta, *J. Geophys. Res.* **89**, 4559 (1984); (*4*)].
27. The cumulative kinetic energy for each gridpoint (x, y) on the surface is given by:

$$E_k(x,y) = \frac{1}{2}\rho(x,y)\int_0^T \dot{u}^2(x,y,t)dt$$

where k is the component of motion, ρ is the density, $\dot{u}(x,y,t)$ is the velocity seismogram, and T is the duration of the seismogram. The cumulative energy includes the amplitude and duration of the signal. The total energy is the sum of all three components: $E_{tot}(x,y) = E_{118}(x,y) + E_{28}(x,y) + E_v(x,y)$.
28. There are formulas for relating the height of structures with the period of the lowest-mode response. For example, with $h(ft) = (period/0.035)^{1.333}$ [*Uniform Building Code* (International Conference of Building Officials, Whittier, CA, 1988)], a 3.0-s period corresponds to a 115-m-high steel frame building. Such formulas serve as a guide; more flexible buildings or buildings made of different materials may be significantly shorter for a given period. For example, the Sherman Oaks building has a lowest-mode period of 3 s (0.33 Hz) but is 50.6 m high (13 stories) [Chapter 2, *Earthq. Spectra Suppl. C* **11**, 13 (1995)].
29. The classification of soils and rock in geotechnical engineering depends on the S wave velocity. A firm to hard rock has an average shear-wave speed greater than 700 m/s [R. Borcherdt, *Earthq. Spectra* **10**, 617 (1994)]. The lowest velocity in our model is 1.0 km/s (Table 2).
30. Many papers document the amplification of seismic waves due to local near-surface geology [for example, K. Aki, *Am. Soc. Civil Eng. Proc. Spec. Conf. Earthq. Eng. Soil Dyna.* **2**, 1 (1988)].

Site Amplification in the Los Angeles Basin from Three-Dimensional Modeling of Ground Motion

by K. B. Olsen

Abstract It is well established that sedimentary basins can significantly amplify earthquake ground motion. However, the amplification at any given site can vary with earthquake location. To account for basin response in probabilistic seismic hazard analysis, therefore, we need to know the average amplification and intrinsic variability (standard deviation) at each site, given all earthquakes of concern in the region. Due to a dearth of empirical ground-motion observations, theoretical simulations constitute our best hope of addressing this issue. Here, 0–0.5 Hz finite-difference, finite-fault simulations are used to estimate the three-dimensional (3D) response of the Los Angeles basin to nine different earthquake scenarios. Amplification is quantified as the peak velocity obtained from the 3D simulation divided by that predicted using a regional one-dimensional (1D) crustal model. Average amplification factors are up to a factor of 4, with the values from individual scenarios typically differing by as much as a factor of 2.5. The average amplification correlates with basin depth, with values near unity at sites above sediments with thickness less than 2 km, and up to factors near 6 above the deepest ($\approx$ 9 km) and steepest-dipping parts of the basin. There is also some indication that amplification factors are greater for events located farther from the basin edge. If the 3D amplification factors are divided by the 1D vertical *SH*-wave amplification below each site, they are lowered by up to a factor of 1.7. The duration of shaking in the 3D model is found to be longer, by up to more than 60 seconds, relative to the 1D basin response. The simulation of the 1994 Northridge earthquake reproduces recorded 0–0.5 Hz particle velocities relatively well, in particular at near-source stations. The synthetic and observed peak velocities agree within a factor of two and the log standard deviation of the residuals is 0.36. This is a reduction of 54% and 51% compared to the values obtained for the regional 1D model and a 1D model defined by the velocity and density profile below a site in the middle of the basin (DOW), respectively. This result suggests that long-period ground-motion estimation can be improved considerably by including the 3D basin structure. However, there are uncertainties concerning accuracy of the basin model, model resolution, the omission of material with shear velocities lower than 1 km/s, and the fact that only nine scenarios have been considered. Therefore, the amplification factors reported here should be used with caution until they can be further tested against observations. However, the results do serve as a guide to what should be expected, particularly with respect to increased amplification factors at sites located above the deeper parts of the basin.

Introduction

The metropolitan area of the greater Los Angeles area is underlain by a deep sedimentary basin. Ground motions in such basins can be significantly amplified, as was the case in Mexico City during the 1985 M_u 8.1 Michoacan earthquake, and in the South Bay of San Francisco during the 1989 **M** 7 Loma Prieta event. This study explores ground-motion amplification of seismic waves due to the deep LA basin.

Ground-motion simulations in elastic media that include complicated 2D or 3D velocity structures, even for simplified source implementations such as plane waves (e.g., Frankel and Vidale, 1992; Olsen and Schuster, 1995; Olsen *et al.,* 1995a) or line/point sources (e.g., Yomogida and Etgen, 1993; Scholler *et al.,* 1994; Graves, 1995) have shown significant basin effects. These results were further consolidated

by the first ground motion simulations including both the 3D basin structure and the finite-fault source effects (Frankel, 1993; Olsen *et al.,* 1995b; Olsen and Archuleta 1996). While all of the 3D studies have been limited to low frequencies ($\lesssim$1 Hz) or very limited spatial volume, due to extensive computational requirements, they all demonstrated significant 3D effects from the basin structures. These effects include the generation of surface waves at the basin edges, and a strong correlation between the duration of shaking and the site location within the basin. Such correlation suggests that the accuracy of long-period attenuation relations may be improved by including the amplification effects of sedimentary basins. For the purposes of probabilistic seismic hazard analysis, we need to know the average amplification factor at each site for all sources of concern throughout the region, as well as the intrinsic variability of the response with respect to the different earthquake locations. Given a lack of observations, the response of the Los Angeles basin is explored numerically using the Southern California Earthquake Center (version 1) 3D velocity model (Magistrale *et al.,* 1998) and a regional 1D rock model (Hadley and Kanamori, 1977). Nine different earthquake scenarios are considered, including two large earthquakes on the San Andreas fault and seven moderate-sized earthquakes on the Los Angeles fault system. The scenarios use variable slip distributions and rise times related to the magnitude. These scenarios are intended to reflect some of the variability of basin response for all sources of concern in the region. From the simulations, I compute 3D/1D ratios of peak velocities and 3D-1D differences of durations. The kinematic earthquake rupture (Olsen and Archuleta, 1996) and viscoelastic wave propagation (Robertsson *et al.,* 1994; Blanch *et al.,* 1995) are numerically modeled using a 3D finite-difference method.

This article is divided into the following parts. After the introduction, the LA basin models and earthquake scenarios are described. The following section describes the finite-difference scheme and the finite-fault source implementation used in the simulations. The Los Angeles basin amplification is then presented, including the response to 1D vertical SH waves, amplification maps for the nine scenarios and their average, correlation of the amplification with basin depth, and the basin effects on durations. Finally I discuss the accuracy and limitations of the basin amplification results, including comparison of the amplification results to data from the Northridge earthquake. For a discussion of the wave propagation using synthetic seismograms and snapshots, see the Appendix.

Description of the Earth Models and Scenario Earthquakes

Basin Models

In order to compute both 3D and 1D ground motions, I use two elastic models of the Los Angeles area: a 3D model assembled by Magistrale *et al.* (1998) (M3D), and the 1D regional model given by Hadley and Kanamori (1977) (HK1D). Outside the 3D basin structures the models are identical. The spatial resolution of the model is approximately 0.5 km (H. Magistrale, written comm., 1995). Within the basins, the *P*-wave velocity is determined from the depths and ages estimated for four geological horizons (Faust, 1951) and calibrated with local *P*-wave velocity models for the basins. The density is estimated from the *P*-wave velocity using the Nafe-Drake relation (Nafe and Drake, 1960). The density is used to find Poisson's ratio using the relation of Ludwig *et al.* (1970). Finally, the *S*-wave velocity is computed from the *P*-wave velocity and Poisson's ratio. Although surficial sediments have lower velocities, numerical considerations impose a minimum *S*-wave velocity of 1.0 km/sec at the earth's surface. The corresponding *P*-wave velocity is 2.4 km/sec.

Figure 1 shows a topographic map of southern California. The larger rectangular area depicts the extent of the model for the San Andreas Fault (SAF) scenarios. The smaller rectangle shows the region used for modeling the remaining scenarios, which is further shown in Figure 2 including the surface projections of the fault planes associated with the earthquake scenarios. Note that the reference frame of the model in Figure 2 is rotated 28° counterclockwise from North to minimize the computational requirements for the simulations. The axis of the main basin trends approximately 118°, as does the San Andreas fault. Throughout this article, I use azimuths of 118° and 28° to analyze the horizontal ground motion for the earthquake simulations. The

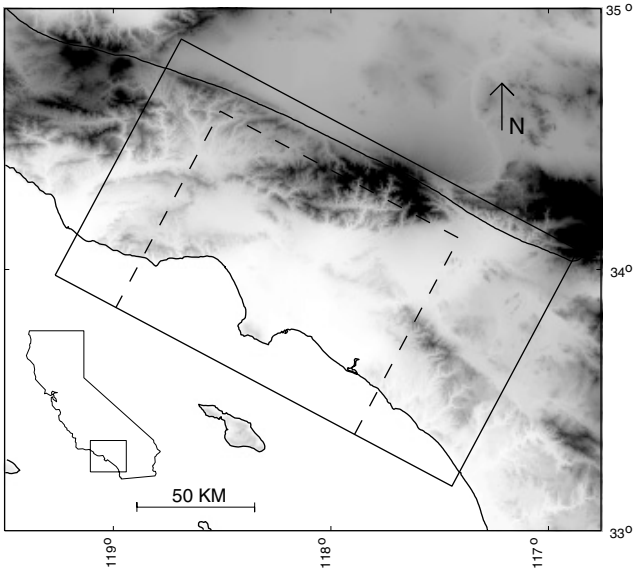

Figure 1. Topographic map of southern California centered on the Los Angeles region. The dashed rectangle shows the areal extent of the basin model used in this study. The area within the solid rectangle was used for the SAF scenarios. Also shown is the trace of the San Andreas fault.

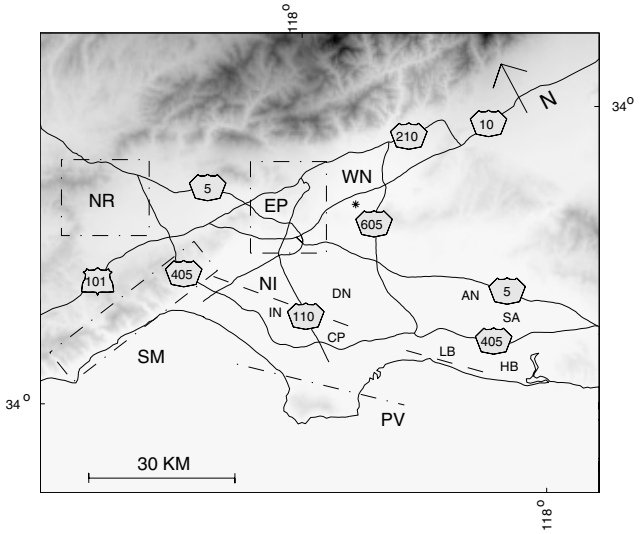

Figure 2. Topographic map of the Los Angeles area model. The dash-dot lines show the surface projections of faults where I have simulated ruptures in this study: Palos Verdes (PV), Elysian Park (EP), Santa Monica (SM), Newport-Inglewood (NI), and the faults that ruptured during the 1994 **M** 6.7 Northridge (NR), the 1933 **M** 6.4 Long Beach (LB), and the 1987 **M** 5.9 Whittier-Narrows (WN) events. The thin solid lines depict major freeways in the modeling area. AN, Anaheim; CP, Compton; DN, Downey; HB, Huntington Beach; IN, Inglewood; and SA, Santa Ana.

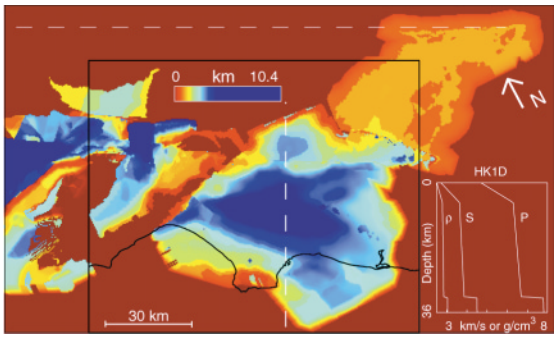

Figure 3. 3D image of the isosurface for an *S*-wave velocity of 2.5 km/sec for the area within the large rectangle shown in Figure 1. The northwest-southeast trending dashed white line is my approximation of the SAF trace. The northeast-southwest trending dashed white line is a profile used to display synthetic seismograms (see Appendix). The black rectangle shows the area used for the amplification study in this article. The thick black contour is the coastline. The 1D regional model (HK1D) is shown in the lower right corner.

3D nature of the model is characterized in Figure 3 by an isosurface corresponding to an *S*-wave velocity of 2.5 km/s. The large depression is the Los Angeles basin. The smaller basin to the northwest is located below the San Fernando Valley (SFV), separated from the Los Angeles basin by the Santa Monica Mountains, with the Ventura basin continuing to the North. A relatively small basin is located below the San Gabriel Valley (SGV), and the larger, but shallower Chino basin extends the LA basin to the East. Finally, the San Bernardino basin continues the Chino basin toward the east to the SAF. The 1D regional model (HK1D) is shown as an inset in Figure 3. The topography above sea level is not included in the simulations.

Earthquake Scenarios

I have selected nine scenario earthquakes to calculate the basin amplification, namely a bilateral strike-slip rupture on the Palos Verdes fault (PV), blind thrust on the Elysian Park fault (EP), thrust on the Santa Monica fault (SM), southeast (SAFN) and northwest (SAFS) propagating ruptures on a 170 km-long stretch of the SAF, northwest propagating rupture on the Newport-Inglewood fault (NI), and approximations of the 1994 **M** 6.7 Northridge (NR), 1933 **M** 6.4 Long Beach (LB), and 1987 **M** 5.9 Whittier-Narrows (WN) earthquakes (Fig. 2, Table 1). These earthquakes are all within the "geological reasonable scenarios" defined by Dolan *et al.* (1995).

Finite-Difference Modeling

The physical model is discretized with a grid spacing equivalent to 5 nodes per minimum shear wavelength of 2.5 km, the rule-of-thumb commonly used for fourth-order schemes (e.g., Levander, 1988) which limits the maximum resolved frequency to 0.5 Hz. The full model is discretized at 0.4 km spacing into 10–24 million grid points, dependent on the earthquake scenario. Absorbing boundary conditions (Clayton and Engquist, 1977) are applied to the sides of the computational model. To further reduce artificial reflections the boundaries of the model are padded with a zone of attenuative material (Cerjan *et al.,* 1985). The 3D modeling parameters are listed in Table 2. All scenarios are kinematically simulated using variable slip distributions, radially propagating outward with a constant rupture velocity. I used a rupture velocity of 2.7 km/s for the SAF scenarios and 3 km/s for all other finite-fault scenarios in this study. The slip distributions (Fig. 4) are taken as variations of the kinematic inversion results for the 1992 Landers (Wald and Heaton, 1994) and 1994 Northridge (Wald *et al.,* 1996, combined result) events. I use a triangular slip rate function in the 3D simulations. The rise time is 3 sec for the SAF ruptures, 0.2 sec for the Whittier Narrows earthquake, and 1 sec for all remaining scenarios. The source is implemented in the finite-difference grid by adding $-M_{ij}(t)/V$ to $S_{ij}(t)$ where $M_{ij}(t)$ is the ijth component of the moment tensor for the earthquake, $V = dx^3$ is the cell volume, and $S_{ij}(t)$ is the ijth component of the stress tensor on the fault at time t. The synthetic seis-

mograms are lowpass filtered to frequencies less than 0.5 Hz (Butterworth filter with 4 poles and 2 passes). I use a staggered-grid finite-difference scheme to solve the 3D elastic equations of motion (Levander, 1988; Graves, 1996); the accuracy is fourth-order in space and second-order in time. The numerical implementation of the 3D scheme is described in Olsen (1994). Viscoelasticity is implemented using stress relaxation independently for *P* and *S* waves (Robertsson *et al.,* 1994; Blanch *et al.,* 1995) using a standard linear solid model with one relaxation peak. The accuracy, relative to a frequency independent of the attenuation model, of the smallest Q in the model, $Q_s = 100$, is estimated to be less than about 5% for the central 1/3 of the bandwidth of interest (see Blanch *et al.,* 1995; Fig. 4). There are essentially no constraints on the values of Q for the area of interest, and no well-established relation between Q and velocity is available. I assumed that $Q_s = 0.1\ V_s$ (m/s) and $Q_p = 1.5\ Q_s$ which, to my knowledge, is commonly used in absence of better constraints on Q.

Los Angeles Basin Amplification

I use ratios of 0–0.5 Hz horizontal peak velocities for the 3D and 1D models throughout the 115 km by 95 km area shown in Figures 1 and 2. The 3D/1D ratios have the advantage of eliminating the geometrical spreading effects included in the 3D response and the 1D reference value for a given site. The conventional corrections for such effects using $1/r$ attenuation for body-wave propagation can be misleading for traces that include strong surface waves. A disadvantage of the method is that artifacts may show up in the amplification maps due to singularities in the rupture pattern. However, such effects are found to be small for the scenarios in this study. In this section I emphasize the amplification patterns for the scenarios, and the wave propagation underlying the amplification is discussed more rigorously in the Appendix.

1D Vertical SH-wave Amplification

The amplification observed above the Los Angeles basin is only partly controlled by the 3D basin structure. Another contribution to the amplification arises from the differences in velocities and densities between the two models in the area where the basin is located (lowest *S*-wave velocity is 2.7 km/s for the 1D model, 1.0 km/s for the 3D model). To estimate the latter contribution I carried out a series of 1D simulations where the models were given by the velocity and density profiles of the 3D model (hereafter referred to as the 1D vertical *SH*-wave amplification). The source was a vertically incident plane *SH* wave with an isosceles triangular slip rate function and a rise time of 1 sec, and the response was computed using a finite-difference method. The 0–0.5 Hz 1D vertical *SH*-wave amplification, relative to that at a site in the background model, are shown in Figure 5. These ratios reflect the amplification due to the lower impedance for vertically propagating *SH* waves in the 3D basin. The ratios are controlled by the variation of the impedance within the basin and the smoothing effect of the bandwidth of the source-time function. The largest peak velocity amplification factor due to the differences in impedance is about 1.7 obtained above large parts of the basin. In the following I will use the 1D vertical *SH*-wave amplification to separate the amplification due to the 3D basin structure from the total amplification.

Scenario Amplification Maps

Figure 6 shows 3D/1D amplification values for the nine earthquake scenarios described previously, corrected for the 1D vertical *SH*-wave amplification. Note that both the pattern and amplitudes of the amplification distributions for the nine scenarios vary considerably within the model area. While the deeper basin areas are generally characterized by

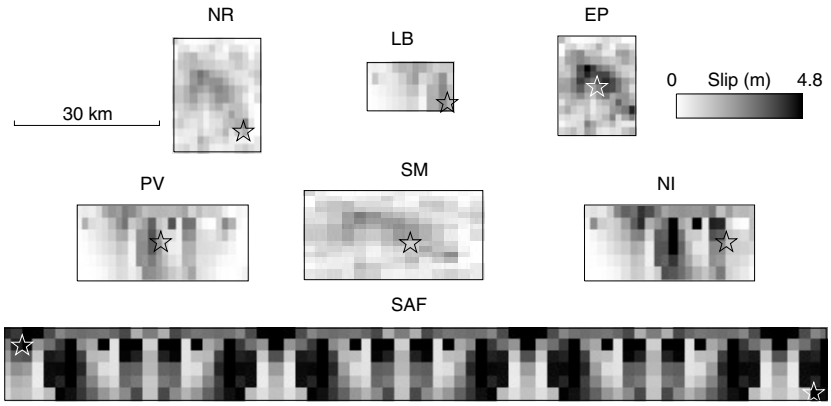

Figure 4. Variable slip distributions for the nine earthquake scenarios. The stars depict the hypocenters in the simulations.

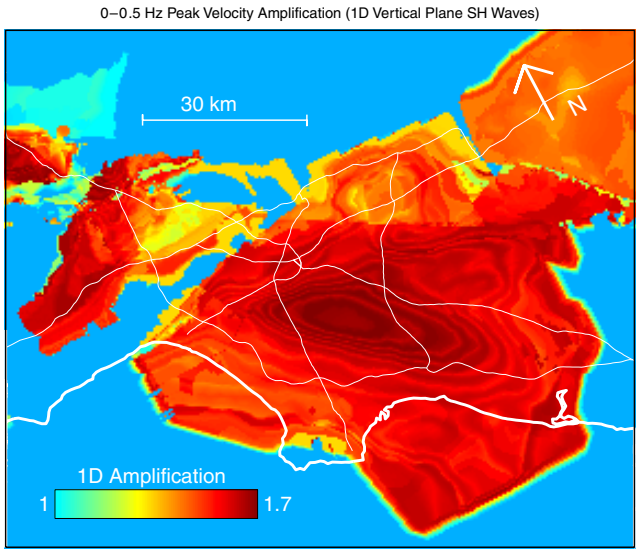

Figure 5. Image of 0–0.5 Hz peak velocities for a series of 1D simulations, normalized to the value in rock. The models used in the simulations are the 1D velocity and density profiles directly below each site in the 3D basin model, and the source for the simulations is a vertically incident *SH* wave with a rise time of 1 sec. The thick line is the coastline and the thin solid lines depict major freeways in the modeling area.

increased 3D/1D ratios, some of the largest amplification tends to occur above the most steeply-dipping basin boundaries and the basin edges, similar to the results by Olsen *et al.* (1995a) for the Salt Lake Basin. This amplification is typically caused by the generation of surface waves at the basin edges, along with resonance in shallower sub-basins such as the SGV (see Appendix).

The largest basin amplification is obtained for the EP (11.2), NR (10.8) and SAFS (8.1) events (Figure 6). Compared to PV, EP, LB, NI, SM, and WN, the NR and SAF from southeast and to a lesser extent, the SAFN generate generally larger amplification above the basin. This pattern suggests that the amplification increases with distance from the causative fault to the basin structure. A possible reason for this pattern is that the larger-amplitude surface waves generated for the distant events, in part at the basin edges (see Appendix), are more prone to amplification than are the predominant body waves impinging onto the basin sediments from the nearby earthquakes. This interpretation is supported by evidence from the variability of Northridge aftershock ground motions in the San Fernando Valley (Hough *et al.*, 1995).

Mean LA Basin Amplification

In order to construct an amplification map for Los Angeles that combines the variations in fault location and rupture mechanism, I have calculated the mean 0–0.5 Hz peak velocity ratios with and without correction for the 1D vertical *SH*-wave amplification. The average, maximum values, and the standard deviation for the nine earthquake scenarios described above are shown in Figure 7. The LA and SGV basins generally show mean amplification above 3, with localized areas above 4. While some of the largest mean amplification occurs above the deepest part of the basin, considerable mean amplification (>3.5) is found near the eastern and western edges of the LA basin as well as in the SGV. The overall largest amplifications (up to 11.2) and 18.5 with and without correction for 1D vertical *SH*-wave amplification, respectively) occur near Palos Verdes, Inglewood, and Santa Ana and Anaheim. The estimated standard deviation (of the natural-log amplification) shows generally lower values for larger mean amplification. For example, the standard deviation is less than 0.8 at most sites where the total mean amplification is larger than 3. The largest uncertainties above the basin are found on Palos Verdes, in the southern SFV, and northwest of SFV. The large uncertainty in the southern SFV is due to strong amplification in this area from NR, PV, and SAFN. Finally, the large uncertainty in the southern part of and to the northwest of SFV is due to relative large amplification from SAFS.

Note, that the variation in the 3D mean basin amplification is in part controlled by the azimuth of the incident waves. For example, the largest amplification due to the

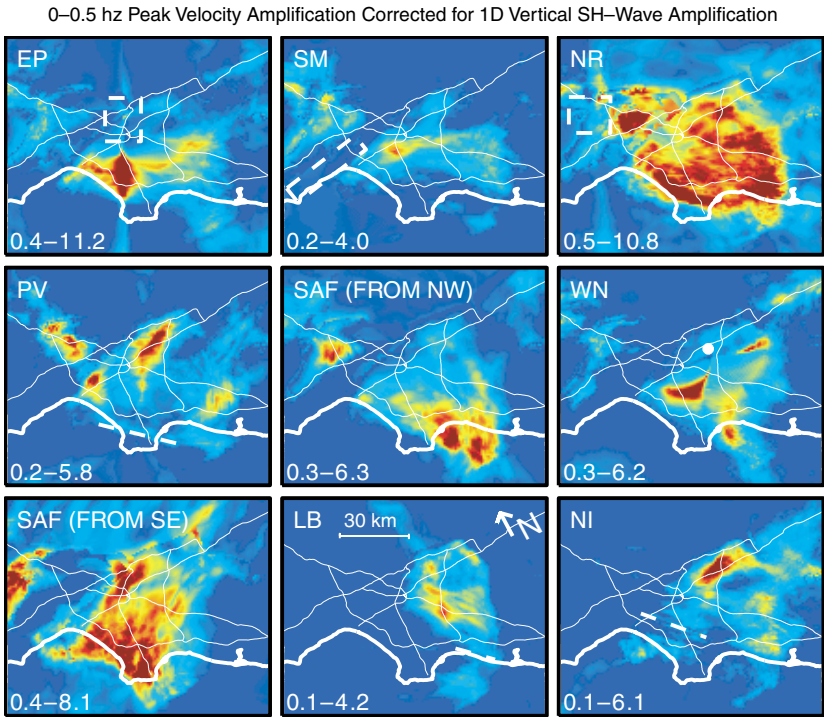

Figure 6. Maps of 3D/1D 0–0.5 Hz peak velocity ratios for nine scenarios (see Figures 1 and 2), divided by the 1D vertical *SH*-wave amplification (Figure 5). The thin white lines show major freeways in the Los Angeles area. The thick white line is the coastline. The range of amplification values is listed for each scenario.

SAFN occurs in the southern end of the basin, while that for the SAFS occurs in the western parts. This pattern is due to reflections from the basin boundaries and surface wave generation at the edges. For more discussion of the wave propagation of the individual scenarios, see the Appendix.

Amplification Versus Basin Depth

Another way of characterizing the basin amplification is to average values for sites located above similar velocity/density profiles in the basin. Here I choose to average the values for sites with common depth to the isosurface of 2.5 km/sec. Figure 8 shows these values for the nine scenario earthquakes as well as the mean and log standard deviation. I have omitted values for depths larger than 6 km due to their limited number. I have also omitted values for a small area of Cretateous outcrops in the vicinity of the SFV where the velocities may be overestimated (Magistrale, personal comm., 1999). The amplification generally increases gradually with increasing depth to the isosurface. However, exceptions are SAFS and NR, which both show average amplification of up to about 3 for sites with depths less than 2 km. These shallow basin sites are distributed fairly evenly along all edges of the basins within the model, and the increased shallow amplification for the two scenarios is caused by surface wave generation and resonance (see Appendix). The NR scenario is also responsible for the largest amplification values (up to about 6.5), as noted from the scenario amplification maps. The least amplification with depth is obtained for the NI, LB, and PV scenarios. In fact, these and other scenarios generate deamplification at shallow basin sites, caused by the transfer of energy from the initial arrivals to secondary phases in the 3D model (see Appendix). The mean amplification values for the scenarios as a function of depth to the isosurface gradually increase from 1 outside the basin to about 3.3 above the deepest part of the basin. Figure 9 shows the values from Figure 8, divided by the 1D vertical *SH*-wave amplification (Figure 5). These corrected amplification factors are less than about a factor of 4, largest above the deepest part of the basin. The mean value increases to about 2 above the basin.

Basin Effects on Durations

Several ground-motion modeling studies have found that durations are significantly increased from 3D basin effects, in particular by the generation of surface waves at the basin edges (e.g., Vidale and Helmberger, 1988; Olsen *et al.,* 1995a,b). It is therefore important to understand to what extent the basin structure extends the ground-motion durations for the Los Angeles basin. In this section I compare the difference in duration between the 3D (model M3D) and 1D (model HK1D) simulations for the nine earthquake scenarios. As for the peak velocity computation, the source was identical in the 1D and 3D simulations for each scenario. The duration is measured as the cumulative time for which the vector ground velocity exceeds a threshold value (Tumarkin and Archuleta, 1997) of 5 cm/sec. Figure 10 shows the 3D-1D durations for the nine scenarios. Note that unlike the peak velocity ratios shown in Figures 6 to 9, the durations are directly related to the magnitude of the simulated earthquakes. The magnitude dependence is shown by a rela-

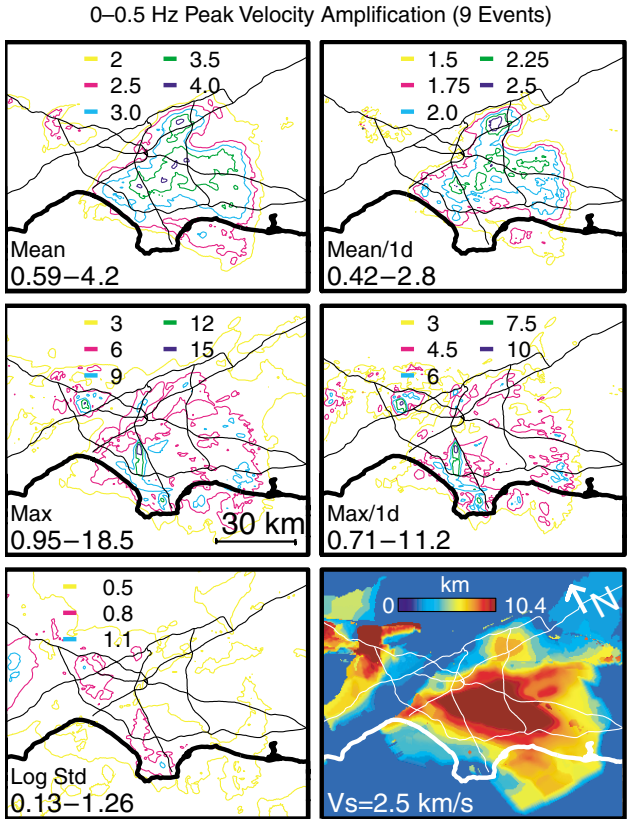

Figure 7. Maps of the 3D/1D 0–0.5 Hz peak velocity ratios and their uncertainties. Mean values without (top left) and with (top right) correction for 1D vertical *SH*-wave amplification, the maximum values without (middle left) and with (middle right) correction for 1D vertical SH-wave amplification, and the standard deviation of the natural log of the amplification (bottom left). The thin lines show major freeways in the area. The bottom right figure shows the isosurface for an *S*-wave velocity of 2.5 km/sec.

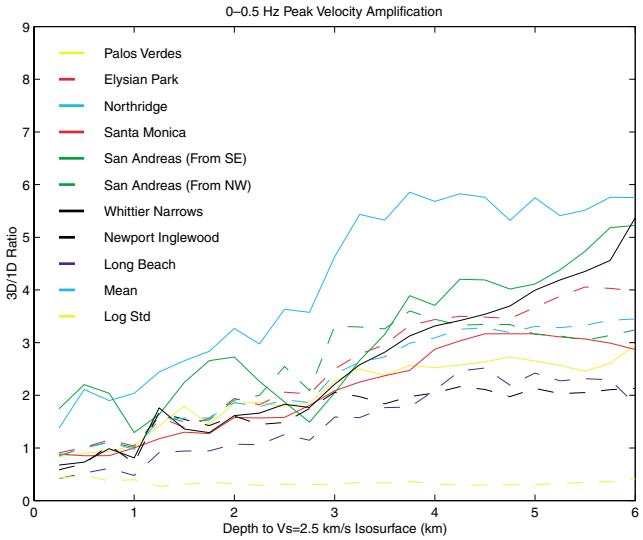

Figure 8. 3D/1D 0–0.5 Hz peak velocity ratios for the 9 scenarios shown in Figure 6, as well as their mean and log standard deviation, averaged for sites with common depth to the isosurface for an *S*-wave velocity of 2.5 km/sec.

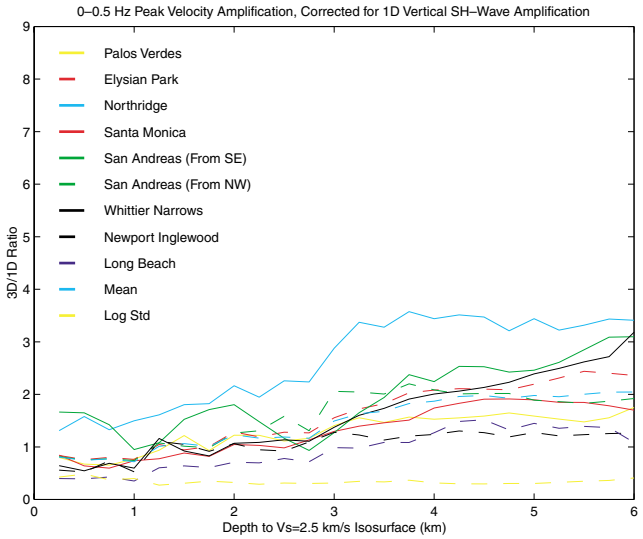

Figure 9. Same as Figure 7, but divided by the 1D vertical *SH*-wave amplification (Fig. 5).

tive large area affected by the 3D-1D durations for the SAF scenarios compared to some of those for the smaller events. The amplification south and west of the basin for the SAF scenario is a result of predominantly southward and westward propagating surface waves generated by the wavefield impinging onto the basin structure from the northwest and northeast. However, the areas affected by and maximum 3D-1D durations for the **M** 6.7 NR scenario are comparable to those for the larger SAF events. These results show, in addition to the effects of earthquake size and directivity, the importance of the fault proximity to the basin structure.

Accuracy and Limitations of Basin Amplification Results

Comparison to Data

Strong-motion recordings from the 1994 **M** 6.7 Northridge and 1987 **M** 5.9 Whittier-Narrows earthquakes are available for comparison with the simulations to examine the accuracy of the 3D modeling obtained in this study. Unfortunately, only the Northridge recordings have sufficient signal-to-noise ratio for frequencies below 0.5 Hz.

Figure 11 shows a comparison between 0.1–0.5 Hz data and synthetics for 11 stations representing various azimuths and distances from the causative fault. For each station, the comparisons are made at the same scale for all three components and for the available record length of the data. The fits among the phases vary considerably. The best results are obtained for stations located near the source, such as SSA

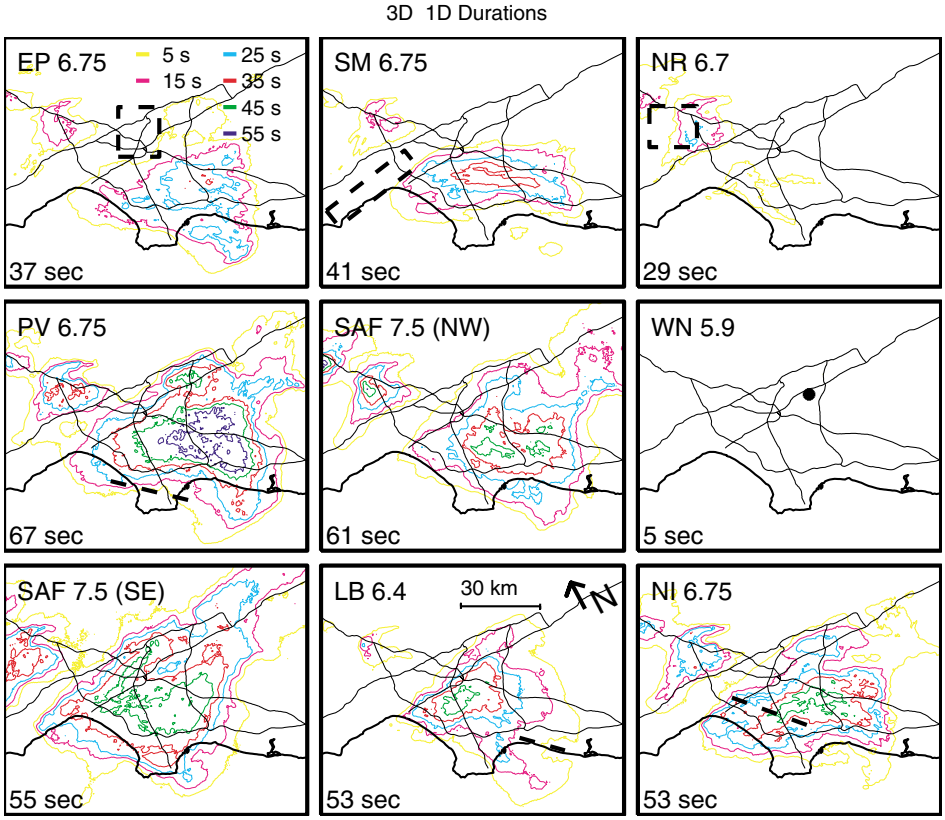

Figure 10. Maps of the 3D-1D durations for the nine scenarios shown in Figure 6. The thin lines show major freeways in the Los Angeles area and the thick line depicts the coastline. The range of the 3D-1D durations are listed for each scenario.

(Santa Susanna) and JFP (Jensen Filtration Plant). The fits are degraded near the Santa Monica Mountains and at large distances from the fault. The duration and amplitude of data and synthetics agree relatively well.

Figure 12 compares average horizontal 0.1–0.5 Hz peak velocities from the Northridge simulation at 59 sites in the LA basins to those computed from data. Almost all of the peak velocities are fit within a factor of 2 within this frequency range. The residuals are generally small above the basin, suggesting that the strength of anelastic attenuation used in the simulation was appropriate. The log standard deviation of the residuals for the 59 sites is 0.36, a reduction of 54% and 51% compared to the values obtained for the regional (HK1D) model and a 1D model defined by the velocity and density profile below the strong motion site DOW in the middle of the LA basin, respectively. This result suggests that long-period ground motion estimation can be improved considerably by including the 3D basin structure.

Omission of Low Velocities

I realize that the minimum velocity of 1 km/sec used in the simulations is unrealistically high for the basin sediments. In fact, the isosurface for $V_s = 1$ km/sec extends to a maximum depth of 1.3 km in the center of the LA basin. However, it is presently not feasible to include considerably lower velocities in the simulations with a maximum resolved frequency of 0.5 Hz. I therefore leave this important task for future work.

Reference Model

The 1D corrections were based on a smooth version of the regional model of Hadley and Kanamori (1977), which does not include the lower basin-sediment seismic velocities. One could also use the velocity profile below each site as the 1D reference model, an approach where the layering may cause pronounced wave guides. In order to examine the extent of such wave guide effects, I calculated the normalizing ground motion for Northridge using a plane-layered structure defined by the velocity profile at Downey (a deep sediment site in the center of the LA basin), with the source defined as in the M3D and HK1D models. Using the peak velocities at Downey from this simulation as the normalizing ground motion for that obtained from the 3D model decreased the amplification by 36% to 2.8 from the factor of 3.8 obtained at Downey in Figure 6. These results suggest that wave-guide effects can account for significant amplification. However, inclusion of the wave-guide effects would require separate calculations for each basin site, a task currently unrealistic due to computer limitations.

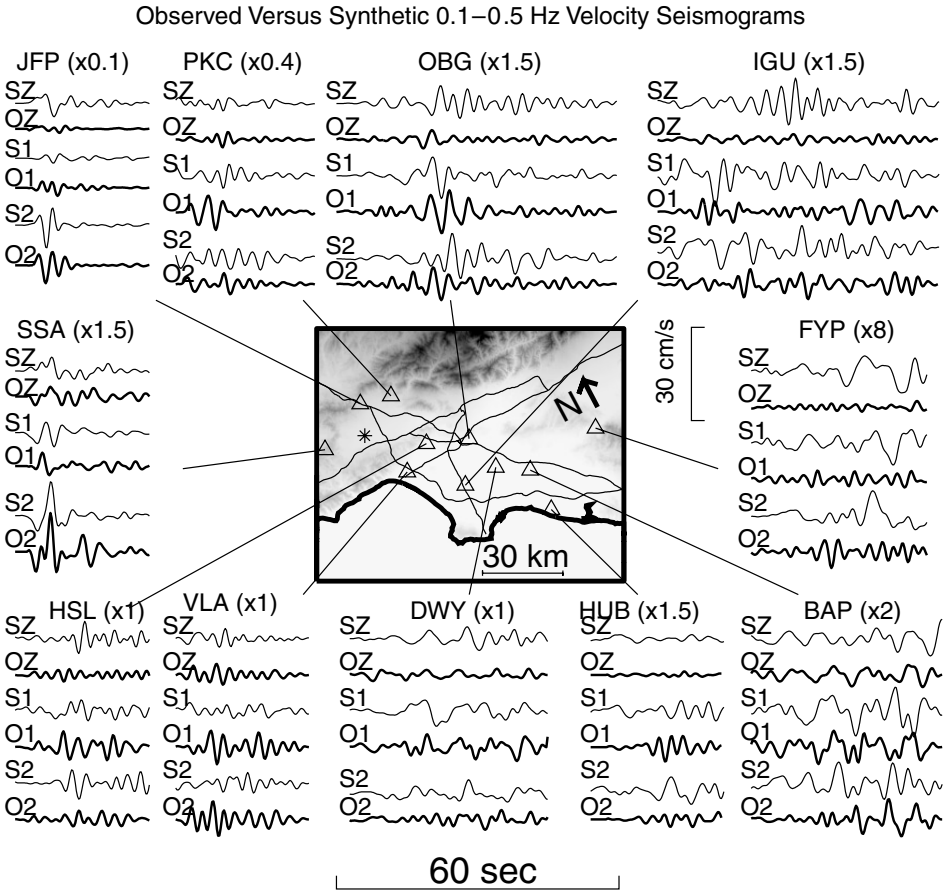

Figure 11. Comparison of observed versus synthetic 0.1–0.5 Hz waveforms at 11 sites within the model. O and S depict observed (thick traces) and synthetic (thin traces) seismograms, respectively, and Z, 1, and 2 depict vertical, 118°, and 28° horizontal components, respectively.

Number of Scenarios

The main limitations of the average amplification map for Los Angeles result from the relatively small number of scenario earthquakes (nine) and their maximum frequency (0.5 Hz) used for its construction. It will be important to incorporate more simulations of geologically reasonable scenarios in order to reduce the uncertainty of the average ratios, and to increase the highest frequencies to capture the entire spectrum of amplification effects. Unfortunately, both of these tasks are limited by the large computational requirements for the simulations. However, considering the recent explosive increase in computational power, it may be feasible to construct more accurate and reliable amplification maps in the near future. These maps should include the effects of realistic rupture parameters and anelastic attenuation as well.

Conclusions

I have used 3D/1D 0–0.5 Hz peak velocity ratios to construct site amplification maps for the Los Angeles basin for nine earthquake scenarios (**M** 6.75 earthquakes on the Palos Verdes, Elysian Park, Santa Monica, Newport-Inglewood faults, approximations to the **M** 6.7 1994 Northridge, the **M** 6.4 1933 Long Beach, and the **M** 5.9 1987 Whittier-Narrows events, and two **M** 7.5 earthquakes on a 170-km long stretch of the San Andreas fault). The individual scenarios show amplification of peak velocities up to an order of magnitude relative to the background model. The distribution of mean peak velocity ratios, as calculated from the nine scenarios, has a maximum of 4.2. In general, both the individual scenarios and their mean values show that the largest amplifications occur above the deepest parts of the basin and above the steeply-dipping basin boundaries. The largest mean amplification is furthermore associated with relatively small uncertainties. The largest uncertainties of the mean amplification above the basin (log standard deviation > 1.1) are associated with sites on Palos Verdes, in the southern part of SFV, and northwest of SFV. For the nine scenario earthquakes, the amplification tends to increase with distance from the causative fault to the basin structure. It is possible that this pattern is due to stronger amplification of the more complex wavefield impinging onto the basin

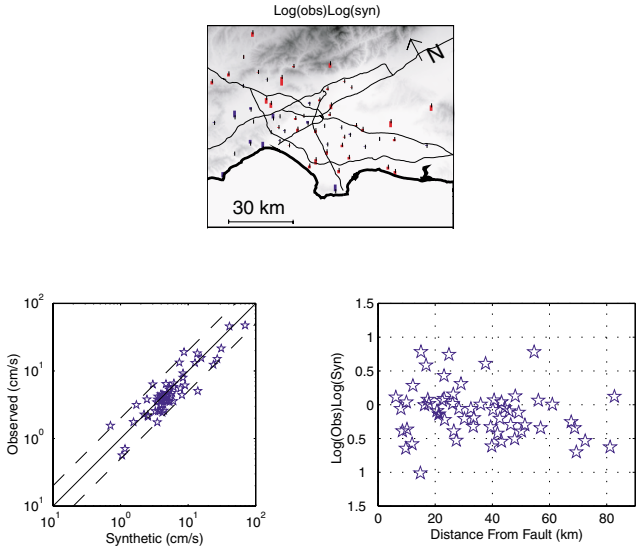

Figure 12. Comparison of observed versus synthetic 0.1–0.5 Hz peak velocities for 59 sites in the Los Angeles area for the 1994 Northridge earthquake. *Top* Difference between the log of the observed and synthetic peak velocities at each of the 59 sites, represented by the length of the bars; blue depicts underprediction, red depicts overprediction. *Bottom left:* Observed versus synthetic peak velocities. The dashed lines represent factor-of-two discrepancies. *Right:* Difference between the natural log of the observed and synthetic peak velocities versus distance from the fault.

structure from the distant earthquakes compared to that of the predominant body waves from nearby earthquakes. The amplification is caused by a combination of effects from the 3D basin structure and differences in impedance between the 1D and 3D models. As an estimate of the latter, 1D vertical *SH*-wave amplification in profiles of the 3D model accounts for amplifications of up to 1.7 above the basins. After correction for this effect, the maximum amplification averaged over sites above similar basin structure for the scenario earthquakes is 6.5, associated with sites located above the deeper part of the basin. Durations are significantly increased by the 3D basin structure. Compared to the smaller earthquakes, the **M** 7.5 San Andreas events generate extended durations over a much larger area, particularly above and beyond the southern, eastern, and western parts of the basin. The largest 3D–1D durations are obtained for the Palos Verdes (67 sec), Long Beach (53 sec), Newport-Inglewood (53 sec), and San Andreas (55/61 sec) earthquakes, for basin sites.

I used the simulation of the 1994 Northridge earthquake to validate the amplification results for the LA basin. The 0–0.5 Hz synthetic seismograms are in satisfactory agreement with data, in particular at near-source stations. In addition, the discrepancy between synthetic and observed peak velocities is less than a factor two at most sites and the log standard deviation of the residuals is 0.36. This value represents a reduction of 54% and 51% compared to the values obtained for the regional 1D model (HK1D) and a 1D model defined by the velocity and density profiles below site DOW in the middle of the basin, respectively. Thus, the results for Northridge suggest that estimation of long-period ground motion can be improved considerably by including the 3D basin structure in the modeling.

Acknowledgments

The computations in this study were carried out on SGI Origin 2000 computers at MRL, at University of California, Santa Barbara (NSF Grant CDA96-01954) and Los Alamos National Laboratories, with support from NSF Grant EAR 96-28682 and the Southern California Earthquake Center (SCEC). SCEC is funded by NSF Cooperative Agreement EAR-8920136 and USGS Cooperative Agreements 14-08-0001-A0899 and 1434-HQ-97AG01718. This manuscript has been improved by careful reviews by Steve Day, Ned Field, and an anonymous reviewer and from useful comments by Norm Abrahamson, Paul Somerville, Jamie Steidl, Ralph Archuleta, and Alexei Tumarkin. Appendix

So far in this study, the assessment of the Los Angeles basin amplification effects has been carried out with little reference to the underlying physics of wave propagation. However, it is important to understand the mechanisms causing the spatially variable amplification in order to improve the ground-motion estimates in the future. This appendix contains a brief analysis of three-component 1D and 3D synthetic seismograms along a profile across the LA basin for the nine earthquake scenarios described earlier in the article. I also show snapshots to support the interpretation of the wave propagation for three selected events, the Newport-Inglewood (NI), Northridge (NR), and San Andreas from southeast (SAFS). The identification of the phases is aided by particle-motion analysis.

Figures A.1–A.3 show 3D and 1D synthetic seismograms along the profile shown in Figure 3 for the nine scenarios. The profile is selected to intersect the deepest part of the LA basin, and it is located above some of the sites representing the largest amplification in the model area (see Figure 6 and 7). In particular, the profile is located near the peaks in amplification obtained in the San Gabriel Valley and the main trough of the LA basin. The synthetics are scaled by the same factor for each component for each scenario, but by different factors between the scenarios. The distance measures used in the following discussion refer to those shown in Figures A.1–A.3.

The differences between the 3D and 1D seismograms explain the genesis of some of the strong basin effects described in earlier sections, and help separate the basin effects from those due to geometrical spreading. Typically, the 1D seismograms contain only the direct arrivals from the source, while secondary arrivals due to phenomena such as surface wave generation and resonances can be seen in the 3D traces. Compared to the 1D traces, the 3D seismograms are generally characterized by much prolonged duration, as shown in Figure 10.

Elysian Park (EP)

The main feature of the 1D traces for EP is the direct *S* wave on all components, strongest on the vertical, with a phase shift near 50 km from the source radiation pattern. Part of the energy of the direct arrival is converted to secondary arrivals with extended durations in the 3D synthetics. A Love wave is generated near the north-northwestern boundary of the main trough and propagates toward the south. A secondary phase with lower predominant frequency on the 118° and vertical components is generated in the center of the basin (30–50 km). Note that this secondary phase is most energetic above the steeply dipping southwestern flank of the trough (35 km).

Santa Monica (SM)

Similar to EP, the thrust rupture for SM generates considerable energy on the vertical component, directed into the LA basin trough (energetic 1D arrivals at 10–50 km). This energy is amplified between 30 and 50 km in the 3D model, and the duration is much prolonged by dispersive surface waves, in part Rayleigh waves. These surface waves are, among other directions, propagating southwest from the northern boundary of the trough (50 km). The largest amplitude of these phases appear towards the center of the basin (35–45 km).

Long Beach (LB)

This relatively small event caused the smallest maximum amplification among the scenarios. The mostly horizontal energy from the rupture is seen to propagate towards northeast on the 118° component. Note the surface (Love)

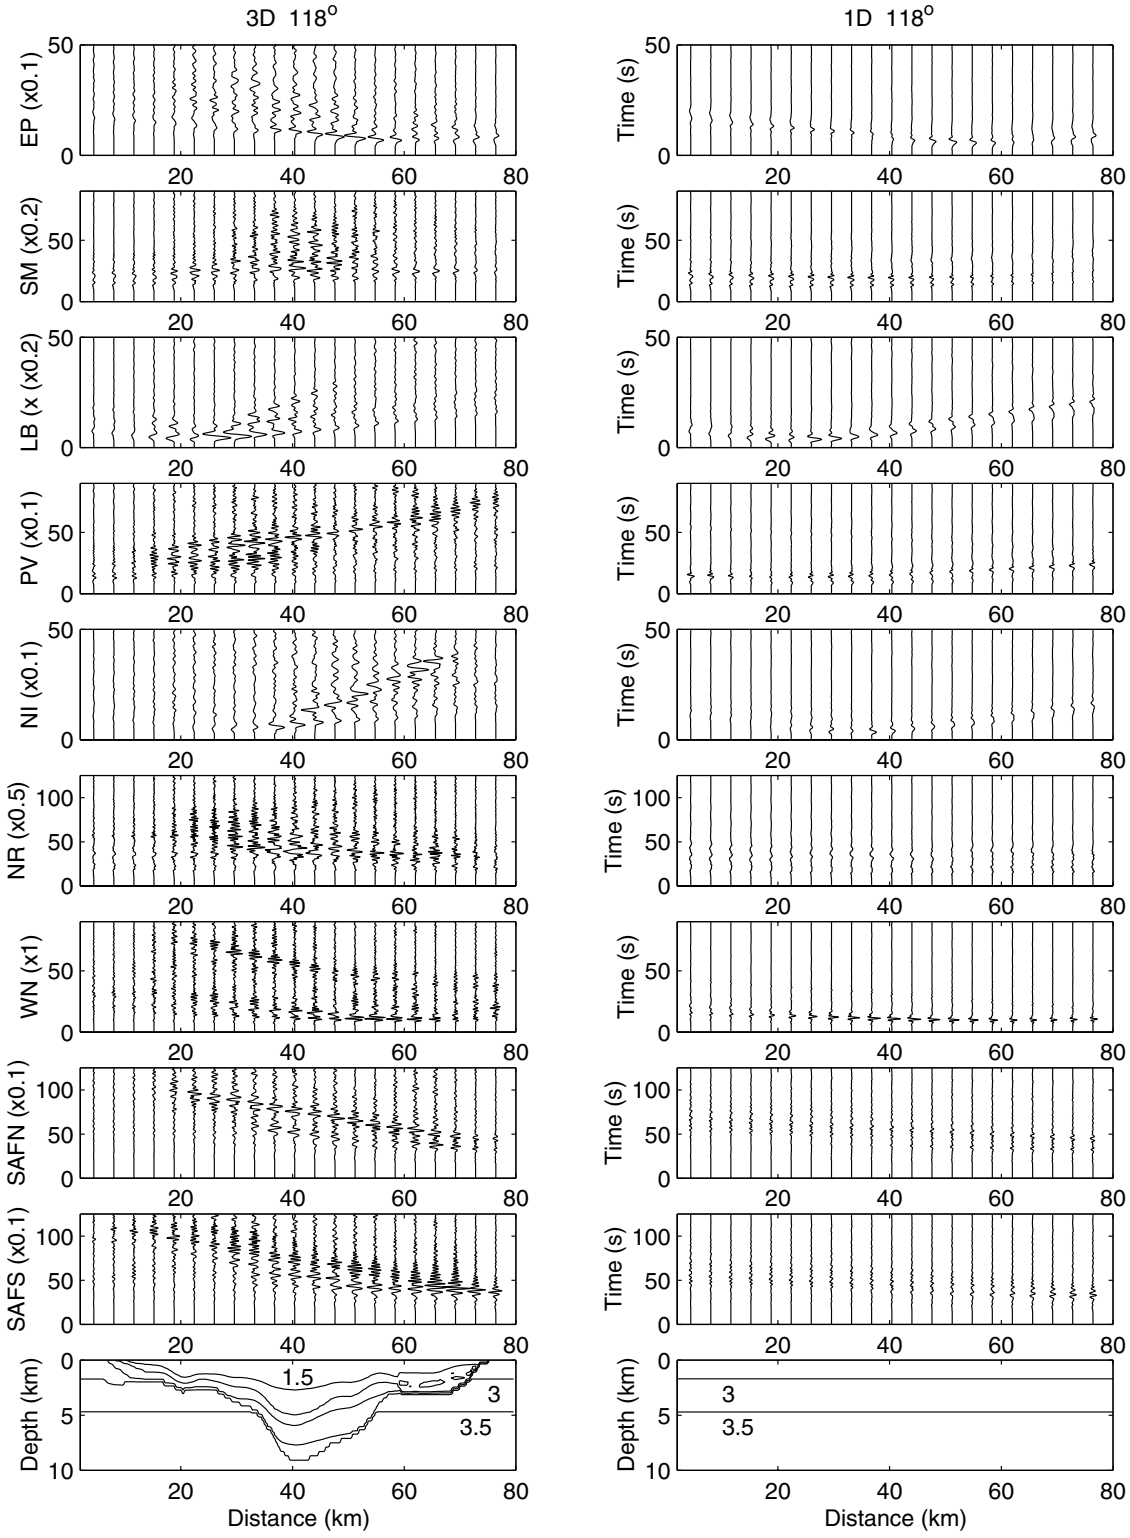

Figure A.1. 118° 3D and 1D synthetic seismograms for each of the nine scenarios along the profile shown in Figure 3. The traces are scaled by the same factor for the different components for each scenario, but a different factor (listed in the label) among the scenarios. The bottom panels show cross sections of the 3D and 1D models along the profile. Contours (some labeled) vary between 1.5 km/sec and 3.5 km/sec with a spacing of 0.5 km/sec.

Figure A.4. Snapshots of simulated wave propagation in the Los Angeles area for NI along 118°, 28°, and vertical from 6.25 to 75 s after the origin time of the rupture. Light (dark) shading depicts negative (positive) particle velocity. The particle motion is scaled by a constant for all snapshots. The dashed line depicts the surface fault trace. The thin lines show major freeways in the Los Angeles area.

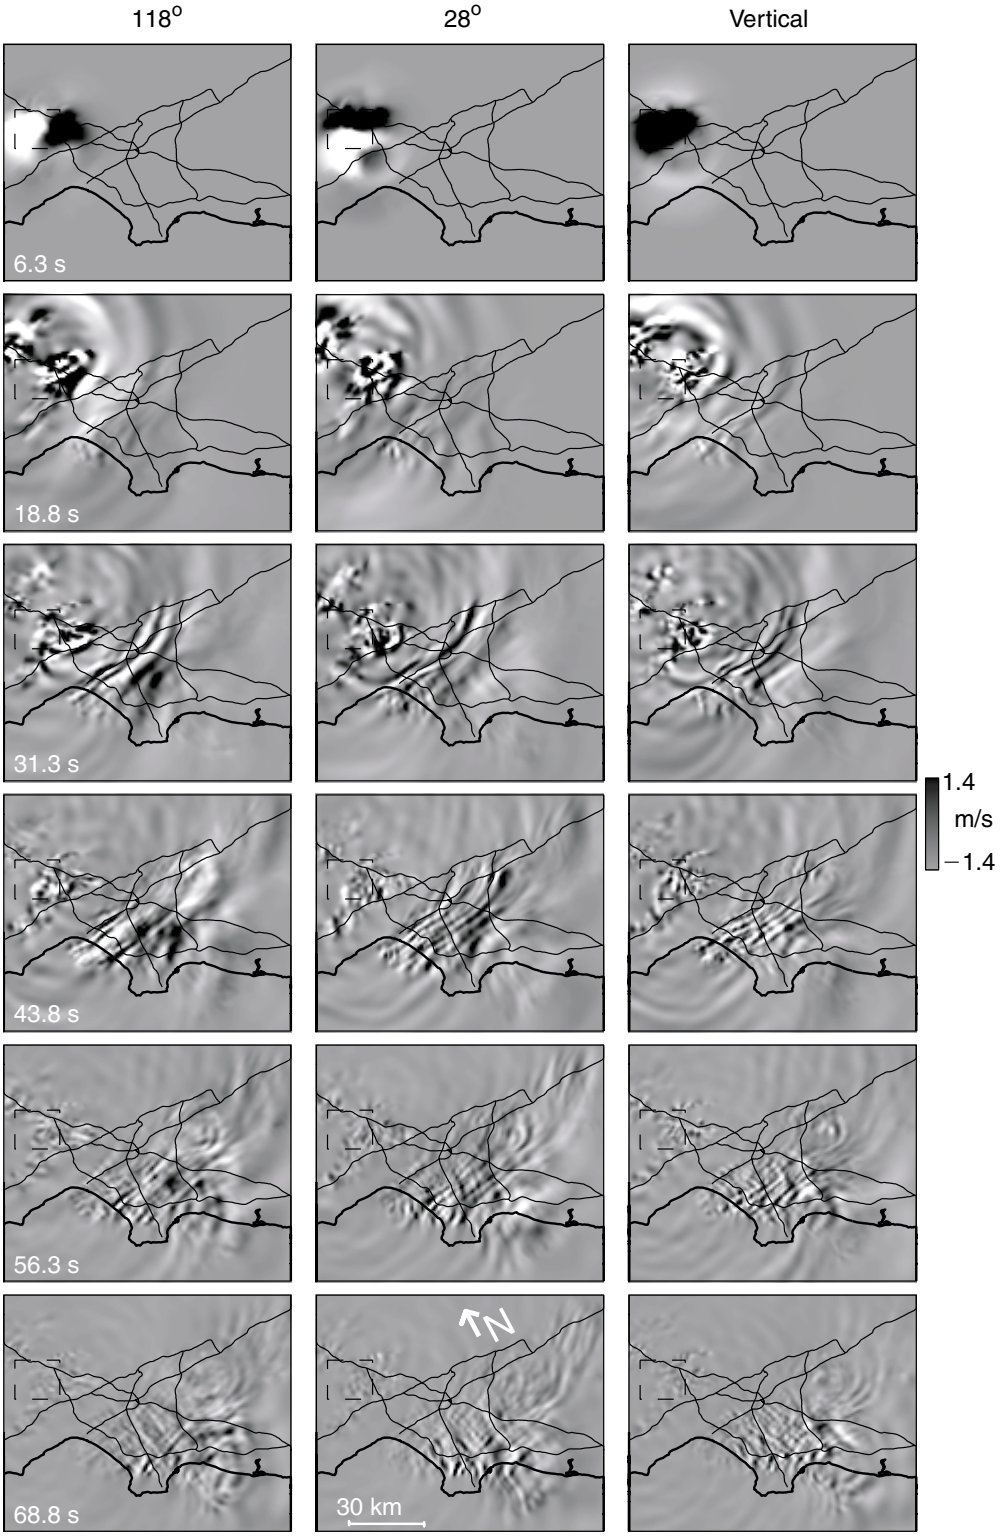

Figure A.5. Same as Figure A.4, but for NR.

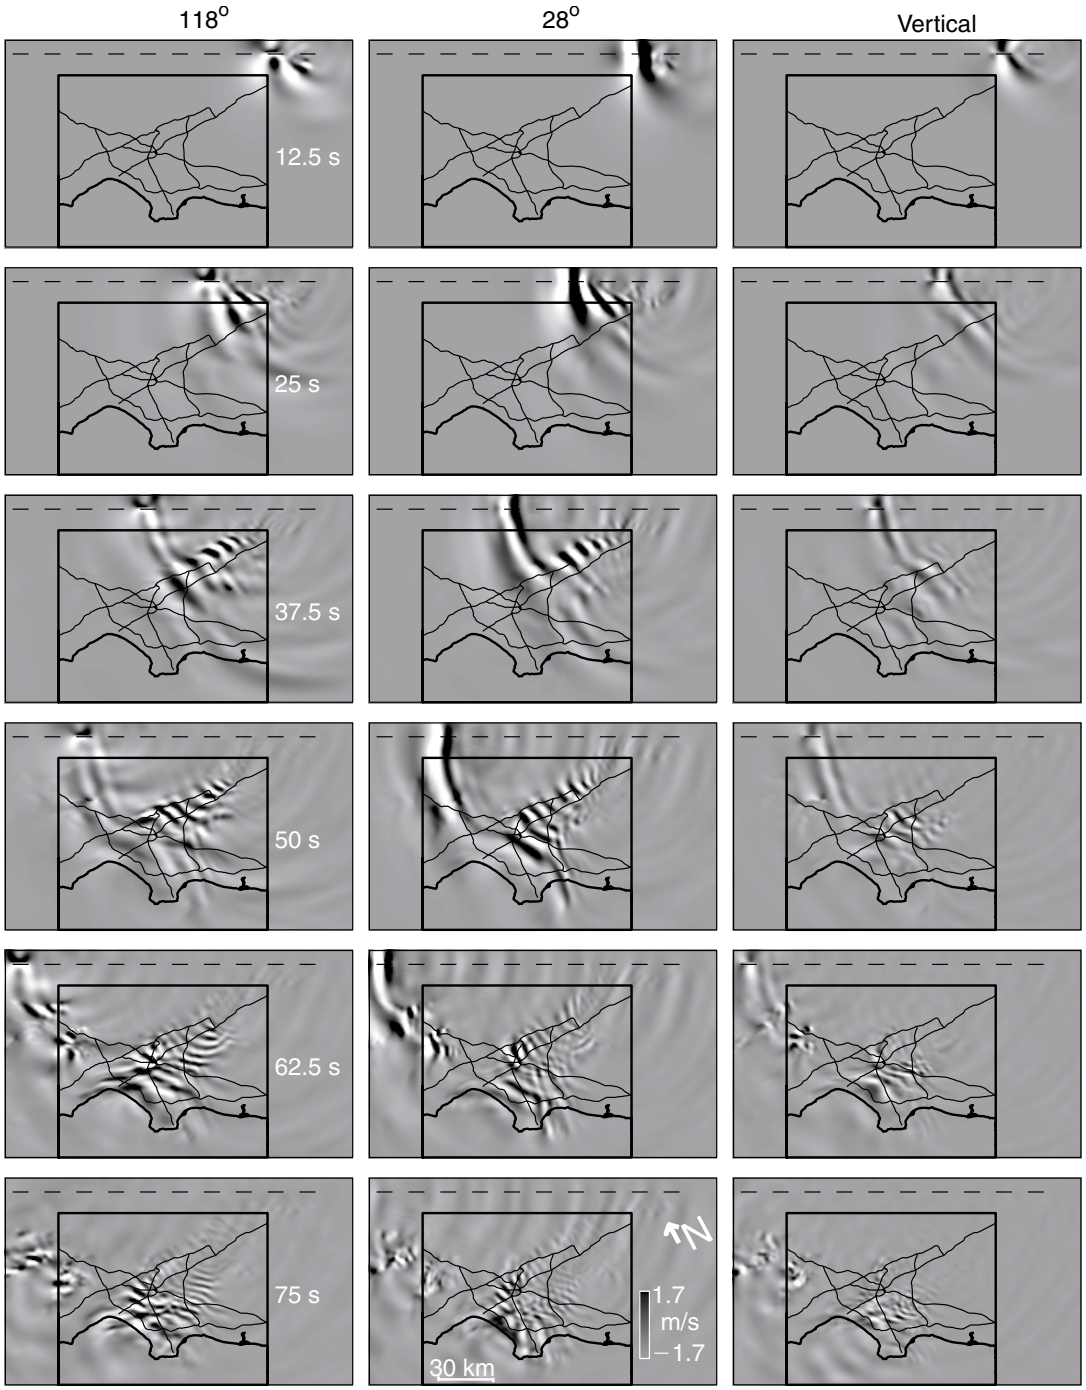

Figure A.6. Same as Figure A.4, but for SAFS.

waves generated near the fault (25 km), propagating southwest and particularly northeast toward the deepening basin. Also note how the 1D amplitudes are stronger than the 3D ones, northeast from about 50 km, causing deamplification for basin depths less than about 2 km in Figures 6–7. This is due to transfer of energy from the initial to secondary phases caused by basin effects in the 3D model.

Palos Verdes (PV)

This strike-slip event generates predominantly horizontal energy, which along the profile is strongest near the fault on the 28° component. Strong reverberating energy appear in the shallow southwestern end of the basin along 118°. A Love wave generated at the steeply dipping flank propagates toward northwest which, in turn, reflects back in southern

directions, in particular on the 28° component, after about 70 sec. As for LB, PV generates deamplification in the southern part of the basin (compare 1D and 3D on the 28° component).

Newport-Inglewood (NI)

The northwest-southeast trending strike-slip fault responsible for the NI scenario is located along the southwestern slope of the LA basin trough. The northwest-propagating rupture and the fault geometry is favorable for direction of energy toward northwest and northeast (see snapshots in Figure A.4, at 6.25–25 sec). Note how the predominantly northeast-propagating *SH*/Love-wave (40–70 km on 118° in Figure A.1) generates strong resonance on the 28° component in the San Gabriel Valley (SGV) (60–70 km). The snapshots at 25 sec and later times explain this transfer of energy: the northeast-propagating phase with predominant transverse motion is redirected toward east-southeast by the shallowing sediments in SGV. The part of the energy directed towards northwest generates resonance in the deepest part of SFV near the I5/I405 intersection (see snapshots at 25 sec and later). *SH*/Love wave energy is generated close to the I10/I405 intersection near the basin edge, which propagates toward southeast along the I405 (snapshots, in particular 28°, at 25 sec and later).

Northridge (NR)

The simulation of the 1994 Northridge event generated the largest amplification among the nine scenarios covering the widest area (see Figure 6). The strong amplification is shown by the large differences between the 3D and 1D synthetics in Figures A.1–A.3. The amplitude is comparably large on all components of the 3D traces with much extended durations in some areas. The 28° and vertical components show strong resonance in the San Gabriel Valley (60–70 km). Surface waves are generated at both southwestern and northeastern boundaries of the trough (20 and 50 km), producing a criss-cross pattern in the LA basin by refraction and reflection at the basin boundaries (see snapshots in Figure A.5 at 31 sec and later). The surface waves include a large-amplitude Rayleigh wave generated just south of the Santa Monica Mountains after the wavefield has entered the LA basin (seismograms at 35–50 km and snapshots in Figure A.5 at 31.3 s and later).

Whittier-Narrows (WN)

This scenario generated deamplification for sites with depths less than about 1 km (see Figures 8–9), as indicated by the larger amplitude on the 1D traces compared to those in the 3D synthetics. *SH*/Love waves are generated near the northeastern boundary of the trough at about 10 sec and 40 sec (118°), propagating toward northeast and particularly southwest. Resonance is seen in the SGV on the 28° component.

San Andreas (SAFN and SAFS)

The strike-slip SAF scenarios generate predominantly *SH* energy, with the 28° component amplified near the fault due to directivity effects, as pointed out by Olsen *et al.* (1995b). The much extended duration here is due not only to basin effects, but also the rupture duration in excess of 60 sec. A Love wave with southerly propagation direction and particularly strong dispersion for SAFS is generated when the wavefields enter the SGV, causing increased amplification at 55–70 km on the 28° component. Resonance is generated in the LA basin between at 40–60 km (see also snapshots in Figure A.6, 50 sec and later), where the particle motion differs from that of a Rayleigh wave. The Love waves are amplified (see Figure 6) upon striking the southern boundary of the basin (25–35 km on the 118° component).

The 1987 Whittier Narrows, California, Earthquake: A Metropolitan Shock

EGILL HAUKSSON

Department of Geological Sciences, University of Southern California, Los Angeles

ROSS S. STEIN

U.S. Geological Survey, Menlo Park, California

Just 3 hours after the Whittier Narrows earthquake struck, it became clear that a heretofore unseen geological structure was seismically active beneath metropolitan Los Angeles. Contrary to initial expectations of strike-slip or oblique-slip motion on the Whittier fault, whose north end abuts the aftershock zone, the focal mechanism of the mainshock showed pure thrust faulting on a deep gently inclined surface [*Hauksson et al.*, 1988]. This collection of nine research reports spans the spectrum of seismological, geodetic, and geological investigations carried out as a result of the Whittier Narrows earthquake.

Although unseen, the structure was not unforeseen. *Namson* [1987] had published a retrodeformable geologic cross section (meaning that the sedimentary strata could be restored to their original depositional position) 100 km to the west of the future earthquake epicenter in which blind, or subsurface, thrust faults were interpreted to be active beneath the folded southern Transverse Ranges. Working 25 km to the west, *Hauksson* [1987] had also found a surprising number of microearthquakes with thrust focal mechanisms south of the Santa Monica mountains, another clue to a subsurface system of thrust faults. Finally, *Davis* [1987] had presented a preliminary cross section only 18 km to the west of Whittier Narrows that identified as "fault B" the thrust that would rupture later that year. Not only was the earthquake focus and its orientation compatible with the 10-15 km depth and north dipping orientation of Davis' proposed thrust, but fault B appears to continue beneath the northern flank of the Los Angeles basin, skirting within 5 km of downtown Los Angeles, an area of dense commercial high-rise building development. These results are refined and extended by *Davis et al.* [this issue].

Six years ago, the 1983 M=6.5 Coalinga, California, earthquake signaled the importance of concealed thrust faulting in regions of continental compression. *Stein and King* [1984] showed that the youthful fold at the epicenter, appropriately named "Anticline Ridge" by petroleum geologists a century ago, had grown 0.75 m in amplitude during the earthquake, indisputable evidence that folds can grow suddenly by repeated earthquakes rather than by steady progressive deformation. "Coalinga's Caveat," suggested *Stein* [1984], was that earthquake hazards reduction in the United States was focused exclusively on the identification and study of surface faults, whereas active folds, and the faults they may conceal, remained largely unexplored and unassessed.

Serendipity favored us with remarkably good observations for so small an earthquake. The shock occurred where the two seismic networks, the California Institute of Technology/U.S. Geological Survey southern California network and the University of Southern California Los Angeles basin network, overlap. These networks captured high- quality recordings, whose interpretation was further refined by a calibration blast detonated near the epicentral area [*Perkins*, 1988] and by high fidelity recordings at digital broadband seismic stations located in northern California. An unusually dense and ideally configured geodetic leveling network had been fortuitously surveyed a year before the earthquake; resurvey of the bench marks following the earthquake enabled accurate portrayal of the surface deformation, even though it amounted to less than 50 mm at maximum, or just 7% of the deformation associated with the Coalinga earthquake. Borehole dilatometers (precision pressure gages) dispersed around southern California gave additional insight about the static or net deformation caused by the earthquake. Some 300 strong ground motion instruments recorded ground accelerations throughout the Los Angeles basin, enabling study of the response of the soil and structures to the shaking. Finally, the wealth of oil well logs from a history of oil exploration in the Los Angeles, Santa Maria, and Ventura basins has given geologists the tools with which to deduce the concealed geologic structures.

THE EARTHQUAKE SOURCE

The source parameters of the Whittier Narrows mainshock have been studied using local seismic network data [*Hauksson and Jones*, this issue], local strong motion data [*Wald* et al., 1988], regional broadband data from northern California [*Bolt et al.*, this issue], and regional as well as teleseismic data [*Bent and Helmberger*, this issue]. *Hauksson and Jones* [this issue] show that the mainshock ruptured a west striking thrust fault dipping gently to the north and that the largest aftershock occurred on a west-northwest striking steeply dipping strike-slip fault. Also by using local network data, *Hauksson and Saldivar* [this issue] demonstrate that the compressional tectonics highlighted by the Whittier Narrows sequence is also present throughout Santa Monica Bay, which extends 80

0148-0227/89/89JB-00407$02.00

km to the west of Whittier. Two-thirds of the focal mechanisms in the bay indicate thrust motion, with much of the seismicity occurring beneath mapped offshore folds.

Hauksson and Jones [this issue] report a ring of aftershocks with a 5 km diameter centered on the mainshock at 12 km depth. To satisfy both long- and short-period body waveforms, *Bent and Helmberger* [this issue] find that the mainshock consisted of two subevents, in which the first event locates at 15 km depth and released 16% of the total seismic moment and was followed by a second subevent 1 s later at a depth of 12 km. Bent and Helmberger suggest a very high static stress drop of about 75 MPa (750 bars), although the geodetic data require a drop of only 18±5 MPa. The dip inferred for the north dipping nodal plane varies from the 11°±15° of *Bolt et al.* [this issue] to 40° for *Bent and Helmberger* [this issue] and *Linde and Johnston* [this issue]. The lower bound on the moment, $1.1\pm0.2 \times 10^{25}$ dyn cm (equivalent to a moment magnitude M=6.0), well constrained by the geodetic data of *Lin and Stein* [this issue], is compatible with all seismic estimates of the moment. The geodetic data also afford reliable estimates of the fault slip, 1.1±0.3 m, for a fault with a diameter of about 5 km, coincident with the ring of early aftershocks surrounding the mainshock.

Linde and Johnston [this issue] find no evidence for precursory or postseismic strain transients from the borehole dilatometer records, which serve as ultra-long-period seismographs. Two days following the Whittier earthquake it was suggested that the rate of aftershock activity was unusually small, because most of the seismic strain release following the mainshock was accommodated by a few large aftershocks. The largest aftershock of October 4, 1987, stimulated a study of the probability of occurrence of such damaging aftershocks; *Reasenberg and Jones* [1989] constructed an algorithm that allows rapid evaluation of such probabilities for mainshock-aftershock sequences in California.

Strong Ground Motion

The Whittier Narrows earthquake was recorded by more strong motion instruments than any other earthquake [*Brady et al.*, 1988; *Shakal et al.*, 1988; *Trifunac*, 1988]. These records provide for the first time a contour map of strong ground motions in the Los Angeles basin and San Fernando Valley [*Trifunac*, 1988]. They also illustrate how modern high-rise buildings respond to ground accelerations [*Brady et al.*, 1988]. At one site, ground motion amplification was observed at a station in San Fernando Valley, with 0.63 g at an epicentral distance of 44 km [*Shakal et al*, 1988], reminiscent of that seen in Mexico City resulting from the (M_S=8.1) 1985 earthquake 300 km away [*Singh et al.*, 1987]. Despite local influences on ground motion, *Vidale* [this issue] is able to discern the seismic radiation pattern of a double couple source in the accelerations, by forming a ratio of the peak acceleration at 0.3-6.0 Hz of the mainshock to the largest aftershock at 43 stations, thereby canceling most site effects.

Geological Structure and Convergence Rates

Perhaps the most important work to emerge from the Whittier Narrows earthquake is a new assessment and synthesis of the strongly folded structures in the Los Angeles basin and adjacent areas. These studies, begun before the earthquake hit [see, for example, *Namson and Davis*, 1988], have assumed much greater importance in its wake. The folds and surface faults in the upper 4-5 km can be used to infer the location, orientation, and cumulative slip of the blind faults they mask. The age of the youngest folded strata can be used to deduce a shortening rate across the basin; from this, slip rates on the candidate faults can be tentatively assigned. The logs of tens of thousands of oil wells in the basin make such an analysis possible. Nevertheless, this work is hampered by the lack of publicly available seismic reflection and refraction profiles across the structures and by the variegated history of the basin itself: 3-5 m. y. ago the region was pulled apart; this pattern reversed about 2 m. y. ago when the current episode of compression began. Geologists must contend with the deformation from both episodes to deduce the displacement history of the blind thrust faults.

Davis et al. [this issue] infer 22 km of north-south convergence on top of the crystalline basement rocks and argue for a 30 km displacement on an hypothesized basal detachment between the San Andreas fault to the north and the California continental borderland in the Pacific Ocean. This results in a minimum estimated Quaternary convergence rate of 6-14 mm/yr, with perhaps 2-5 mm/yr of slip on the fault which ruptured during the Whittier Narrows earthquake and similar slip rates on one other blind and one other surface fault system that span the region between the San Andreas and the Pacific Ocean to the south. The contraction rate proposed by *Davis et al.* [this issue] is much higher than previous estimates [see *Ziony and Yerkes*, 1985] and thus occupies a central role in the problem of assessing earthquake risk. It is now essential that space geodetic networks be established across the basin to measure the contemporary rate of motion.

Earthquake Potential

Several authors [*Davis et al.*, this issue; *Lin and Stein, this issue*; *Hauksson and Saldivar*, this issue] evaluate the earthquake potential of the blind thrust faults. This can be accomplished by comparing the long-term rate of uplift of the Quaternary fold to its coseismic uplift in 1987, by comparing the deduced earthquake fault slip to the long-term slip rate, or by relating the cumulative seismic convergence to the long-term geological convergence rate. All of these approaches yield a similar result, that the historical record of earthquakes in the basin and adjacent Santa Monica Bay, which has been capped by earthquakes of M=6, is deficient. Earthquakes with M=6 should recur every 5-15 years; instead their rate of occurrence is about once every 25 years since 1860. If the convergence rate of *Davis et al.*[this issue] is correct, then either most of the slip occurs aseismically or it occurs during larger and hence less frequent earthquakes.

After discovery of a broad system of active thrust faults beneath a region populated by 11 million people, we are thus left with a conundrum: Is the message writ by the Whittier earthquake that much of the fault slip is accommodated quietly by aseismic creep, in which nothing more damaging than a Whittier Narrows

earthquake can occur, or are we now overdue for a larger event with much more vigorous shaking? Seeking the answer to this question will undoubtedly drive further study. To answer it, we must confirm the geological contraction rate, estimate the total length and individual segment lengths of the thrust faults, and read the record of past events in the geomorphology of the urban landscape. All of these are challenging tasks.

Acknowledgments. We would like to thank Charlie Sammis and Andy Michaels for reviewing this introduction and the authors of the Whittier Narrows Earthquake special section for making preprints of their papers available to us. E. Hauksson was supported by USGS grant 14-08-0001-G1328.

Earth Consultants International

Robert S. Yeats, Ph.D.

Senior Consultant
(541) 737-1226
ryeats@earthconsultants.com

Dr. Yeats has worked since 1971 in earthquake geology, focusing on the three-dimensional investigations of active faults and folds using oil-industry borehole and seismic data, including data from producing oil fields. With his students, he has completed investigations on the Red Mountain, San Cayetano, Santa Susana, Simi, San Gabriel, and Oak Ridge faults in the Ventura basin in addition to fault systems in the Santa Barbara-Carpinteria area, the East Ventura basin, and the San Fernando Valley. In addition, he has completed studies in the northern and eastern Los Angeles basin. This has led to a new understanding of the source dimensions of the 1971 San Fernando, 1987 Whittier Narrows, and 1994 Northridge earthquakes. He has also completed three-dimensional studies of active structures in the Cuyama basin and has mapped on San Miguel, Santa Cruz, and San Nicolas islands in the California Continental Borderland. He curated a relatively complete set of well files (logs, histories, paleo, dipmeter, surveys) for the Ventura, Santa Barbara, Cuyama, and northern Los Angeles basins; most of these are in repositories at the campuses of two California State Universities (Bakersfield CSU Core Repository for Ventura and Santa Barbara basin files, and Long Beach for Los Angeles basin files).

Internationally, he was the first to map active faults in the Himalayan foreland fold-thrust belt of Pakistan and later assisted the government of India in a source characterization of the Himalayan plate-boundary megathrust, which has produced four earthquakes of M≥7.8 since 1897. He was part of a team that discovered the surface rupture accompanying the October 2005 M7.6 earthquake in Kashmir, northern Pakistan. He assisted the New Zealand Geological Survey in their study of active reverse faults in Central Otago as part of an evaluation of hydroelectric power potential of the South Island, including the Clyde Dam, and served as an advisor to the New Zealand government in planning its earth science programs. He also assisted the China Earthquake Administration in a source characterization of four historical earthquakes in Gansu Province and Inner Mongolia in western China. In 2002, he led an ECI team to study the March 2002 Nahrin, Afghanistan earthquake.

He has been a member of the Southern California Earthquake Center since its inception. He has been funded by the earthquake external grants program of the U.S. Geological Survey since the early 1970s and recently completed an evaluation of the source region of the Whittier Narrows earthquake and the earthquake potential of the San Gabriel Valley, the Whittier and Chino faults and the Coyote fold belt in the eastern Los Angeles basin. In 1994-1995, he served on a panel of the Office of Technology Assessment, U.S. Congress, evaluating the reauthorization of the National Earthquake Hazards Reduction Program (NEHRP).

In 1990, he was instrumental in establishing an offshore active tectonics group at Oregon State University. This group has identified nine active strike-slip faults at the Cascadia plate boundary with slip rates of 5-8 mm/yr and is now using late Pleistocene low-stand geomorphic features such as shorelines and river channels to work out slip rates of structures on the Oregon continental shelf. This group, led by his former student Chris Goldfinger, now associate professor in the OSU College of Oceanic and Atmospheric Sciences, pioneered the new field of

turbidite paleoseismology on the northern San Andreas fault and the Cascadia Subduction Zone.

Combining subsurface well and seismic data with surface mapping, his group constructed fault maps at 1:100,000 scale of the Willamette Valley, Oregon. More recently, he has been involved in consulting regarding the seismic and surface-rupture potential of the Southern Whidbey Island and Seattle faults in the Puget Sound region, and served on a seismic review team for a proposed nuclear waste treatment plant at Hanford in eastern Washington.

Also in 1990, he organized a task group in paleoseismology as part of the Inter-Union Commission on the Lithosphere. This group organized paleoseismology workshops in Marshall, California in September 1994, Erice, Italy in September 1995, Beijing, China in August 1996, and Dehra Dun, India, in March 1997. The Marshall workshop led to a special section of the Journal of Geophysical Research in March 1996, devoted to papers on paleoseismology.

EDUCATION

Ph.D. Geology, University of Washington	1958
B.A. Geography, University of Florida	1952

PROFESSIONAL REGISTRATIONS

Professional Geologist:	California, PG 1976
Professional Geologist:	Oregon, PG 177
Professional Geologist:	Washington, PG 998

PROFESSIONAL HISTORY

Senior Consultant, Earth Consultants International, Inc.	1997-Present
Professor of Geology, Oregon State University, Corvallis, Oregon	1977-1997
Chair, Department of Geology, Oregon State University	1977-1985
Associate Professor and Professor of Geology, Ohio University, Athens	1967-1977
Exploitation Engineer, Senior Production Geologist, Senior Staff Geologist. Shell Oil Company, Ventura and Los Angeles, California	1958-1967
Physicien Associé, Institut de Physique du Globe de Paris, France	1993
Visiting Scientist, Seismotectonics Research Section, Geological Survey of Japan, Tsukuba	1992
Visiting Scientist, New Zealand Geological Survey, (now Institute of Geological and Nuclear Sciences), Lower Hutt	1983-1984; 1999
Summer Intern, F.B. Leighton and Associates, La Habra, California	1971

PROFESSIONAL AFFILIATIONS

Geological Society of America (Fellow)

Chairman, Structural Geology and Tectonics Division	1984-1985
Chairman, Cordilleran Section	1988-1989
Cordilleran Section Annual Meeting Co-Chairman, 1980; Chairman 2002	
Associate Editor, GSA Bulletin	1987-1989
Richard H. Jahns Distinguished Lecturer in Engineering Geology (joint with Association of Engineering Geologists)	1995-1996

American Association for the Advancement of Science (Fellow)
Seismological Society of America
Earthquake Engineering Research Institute

American Association of Petroleum Geologists
Michel T. Halbouty Human Needs Award 1998
Outstanding Educator Award, Pacific Section 1991
Coast Geological Society President 1962-1963
American Geophysical Union

COMMITTEE MEMBERSHIPS

Southern California Earthquake Center
Office of Technology Assessment Panel, U.S. Congress, for the Reauthorization of the National Earthquake Hazard Reduction Program 1994-1995
Member of committee reviewing earth-science programs for the Department of Scientific and Industrial Research, New Zealand, prior to a reorganization of those programs 1989-1990
Inter-Union Commission on the Lithosphere
Chairman, Working Group 1, Recent Plate Movements and Deformation 1987-1990
Chairman, Task Group II-3, Paleoseismology of the Late Holocene 1990-1997
Member, Oregon State Board of Geologist Examiners 1981-1983
Member, Geophysics Study Committee, National Research Council 1987-1994
Member, U.S. Geodynamics Committee 1992-1994
Head of U.S. delegation to international conference on neotectonics of South Asia, Dehra Dun, India, 1986

SELECTED PROJECT EXPERIENCE

Pacific Northwest, USA

Senior Consultant, Brightwater Wastewater Treatment Plant near Woodinville, Washington. ECI was hired by Sno-King Environmental Alliance to review potential hazards to this plant. We found that the treatment plant proposed by King County lies within the newly discovered Southern Whidbey Island fault zone, and we recommended trenching the footprints of all surface facilities prior to permitting. We also assisted the City of Woodinville in developing its response to the proposed plant, including preparing a GIS layer to their planning documents locating aeromagnetic and LiDAR lineaments in the City and its urban growth boundary. Dr. Yeats also assisted the city of Woodinville in upgrading their local seismic ordinances.

Review Panel Member, Re-evaluation of Earthquake Hazards to Proposed Nuclear Waste-Treatment Plant at Hanford, Washington. Dr. Yeats, together with other experts, served as member of a review panel under contract to the U.S. Army Corps of Engineers through the URS Corporation that evaluated tectonic models leading to a seismic hazard assessment of the Yakima fold belt, where the proposed nuclear waste treatment plant would be located. The panel reviewed a previous analysis done in 1996 by Geomatrix and found (in 2006) that the hazard is higher than previously estimated, based on new information on seismicity and crustal strain. The apparent emphasis of the Geomatrix analysis on one blind structure, the Toppenish Ridge, is due to a recurrence interval measured in tens of thousands of years and the removal of pre-Holocene evidence by Missoula floods.

Senior Consultant, Seismic Hazard Review of Portland General Electric Dams in Northwestern Oregon. PGE undertook a vulnerability assessment of their hydroelectric dams in the Cascade Mountains, Coast Range and Willamette Valley in light of the new

findings regarding active crustal faults in Oregon. Under contract to Golder Associates, ECI provided seismic hazard data within 100 km of each of the PGE dams, and served as a peer reviewer of the final hazard analysis.

Senior Consultant, Harbor West Condominium Insurance Claim. A condominium built out over the water in West Seattle was heavily damaged in the 2001 Nisqually earthquake, and the insurance company denied its claim for compensation because of its conclusion that the damage was due to poor construction. Working with ECI's engineering seismologist, we determined that damage was concentrated at the site because of focusing of seismic waves from the slab earthquake along the Seattle fault. Even though the Seattle fault did not rupture, the highest damage occurred along an east-west line updip from the tip of the blind Seattle fault.

Principal Investigator, Active Tectonics of the Central Oregon Shelf. Multichannel seismic profiles, swath bathymetry, sidescan sonar, and submersible investigations led to the recognition of a blind thrust off Newport, Oregon capable of an earthquake as large as M6.7. An offshore anticline is crossed by a late Pleistocene low-stand stream channel that has been warped over its crest. Low-stand shoreline features including beach cliffs, sand bars, and estuaries cut Heceta, Coquille, and Nehalem Banks. These provide evidence of warped shoreline angles, indicating that the shelf is tectonically deformed in late Quaternary time, and that coastal and offshore crustal structures are earthquake hazards.

California

Senior Consultant, Seismic Hazard Review of the Castaic Dam Near the San Gabriel Fault in northern Los Angeles County. As part of the re-certification process for Castaic Dam, ECI provided Golder Associates with an accurate location of the San Gabriel fault near the dam, and an analysis of the slip rates, earthquake magnitudes and probabilities for the San Gabriel and Holser faults.

Senior Consultant, Mission Hills Fault Investigation. This study evaluated the nature of deformation along Balboa Boulevard on the southern flank of the Mission Hills in the San Fernando Valley, following severe damage of gas and water lines as a result of the 1994 Northridge earthquake. A review of oil-industry subsurface well data, multichannel seismic profiles, and surface geology and tectonic geomorphology led to a revised location of the Mission Hills reverse fault.

Senior Consultant, Investigation of Deformation in a Moorpark Development. ECI was consulted after the discovery of extensive deformation of Quaternary gravels in trench excavations in the proposed housing development, placing it in regulatory limbo. We evaluated the geological hazards from surface faulting and folding and determined that nearly all the deformation was older than 50,000 years. The deformation younger than 50,000 years was mapped, the geological hazard was mitigated by engineering design, and the project went forward.

Principal Investigator, Earthquake Hazards of the Northern and Eastern Los Angeles Deformed Zone. We mapped structures that extend through downtown Los Angeles west to Santa Monica and east to the Santa Ana River. These include the Wilshire arch with its axis along Wilshire Boulevard, the blind Las Cienegas reverse fault, the Hollywood pull-apart basin between the strike-slip Hollywood and Santa Monica faults, and the blind

thrusts generating the Montebello and Santa Fe Springs anticlines, the surface expression of the 1987 Whittier Narrows earthquake. The slip rate on the blind thrust generating the Coyote Hills anticline has been determined using dislocation modeling. An earthquake source model for the San Gabriel Basin, northern Puente Hills, and San Jose Hills has been published.

Principal Investigator, Earthquake Hazards of the San Fernando Valley and Santa Susana Mountains. We mapped active subsurface and surface structures that were reactivated during the 1971 and 1994 earthquakes. The 1971 surface rupture follows bedding on the south side of the Mission Hills-Merrick syncline and appears to be in large part a flexural-slip fault. The main 1971 fault is blind and within well depth is called the Northridge Hills thrust. This structure and the Mission Hills reverse fault merge eastward to the Verdugo active fault, which has not ruptured historically. The 1994 blind thrust was not recognized beforehand, but over time, this has uplifted the footwall of the Santa Susana thrust, and future blind thrusts of this type can now be recognized based on their geological signature. Terminations of both 1971 and 1994 aftershock zones correspond to geometric segment boundaries mapped in and adjacent to the Santa Susana Mountains. An analogous reverse-fault earthquake pair, the 1929 Murchison and 1968 Inangahua earthquakes in New Zealand, was analyzed for the New Zealand Institute of Geological and Nuclear Sciences.

Principal Investigator, Earthquake Hazards of the East Ventura Basin. Although much of the San Gabriel fault has been shown not to be active, the southeastern part of this fault in Santa Clarita has evidence of late Quaternary displacement. The Holser and Del Valle faults also show signs of activity.

Principal Investigator, Earthquake Hazards of the Western Ventura Basin and Santa Barbara-Carpinteria Area. The Oak Ridge, San Cayetano, and Red Mountain reverse faults are active, and the first two have demonstrated high slip rates, with earthquake recurrence intervals measured in hundreds of years. The absence of large historical earthquakes makes this region one of particular concern. A set of south-dipping reverse faults was mapped in the Carpinteria and Santa Barbara-Goleta regions using subsurface and surface data. The Santa Clara Valley is being deformed by flexural-slip faulting, which led to studies related to extension of a landfill northeast of Santa Paula.

Principal Investigator, Earthquake Hazards of the Cuyama basin. The southern end of the Salinian block was mapped from the Big Pine fault northwestward past the Morales Canyon oil field. The inactive Russell fault is overridden by the active Whiterock and Morales thrusts, which continue southeast into the Cuyama Badlands. These structures could move at the same time as the adjacent San Andreas fault, although there is no evidence they did so in the 1857 Fort Tejon earthquake of M_w 7.9.

Senior Consultant, Vintage Petroleum This oil company purchased a large number of oil fields in southern California, in areas where Dr. Yeats has done significant work. He was hired to review his work with their staff and conduct a field trip through the Ventura basin.

International

Senior Consultant, Investigation of Earthquake Effects in Nahrin, Afghanistan. Following an earthquake in 2002 where 1,200 people lost their lives, ECI did a damage

assessment of the meizoseismal region, determined isoseismals based on the MSK intensity scale (most appropriate for central Asia), and recommended relocations of destroyed villages based on the near-surface geology.

Senior Consultant, Seismic hazard Evaluation of the Yokosuka, Japan, Naval Base. Working with ECI's engineering seismologist, Dr. Yeats evaluated the potential earthquake sources within 50 km of the site based on geology, historical and instrumental seismicity, and crustal strain based on GPS. These sources included the Nankai and northern Japan subduction zones and several crustal faults.

Senior Consultant, Earthquake Hazards to Port Facilities in Karachi, Pakistan. We determined that the seismic hazard map of Pakistan greatly underestimates the hazard to Pakistan's largest city, with 14 million people, lying close to two major plate boundaries. Our analysis was based on surface geology, an active-fault inventory, and historical and instrumental seismicity.

Principal Investigator, Earthquake Hazards Evaluation of the Himalayan Megathrust, Northwest India. This study included field mapping of active structures, subsurface mapping of the Sub-Himalayan décollement using oil-industry borehole and seismic data, and structural analysis of the Himalaya as a fault-bend fold. When combined with seismic and geodetic data, this permitted the mapping of the megathrust ramp and flat, and an evaluation of the seismic hazard it poses, especially in those parts of India and Nepal that have not ruptured in the last century. Dr. Yeats was co-organizer of a workshop in Dehra Dun that had as its objective the establishment of a national earthquake hazards mitigation program for India. This workshop was followed by a paleoseismology short course, including the first paleoseismological trench investigations in the Himalaya; this course trained most of the young Indian scientists now working on earthquake geology, including studies of the 2001 Bhuj earthquake in Gujarat.

Principal Investigator, Active Faults of Pakistan. Dr. Yeats worked with the Geological Survey of Pakistan to develop an active fault database of northern Pakistan. As part of this project, he described in detail, with Pakistani colleagues, the Salt Range thrust and a set of active faults extending from south of Peshawar to Tarbela Dam. He also participated in a conference in Islamabad in January 2006 to advise the Pakistan government on response to the 8 October 2005 M7.6 earthquake that took the lives of more than 70,000 people, and in the mapping of the surface rupture by a Japanese-led team. Dr. Yeats was also a member of a field survey that discovered and mapped the surface rupture in and near the cities of Balakot and Muzaffarabad. With Chris Madden and Ahmad Hussain, also of ECI, Dr. Yeats is currently updating the fault database for northern Pakistan, including the source fault for the 2005 earthquake and a newly discovered blind thrust that will be evaluated for potential hazard to the Tarbela Dam across the Indus River and the Islamabad-Rawalpindi metropolitan area.

Co-Investigator, Surface Ruptures of the Gulang, Hongyaxi, Gaotai, and Shandan earthquakes in the Hexi Corridor, Western China. This project was organized and funded by the China Earthquake Administration. Mapping had as its objective the comparison of surface faulting and folding to magnitude for reverse faults (although the Shandan rupture turned out to be a spectacularly-exposed strike-slip fault). The results are

being added to a general worldwide comparison of the surface expression of reverse-fault earthquakes.

Principal Investigator, Analysis of the 1968 Inangahua Earthquake, Northwest South Island, New Zealand. The 1929 Murchison and 1968 Inangahua earthquakes in New Zealand, analogs to the 1971 and 1994 San Fernando Valley earthquakes, was analyzed for the New Zealand Institute of Geological and Nuclear Sciences.

Simulations of Ground Motion in the Los Angeles Basin Based upon the Spectral-Element Method

by Dimitri Komatitsch, Qinya Liu, Jeroen Tromp, Peter Süss,* Christiane Stidham, and John H. Shaw

Abstract We use the spectral-element method to simulate ground motion generated by two recent and well-recorded small earthquakes in the Los Angeles basin. Simulations are performed using a new sedimentary basin model that is constrained by hundreds of petroleum-industry well logs and more than 20,000 km of seismic reflection profiles. The numerical simulations account for 3D variations of seismic-wave speeds and density, topography and bathymetry, and attenuation. Simulations for the 9 September 2001 M_w 4.2 Hollywood earthquake and the 3 September 2002 M_w 4.2 Yorba Linda earthquake demonstrate that the combination of a detailed sedimentary basin model and an accurate numerical technique facilitates the simulation of ground motion at periods of 2 sec and longer inside the basin model and 6 sec and longer in the regional model. Peak ground displacement, velocity, and acceleration maps illustrate that significant amplification occurs in the basin.

Introduction

Accurate prediction of hazardous ground shaking generated by large earthquakes requires the ability to numerically simulate seismic-wave propagation in realistic geological models. In this article we demonstrate that, using a detailed model of the Los Angeles, California, basin (Fig. 1) and an accurate numerical technique, ground motion can be accurately modeled down to a period of 2 sec inside the basin model and 6 sec in the regional model.

The Los Angeles basin developed in the Neogene as a result of regional crustal extension associated with the opening of the California Borderlands and rotation of the Transverse Ranges (Luyendyk and Hornafius, 1987; Wright, 1991). Since the early Pliocene, the basin has been deformed by numerous strike-slip, reverse, and blind-thrust faults that accommodate oblique convergence between the Pacific and North American plates (e.g., Davis *et al.*, 1989; Hauksson, 1990; Wright, 1991; Schneider *et al.*, 1996; Shaw and Suppe, 1996; Shaw and Shearer, 1999; Fuis *et al.*, 2003). This tectonic history, combined with varied depositional and diagenetic processes involving the basin sediments, has yielded complex 3D wave-speed and density structures in the Los Angeles basin (e.g., Süss and Shaw, 2003).

Regional studies initially focused on developing average 1D models (e.g., Hadley and Kanamori, 1977; Dreger and Helmberger, 1990). Three-component broadband records of small earthquakes were used in Dreger and Helmberger (1990) to study the sensitivity of synthetic seismograms to perturbations of the crustal model and to construct an average 1D layered model of crustal structure. More recently, taking advantage of the large number of broadband seismic stations and the related wealth of high-quality data, regional tomographic V_p and V_p/V_s models have been constructed (e.g., Hauksson and Haase, 1997; Hauksson, 2000) based upon *P* and *S-P* travel times from local earthquakes and controlled artificial sources. The 3D shape of the southern California Moho has also been imaged (e.g., Ichinose *et al.*, 1996; Lewis *et al.*, 2000; Zhu and Kanamori, 2000). Based upon the teleseismic receiver function technique, Zhu and Kanamori (2000) have shown that very significant variations of Moho depth exist in the region, from 21 to 37 km, with a regional average of 29 km. A deep Moho is found under the eastern Transverse Range, the Peninsular Range, and the Sierra Nevada Range. To the contrary, the central Transverse Range does not have a deep continental root. The crust is much thinner (typically 21–22 km) in the Inner California Borderland and the Salton Trough. In the past few years, the Southern California Earthquake Center (SCEC) has focused on creating 3D wave-speed models of the region (e.g., Magistrale *et al.*, 1996, 2000; Graves, 1999). The SCEC model is a rule-based wave-speed description, calibrated with seven sonic logs, that relates V_p to the age and depth of strata. In contrast, the model we use for our simulations is interpolated from more than 150 sonic logs and 7000 stacking velocities derived from petroleum-industry reflection profiles (Süss and Shaw, 2003). The two models

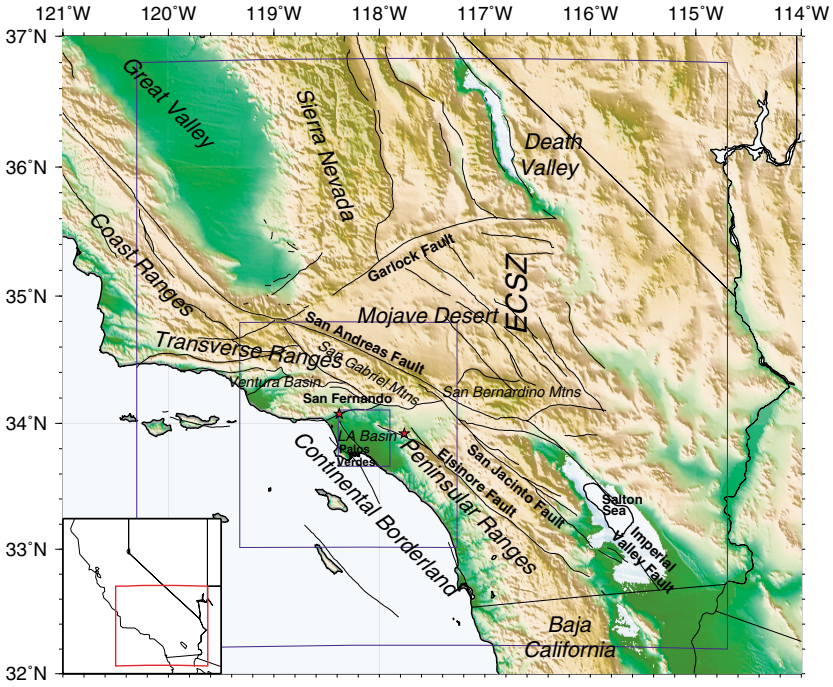

Figure 1. Topographic map of southern California showing the Los Angeles region. The small California map in the lower left-hand corner shows the location of the area represented (red rectangle). The main late Quaternary faults (Jennings, 1975) are also displayed. ECSZ, Eastern California Shear Zone. TriNet stations are indicated by white triangles. The large blue rectangle shows the edges of the computer grid that we use to perform our 3D ground-motion calculations. The two smaller blue rectangles are the edges of the medium- and high-resolution Los Angeles basin models, respectively. The epicenters of the Hollywood and Yorba Linda earthquakes studied in this article are denoted by red stars.

have similar average velocity functions, but our model describes more detailed lateral and vertical wave-speed structure that is observed in borehole and stacking velocity data.

Accurate numerical techniques are needed in order to understand ground motion in complex 3D structures and to study past large earthquakes or hypothetical earthquake scenarios and their impact in terms of seismic hazard, building codes, disaster prevention, and emergency planning. Numerical simulations of ground motion in complex heterogeneous structures have previously been performed based upon techniques that can handle highly heterogeneous 3D models, such as the finite-difference (e.g., Boore, 1972; Frankel and Leith, 1992; Frankel and Vidale, 1992; McLaughlin and Day, 1994; Olsen *et al.*, 1995; Pitarka and Irikura, 1996a; Antolik *et al.*, 1996; Larsen *et al.*, 1997; Kristek *et al.*, 1999; Stidham *et al.*, 1999; Ji *et al.*, 2000; Satoh *et al.*, 2001) and finite-element methods (e.g., Lysmer and Drake, 1972; Bao *et al.*, 1998; Bielak *et al.*, 1999; Garatani *et al.*, 2000; Aagaard *et al.*, 2001).

Several studies have focused more specifically on southern California and the Los Angeles basin (e.g., Frankel, 1993; Olsen and Archuleta, 1996; Pitarka and Irikura, 1996b; Olsen *et al.*, 1997; Wald and Graves, 1998; Graves, 1999; Olsen, 2000; Peyrat *et al.*, 2001; Eisner and Clayton, 2002). The complexity of the seismic response of the Los Angeles basin has been analyzed by many authors in recent years, for example, Hartzell *et al.* (1996, 1998), Wald and Graves (1998), and Olsen (2000). Detailed reviews are available in particular in Wald and Graves (1998) and Olsen (2000). There is evidence that large amplification (factors of 3, 4, or more) can occur between basin sites and hard-rock sites. It has also been shown that site effects caused by topography or local geological features, such as poorly consolidated sediments, can result in very significant amplification of the wave field (e.g., Gaffet and Bouchon, 1989; Frankel and Leith, 1992; Stevens *et al.*, 1993). Such phenomena have been observed in the Los Angeles region, for example, very large accelerations (up to 1.8*g*) at Tarzana Hill during the 1994 Northridge earthquake (e.g., Bouchon and Barker, 1996; Catchings and Lee, 1996; Rial, 1996; Spudich *et al.*, 1996; Komatitsch and Vilotte, 1998). Localization effects can also cause important damage, as illustrated in Santa Monica during the 1994 Northridge earthquake (e.g., Gao *et al.*, 1996; Alex and Olsen, 1998; Davis *et al.*, 2000). Such effects are intrinsically 3D and therefore further illustrate the need for detailed basin models and accurate and flexible numerical techniques.

In this article, we present simulations based on a detailed model of the Los Angeles basin (Süss and Shaw, 2003) and a powerful numerical technique called the spectral-element method (SEM). Using two recent well-recorded small (M_w 4.2) earthquakes in the basin, we show that ground motion can be accurately modeled down to a period of 2 sec inside the basin model and 6 sec in the regional model. The SEM has several distinct advantages over more classical numerical techniques mentioned earlier, as will be illustrated in the Numerical Technique section.

Basin Model

Creating a high-resolution wave-speed model of the Los Angeles basin (Fig. 1) has been the focus of significant attention in recent years. Collaborative efforts in the context of the SCEC have led to the development of models that are

now widely used in the geophysical community (e.g., Magistrale *et al.*, 1996, 2000; Hauksson and Haase, 1997; Graves, 1999). In this article, we use an extension of the more recent model of Süss and Shaw (2003), which describes a complex, heterogeneous 3D wave-speed structure (Figs. 2 and 3) based on more than 85,000 direct measurements from petroleum-industry boreholes and seismic reflection profiles. The model contains a description of the sedimentary basin shape as defined by the contact between lower wave-speed sediments and the higher wave-speed crystalline basement. Wave speeds within the sedimentary sequence were interpolated from sonic log and stacking velocity measurements using geostatistical kriging techniques (Süss and Shaw, 2003). The resultant wave-speed structure is highly complex, reflecting sedimentary, diagenetic, and structural controls, and is substantially different from previous descriptions mentioned earlier. While the original model (Süss and Shaw, 2003) covered only parts of the San Fernando Valley, the improved model used in this article includes the San Fernando, Ventura, Soledad, and Ridge basins and extends northward beyond the Ventura Basin. We constructed a surface defining the top of the crystalline basement for this area, and wave speeds east of the San Andreas Fault were taken from the tomographic model of Hauksson (2000). The top of the crystalline basement in the Ventura Basin was constructed based upon reference surfaces taken from the SCEC-II model (Magistrale *et al.*, 2000), as well as cross sections from Yeats *et al.* (1994) and Huftile and Yeats (1995). The geometry of the Ridge basin and Soledad basin was approximated based upon cross sections in Namson and Davis (1992).

The model and supporting data constrain compressional-wave (*P*-wave) speed (V_p). Shear-wave (*S*-wave) speed (V_s) and density (ρ) models, which are also needed for the simulations, were derived from the V_p model using simple empirical relations. More specifically, *S*-wave speed V_s is defined by dividing V_p by a coefficient that varies linearly from 1.732 in the deepest part of the basin (i.e., a Poisson's ratio of 0.25 at a depth of 8.5 km) to 2 in the shallow sediments near the surface (i.e., a Poisson's ratio of 0.33 at the surface). Based upon well-log information, density is defined by $\rho = V_p/3 + 1280$ (McCulloh, 1960; Stidham *et al.*, 2001), imposing a minimum of 2000 kg m^{-3}.

The basin model is embedded in the regional tomographic model of Hauksson (2000), which gives *P*- and *S*-wave speeds in southern California. In addition, we use the 1D background regional model of Dreger and Helmberger (1990). Note that, by lack of information about density in the area where the tomographic model of Hauksson (2000) is used, we use the 1D regional density profile of Dreger and Helmberger (1990). Until recently, little was known about attenuation in the Los Angeles basin, but low values of the shear quality factor Q_μ had been observed (Hauksson *et al.*, 1987). Based upon the work of Hauksson *et al.* and trial-and-error numerical tests, we decided to use a constant value of $Q_\mu = 90$ in the sediments and no attenuation in the bed-

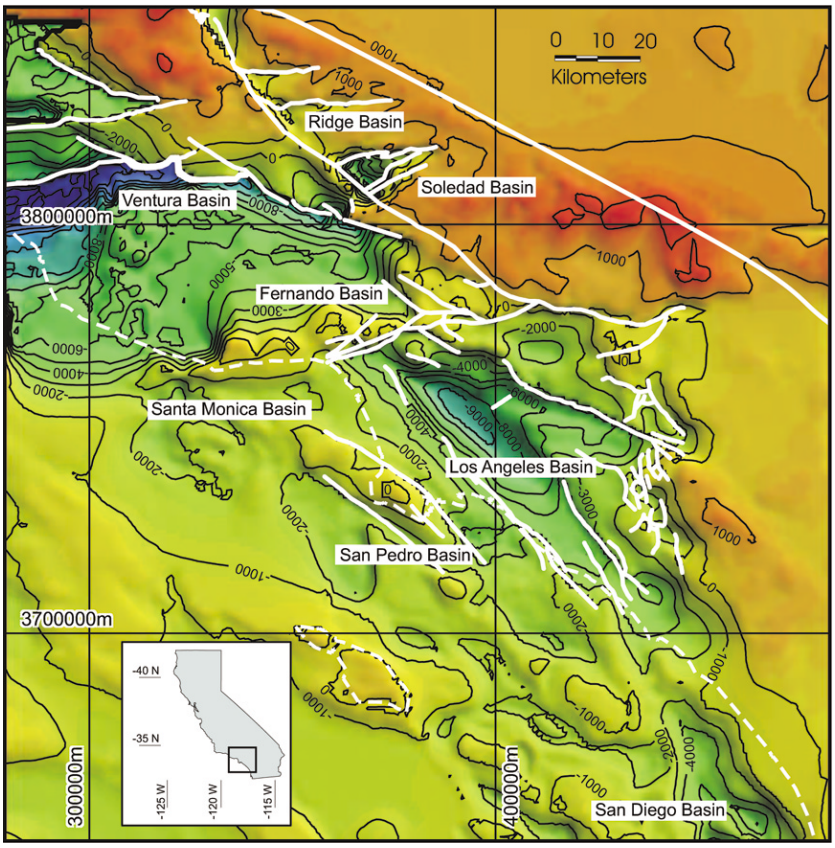

Figure 2. Top view of the surface defining the top of the crystalline basement in the Los Angeles basin model. The coastline is indicated by the white dashed line, and major faults by white solid lines. Red regions denote shallow sediments or no sediments at all, and green and blue the deepest sediments. One can clearly see the deep sedimentary pocket underneath Los Angeles, as well as the very sharp Ventura escarpment.

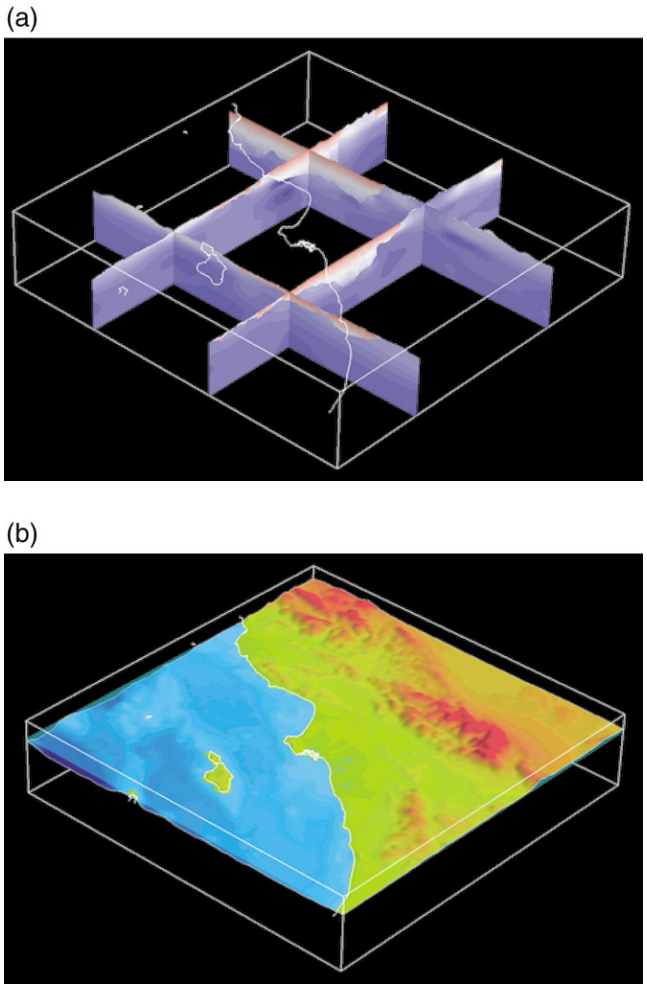

Figure 3. View from the southeast upon the Los Angeles basin model. (a) North–south and east–west cross sections showing *P*-wave speed in the basin model, with blue denoting fast bedrock and white and red slower deep and shallow sediments, respectively. The coastline is shown by the white line. The maximum depth of the basin is 8.5 km underneath downtown Los Angeles. The basin model is embedded into the regional tomographic model of Hauksson (2000) (not shown here). (b) Surface topography and bathymetry. One can clearly see the San Gabriel mountains toward the north, Palos Verdes along the coast, as well as the Ventura, San Fernando, and Los Angeles basins.

rock. It would ultimately be of interest to use the recent attenuation scaling rules of Olsen *et al.* (2003). Lateral variations in crustal thickness are incorporated based upon the regional Moho model of Zhu and Kanamori (2000). Topography and bathymetry are obtained from a U.S. Geological Survey (USGS) digital elevation map (USGS, 2003), as illustrated in Figure 3.

Numerical Technique

We use the SEM to simulate ground motion in the basin, based upon the linear anelastic wave equation. Nonlinear effects are not taken into account in this article. The SEM is a highly accurate numerical method that has its origins in computational fluid dynamics (Patera, 1984). It uses a mesh of hexahedral finite elements on which the wave field is represented in terms of high-degree Lagrange polynomials on Gauss–Lobatto–Legendre interpolation points. The method was used to model seismic-wave propagation in local and regional models in the 1990s (e.g., Cohen *et al.*, 1993; Priolo *et al.*, 1994; Faccioli *et al.*, 1997; Komatitsch, 1997; Komatitsch and Vilotte, 1998; Komatitsch and Tromp, 1999). It was more recently introduced for global wave propagation by Chaljub (2000) and extended for large-scale global wave propagation (Komatitsch and Tromp, 2002a,b; Capdeville *et al.*, 2003; Chaljub *et al.*, 2003).

The main advantage of the SEM is that it combines the flexibility of the finite-element method (e.g., Lysmer and Drake, 1972; Moczo *et al.*, 1997; Bao *et al.*, 1998; Bielak *et al.*, 1999; Garatani *et al.*, 2000) with the accuracy of pseudospectral techniques (e.g., Tessmer *et al.*, 1992; Carcione and Wang, 1993; Igel, 1999). It is more accurate than widely used classical techniques such as the finite-difference method (e.g., Boore, 1972; Virieux, 1986; Graves, 1996; Olsen *et al.*, 1997), in particular for surface waves (e.g., Komatitsch and Tromp, 1999, 2002a), which play an important role in ground-motion seismology.

In the SEM, it is relatively straightforward to densify the mesh near the surface of the model in the low wave-speed sediments, using mesh doubling as a function of depth, as illustrated in Figure 4, assuming that the surfaces do not exhibit large local variations (i.e., that they are smooth enough). Using a coarser mesh in depth significantly reduces the memory requirements and facilitates an increase in the value of the time step, thus enabling larger simulations for a similar computational cost. Due to the geometrical flexibility that the SEM shares with the finite-element method, the mesh can be adapted to topography and bathymetry as well as the shape of the basement surface and the Moho (Fig. 4). Even in the presence of substantial topography, the traction-free boundary condition at the Earth's free surface is satisfied automatically in a SEM (e.g., Komatitsch and Vilotte, 1998; Komatitsch and Tromp, 1999, 2002a).

The choice of high-degree Lagrange polynomial interpolants combined with Gauss–Lobatto–Legendre quadrature results in minimal numerical grid dispersion. Because of this particular choice of integration points and numerical integration rule, the SEM's most important property is an exactly diagonal mass matrix, which leads to a simple explicit time integration scheme without needing to solve a system of linear equations (e.g., Komatitsch and Vilotte, 1998; Komatitsch and Tromp, 1999, 2002a). Because of the fact that the mass matrix is exactly diagonal, another property of the SEM is that it is very well adapted to the parallel distributed memory architecture of modern computers (Komatitsch and Tromp, 2001; Komatitsch *et al.*, 2003), an advantage it shares with the finite-difference method. This implies that the SEM is simpler to implement than traditional finite-element methods.

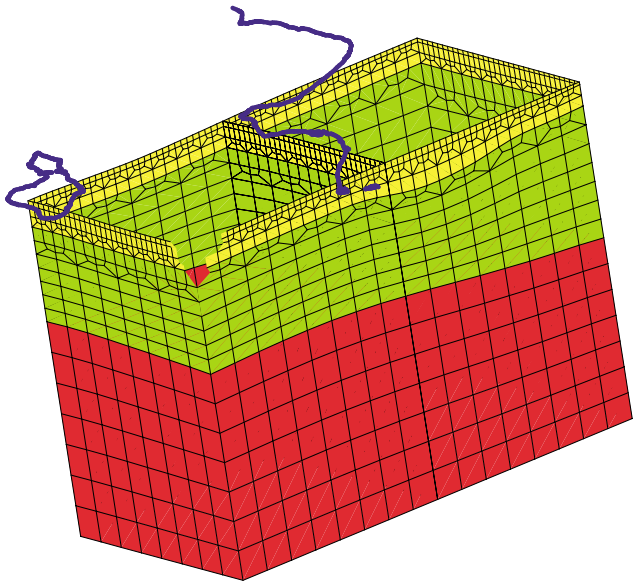

Figure 4. North–south cross section through the mesh of the Los Angeles basin region. For clarity, only the vertical edges of the mesh slices are represented. The blue line shows the Mexican border, the coastline, Palos Verdes, and Santa Catalina Island. The mesh is adapted to the deepest part of the basement surface and to the shape of the Moho taken from Zhu and Kanamori (2000). It is doubled in size twice: first below the low wave-speed surface layer and a second time below the basement. Red represents elements located below the Moho, green elements between the Moho and the bottom of the sedimentary pocket, and yellow elements in the upper part of the model honoring the shape of the surface and the bottom of the sedimentary pocket. Note that for geometrical reasons, we only honor the bottom part of the deep sedimentary pocket (from a depth of 4 km to a maximum of 8.5 km), otherwise we would be unable to mesh the entire structure in regions with very thin (or without) sediments.

In this article, we incorporate 3D variations in *P*- and *S*-wave speeds, density, and attenuation. The mesh covers 516 km × 507 km, from 120.3° W to 114.7° W and from 32.2° N to 36.8° N, incorporates most of the roughly 140 broadband seismographic stations in the TriNet network (www.trinet.org) in southern California, and extends to a depth of 60 km. It is important to honor the major discontinuities in the wave-speed model when creating a mesh of the structure, to avoid numerical diffraction by a staircase discretization of the complex-shaped interfaces (e.g., Zahradník *et al.*, 1993). Therefore, the basin mesh honors the shape of the Moho (Zhu and Kanamori, 2000), the lower part of the sedimentary basin underneath Los Angeles (Süss and Shaw, 2003), as well as topography and bathymetry (USGS, 2003), as illustrated in Figure 4.

In the TriNet network, there are several seismographic stations on the offshore Channel Islands; for this reason the effect of the oceanic water layer is incorporated in the modeling based upon an equivalent load formulation that takes into account the weight of the water column (Komatitsch and Tromp, 2002b). This is a long-period approximation that is valid as long as the wavelength of the seismic signals is large compared to the depth of the oceans. The main limitations of such an approximation are discussed in Komatitsch and Tromp (2002b). In the case of the Los Angeles region, we perform simulations at minimum periods of 2 sec, that is, the wavelength in the oceans is $2 \times 1500 = 3000$ m, which means that the approximation is valid for shallow oceans, typically with a maximum depth of 500–600 m. Fortunately, this is the case in most parts of the model, as illustrated in Figure 3. Paraxial absorbing conditions (Clayton and Engquist, 1977) are used on the vertical edges and the bottom of the grid to simulate a semi-infinite regional medium. More accurate absorbing boundary conditions, such as the perfectly matched layer (e.g., Bérenger, 1994; Chew and Liu, 1996; Collino and Tsogka, 2001; Komatitsch and Tromp, 2003), could be used instead, but, because we use a large mesh, the simpler paraxial conditions are sufficient.

The method is implemented on a PC cluster computer, a so-called Beowulf machine, using parallel programming based upon a message-passing technique, making use of the message-passing interface (Gropp *et al.*, 1996). To take advantage of the parallel machine architecture, the mesh is divided into 144 slices that are distributed over 144 processors using a regular mesh partitioning topology. The mesh contains 672,768 spectral elements. We use a polynomial degree $N = 4$ to sample the wave field; therefore each spectral element contains $(N + 1)^3 = 125$ Gauss–Lobatto–Legendre points. Counting points on common spectral-element edges and corners only once, the mesh therefore contains a total of 45.4 million grid points (i.e., 136 million degrees of freedom, because we solve for the three components of displacement at each grid point). The average distance between grid points at the surface is roughly 335 m. One needs to use roughly five points per wavelength to correctly sample the wave field in the SEM (e.g., Seriani and Priolo, 1994); therefore the mesh resolves waves with a shortest period of about 2 sec. The calculations require 14 Gb of distributed memory. On our cluster it takes about 6.5 hr to compute seismograms with a duration of 3 min. We use a timestep of 9 msec, that is, a total of 20,000 timesteps.

Validation for a One-Dimensional Model

In previous work, we carefully benchmarked the SEM against semianalytical solutions for reference Earth models with and without attenuation (Komatitsch and Vilotte, 1998; Komatitsch and Tromp, 1999; Komatitsch *et al.*, 1999; Komatitsch and Tromp, 2002a) and showed its accuracy for modeling seismic-wave propagation. To demonstrate that the nonstructured mesh represented in Figure 4 is efficient for basin models, we study a simple structure consisting of an anelastic layer over a half-space. We use the model shown in Figure 5, which is known as the SCEC/PEER (Pacific

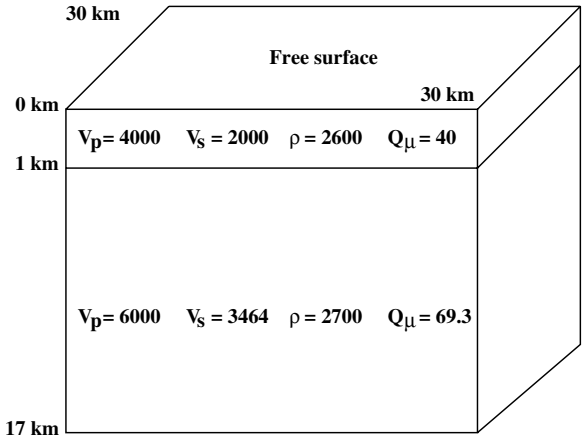

Figure 5. 1D structure used to assess the accuracy of the SEM for an average basin model. The 3D model consists of a layer over a half-space. The horizontal size of the block is 30 km × 30 km, and it extends to a depth of 17 km. This reference model is known as the SCEC/PEER LOH-3 benchmark.

Earthquake Engineering Research Center) LOH-3 benchmark (peer.berkeley.edu). The block has a horizontal size of 30 km × 30 km and extends to a depth of 17 km. Absorbing conditions are used on all sides of the model except the free surface, in order to simulate a semi-infinite medium. Material properties in the half-space are $V_p = 6000$ m s^{-1}, $V_s = 3464$ m s^{-1}, $\rho = 2700$ kg m^{-3}, and a shear quality factor $Q_\mu = 69.3$ for attenuation. In the layer, $V_p = 4000$ m s^{-1}, $V_s = 2000$ m s^{-1}, $\rho = 2600$ kg m^{-3}, and $Q_\mu = 40$. The shear quality factor does not depend on frequency (i.e., the attenuation spectrum is flat). The bulk quality factor Q_κ is infinite in both regions. Wave speeds V_p and V_s are for a reference frequency of 2.5 Hz. The source is a point dislocation located in the half-space below the layer in the middle of the grid, at a depth of 2 km. The only nonzero component of the moment tensor is $M_{xy} = 10^{18}$ N m. The moment-rate time variation of the source is $(t/T^2)\exp(-t/T)$, where $T = 0.05$ sec. The timestep is $\Delta t = 3.25$ msec, and we propagate the signal for 10 sec. A receiver is placed at $x = 6$ km and $y = 8$ km, at a horizontal distance of 10 km from the source, and records the three components of velocity. In Figure 6, we show the results and compare them to a frequency–wavenumber reference solution computed based on a modified version of Apsel and Luco (1983). The two results are almost perfectly superimposed, which allows us to conclude that the method is very accurate for such an average 1D basin model.

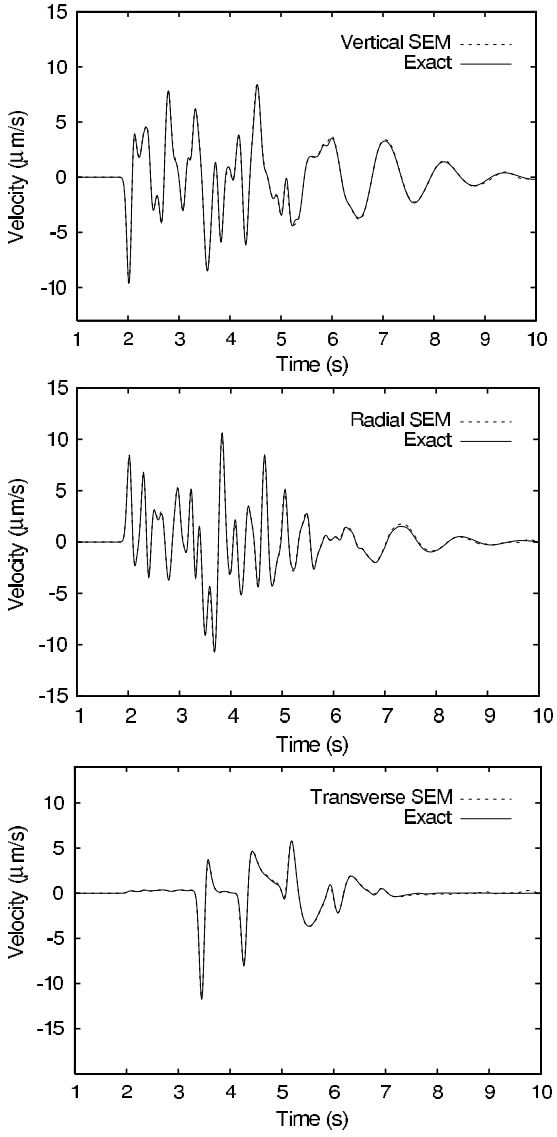

Figure 6. Traces recorded at the surface for the average 1D basin model shown in Figure 5. The source is a point dislocation located in the half-space below the sedimentary layer in the middle of the block at a depth of 2 km. The receiver is located at a horizontal distance of 10 km from the source. The vertical (top), radial (middle), and transverse (bottom) components of velocity computed using the SEM (dashed line) are compared to the solution computed based upon a modified frequency–wavenumber method (Apsel and Luco [1983], solid line). The two curves are almost perfectly superimposed, which illustrates the accuracy of the SEM, including for surface waves.

Simulations of the 9 September 2001 M_W 4.2 Hollywood Earthquake

To assess the quality of the 3D basin model and the 3D SEM simulations, we simulated ground motion for the 9 September 2001 M_w 4.2 Hollywood earthquake. This event was located right inside the basin at a depth of approximately 4.5 km and was well recorded by TriNet; it therefore provides an excellent test of the 3D basin model and the numerical method. Complications associated with source complexity and directivity for larger events (e.g., Wald *et al.*, 1996; Ji *et al.,* 2002) are avoided. To obtain the source mechanism for this event, we performed a 3D centroid moment

tensor (CMT) inversion based upon the basin model and the SEM. We calculated the required 3D Fréchet derivatives numerically (Liu *et al.*, 2002) by minimizing the waveform misfit between data and synthetic seismograms to obtain the best estimated source parameters. The solution is in excellent agreement with first-motion and surface-wave estimates.

Figure 7 shows snapshots of the simulation. The vertical component of velocity at the surface is represented. If the basin model were 1D, one would see concentric circles centered on the epicenter. The highly distorted wave fronts are due to substantial 3D variations in the model. Note that energy gets trapped in the Los Angeles and San Fernando basins due to the low wave-speed sediments. This is particularly clear between 63.8 and 85.4 sec, where ground motion lasts much longer in the basin than in the surrounding mountains and in the Palos Verdes peninsula.

In Figure 8 we compare the results of 3D SEM simulations to three-component displacement data recorded by TriNet stations. Both data and synthetic seismograms are bandpass filtered between 6 and 35 sec with a four-pole two-pass Butterworth filter. We focus our attention on the Los Angeles region, where the detailed Harvard basin model is defined and in which the event took place. Notice that at these periods we can fit the data very well on all three components. The model captures the amplifications and resonance associated with the Los Angeles basin, for example, transverse components at LAF, STS, LGB, and PDR and radial components are PDR, WTT, and LLS. Notice that stations in the San Gabriel mountains (e.g., CHF, BFS, TA2, and MWC) have relatively small displacements on all three components that are well fit by the synthetic seismograms. The good fit to the data demonstrates that the SEM wavefront distortions in Figure 7 capture actual facets of the data. Because the model is a *P*-wave speed model and the largest signals in the seismograms are surface waves predominantly sensitive to *S*-wave speed, we allow for a small station correction in our SEM simulations. This stems from the fact that the *S*-wave speed (V_s) model is based upon a simple scaling relation to *P*-wave speed (V_p). Currently, for simplicity, rather than trying to determine an optimal scaling relation or an independent *S*-wave speed model, we choose to use such a simple scaling, but allow for deficiencies in the V_s model by introducing a station correction. To find the station correction, we calculate the cross correlation between the data and the synthetic seismograms and use this to determine the phase shift between the data and synthetic seismograms as well as the associated amplitude anomaly. In Figure 9 we plot the value of the cross correlation, the time shift, and the associated amplitude anomaly. Note that the corrections are generally small, typically less than plus or minus 2 sec for stations within 200 km of the epicenter. This can only be a temporary solution, and future work will have to focus on building an independent V_s model. We plan to use these station corrections to invert for an improved V_s model, and once this new model is defined, we will no longer use these station corrections.

Figure 10 illustrates that even at periods between 2 and 35 sec, we can fit the data reasonably well on all three components. Figure 11 shows peak ground displacement, velocity, and acceleration. Notice the amplifications in ground velocity and acceleration in the San Fernando Valley toward the north, in particular near its eastern edge. A hard-rock site, such as Palos Verdes along the coast, shows no significant amplification. The same is true in the mountains, most of the energy being trapped in the two basins. Maps such as these can be used to construct synthetic ShakeMaps that would complement the empirically derived ShakeMaps depicting the intensity of ground motion produced automatically by the USGS (www.trinet.org/shake).

Simulations of the 3 September 2002 M_W 4.2 Yorba Linda Earthquake

Next, we simulate ground motion for a second event, the 3 September 2003 M_w 4.2 Yorba Linda earthquake, which occurred at a depth of 7 km. Again we performed a 3D CMT inversion for this event, which is in excellent agreement with first-motion and long-period surface-wave mechanisms. Figure 12 illustrates that for this event we can also fit the data very well at periods between 6 and 35 sec. We show the transverse component of displacement for stations in the Los Angeles area. To illustrate the magnitude of the basin resonance, in Figure 13 we show the same transverse component displacement data compared to SEM synthetic seismograms for the 1D southern California background regional model of Dreger and Helmberger (1990). Note that at basin sites, such as LAF and BRE, the observed amplitudes can be 20 times larger than the 1D predictions, even at long periods. Of course one could attempt to determine the best 1D model for each event–station pair, but this figure illustrates that such models are meaningless because of very large local variations in their response pattern. For example, stations BRE, STS, and RPV trend along the same direction, and yet they have entirely different responses. Note from Figure 12 that the 3D model captures all three stations very nicely. We note that the 1D model of Dreger and Helmberger (1990) was developed to fit regional long-period waveforms, not basin sites.

Figure 14 shows peak ground displacement, velocity, and acceleration for this event. Note that, as for the Hollywood event of Figure 11, the peak ground velocity and acceleration maps are similar in character but that the peak ground displacement map is smoother in nature.

Discussion

Our analyses of the Hollywood and Yorba Linda earthquakes demonstrate that it is feasible to fit three-component seismic data accurately down to a period of 2 sec inside the basin model and 6 sec in the regional model, thereby validating the basin model of Süss and Shaw (2003) and the SEM. Signals with a very wide dynamic range are well cap-

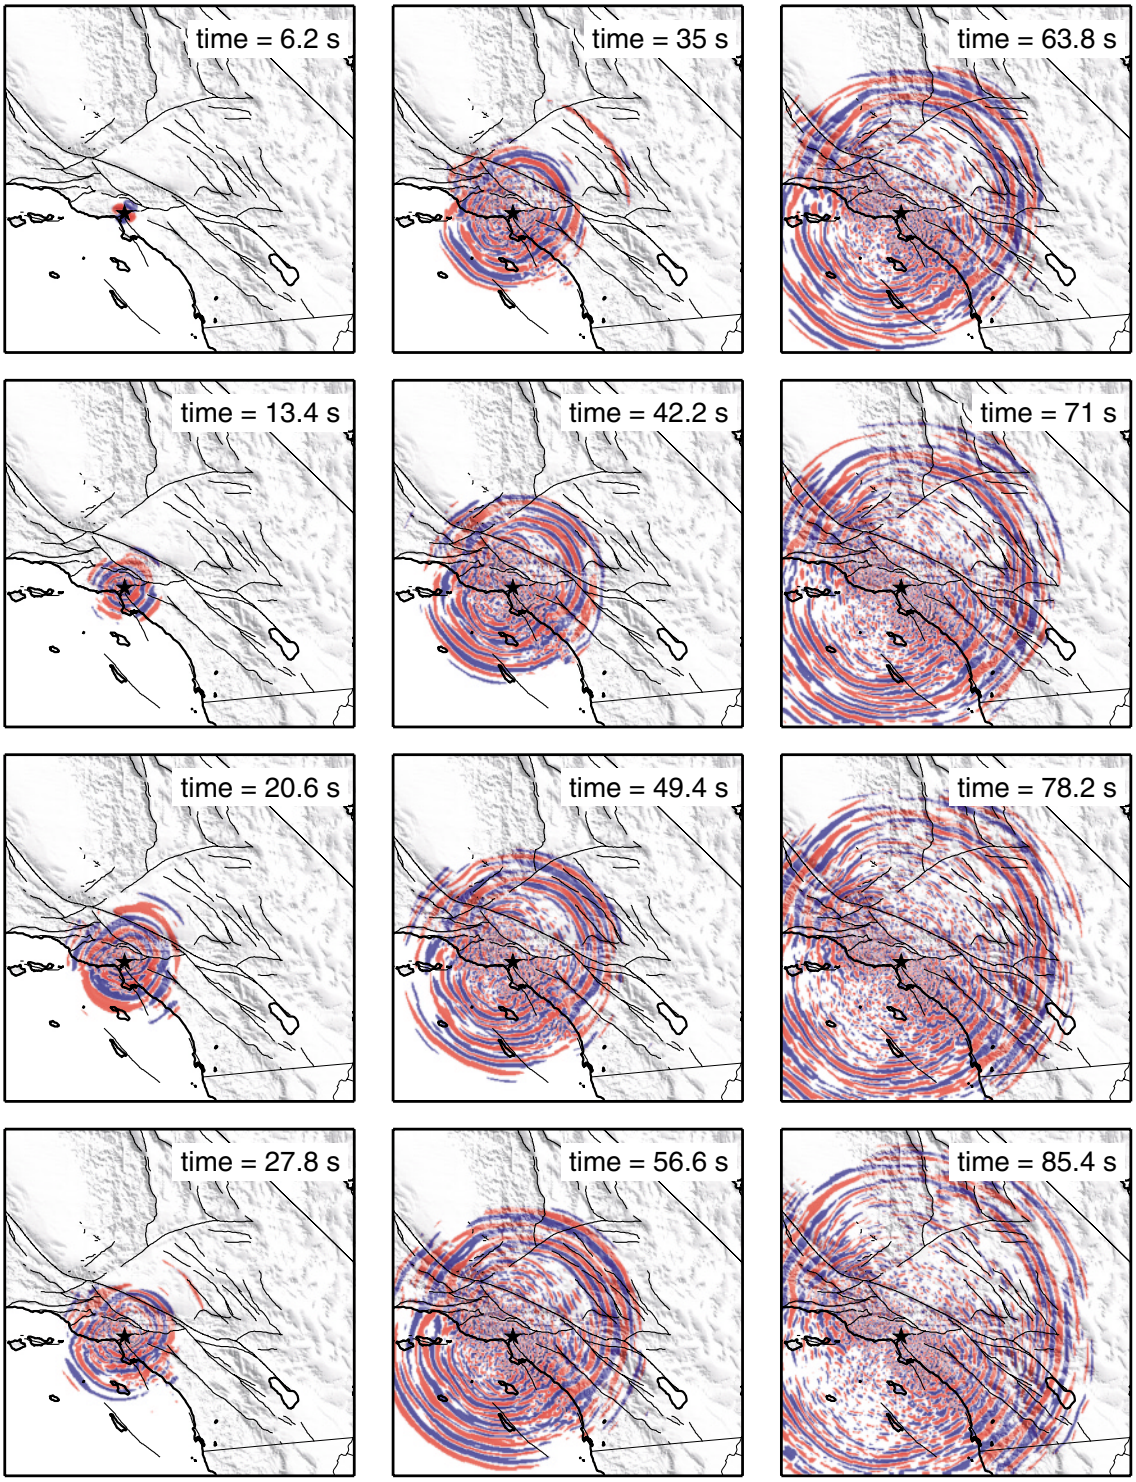

Figure 7. Snapshots of the wave field simulated for the 9 September 2001 M_w 4.2 Hollywood earthquake. The vertical component of velocity is displayed, with red colors denoting positive values and blue negative values. In a 1D model the wave field would consist of concentric circles centered on the epicenter. The wavefront distortions are due to the presence of low wave-speed sediments in the Los Angeles and San Fernando sedimentary basins. Note in particular how ground motion lasts much longer in and around the basin, where energy is trapped because of the presence of sediments. This is particularly clear between 63.8 and 85.4 sec, where ground motion lasts much longer in the basin than in the surrounding mountains and in the Palos Verdes peninsula.

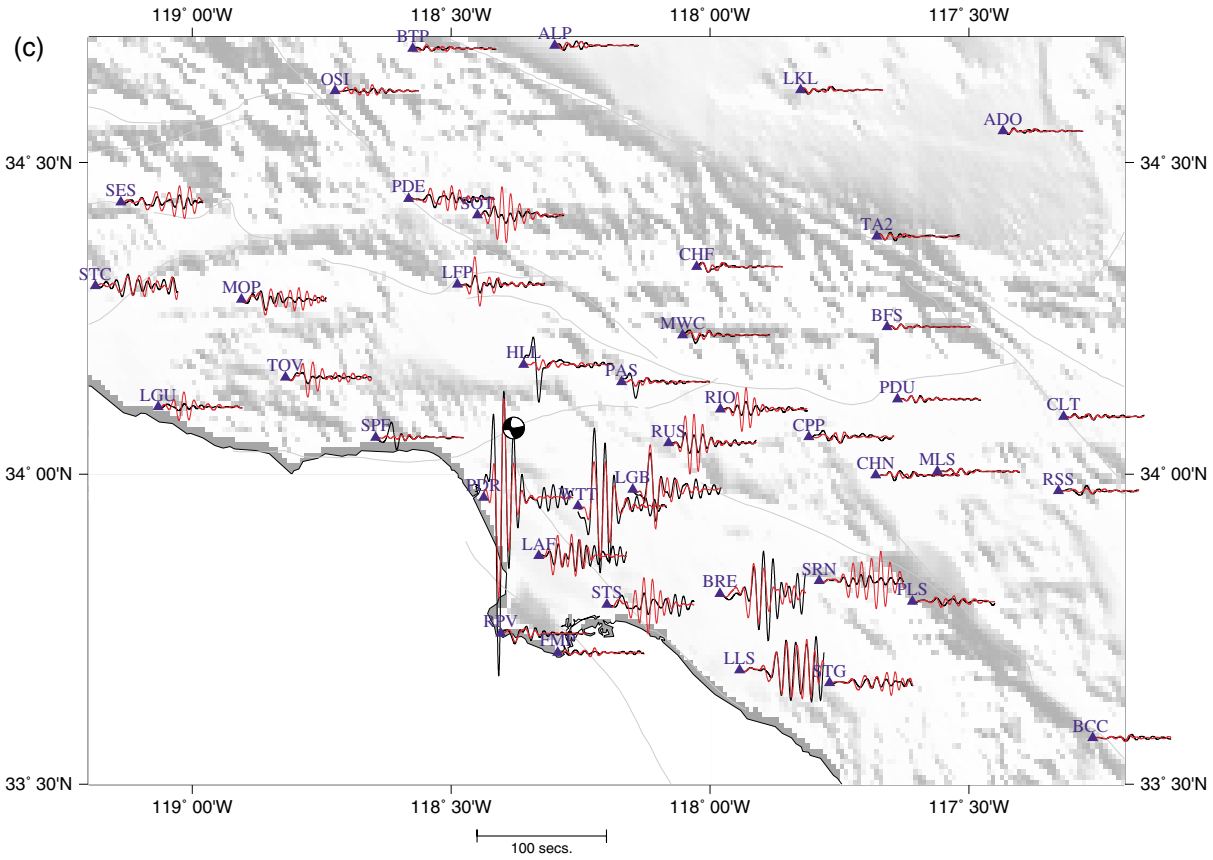

Figure 8. Data (black) and 3D SEM synthetic seismograms (red) for the 9 September, 2001, Hollywood event are plotted on a map of the Los Angeles area. The mechanism and location of the event are indicated by the black-and-white beach ball. The timescale is indicated by the scale bar at the bottom. (a) Vertical component, (b) transverse component, and (c) radial component. Stations are denoted by blue triangles and labeled by their station codes. The instrument response was deconvolved from the data to obtain ground displacement. Both the data and the synthetic seismograms were subsequently bandpass filtered between 6 and 35 sec with a four-pole two-pass Butterworth filter.

tured by the model, and, in particular, stations within the Los Angeles and San Fernado basins are fit well on all three components. The full complexity of the 3D model is included in the simulations, that is, the effect of constant attenuation, topography/bathymetry, and the oceans. Topography and attenuation in particular have a significant effect on wave propagation, as illustrated in Figure 15.

There are, however, some limitations to the model. Figure 16 illustrates that in the Salton Sea area, for instance at stations SAL, ERR, and WES, and at shorter periods in the Mojave Desert, for instance, at station ADO, there is substantial low wave-speed sediment cover that is not included in our model. This causes resonance in the data that is not correctly reproduced. As can be seen in Figure 1, this region is not covered by our basin model, but rather by the regional model of Hauksson (2000). These deficiencies in the background model can be addressed by incorporating low wave-speed layers in selected areas and by expanding our high-resolution model to encompass these problematic areas.

Another issue is the fact that the geotechnical layer, that is, the first tens of meters of sediments, which are highly heterogeneous and often significantly modify ground motion and local amplification (e.g., Anderson *et al.*, 1996), is currently not included in our basin model. This layer will be incorporated in a future version of the model. However, it will be difficult to take into account in our numerical simulations, due to the very low *S*-wave speeds that are involved, which require a very fine grid. Using our current mesh, we are limited to minimum *S*-wave speeds of about 670 m s^{-1}. (Our simulations are designed to be accurate down to a period of 2 sec, the grid spacing at the surface is 335 m, and in the SEM one needs to sample the wave field using approximately five points per minimum wavelength, as mentioned previously.)

An additional difficulty in basin simulations is the lack of detailed knowledge of attenuation. We have used a constant shear quality factor $Q_\mu = 90$ in the sediments, no bulk Q, and no attenuation in the bedrock; this model is, of

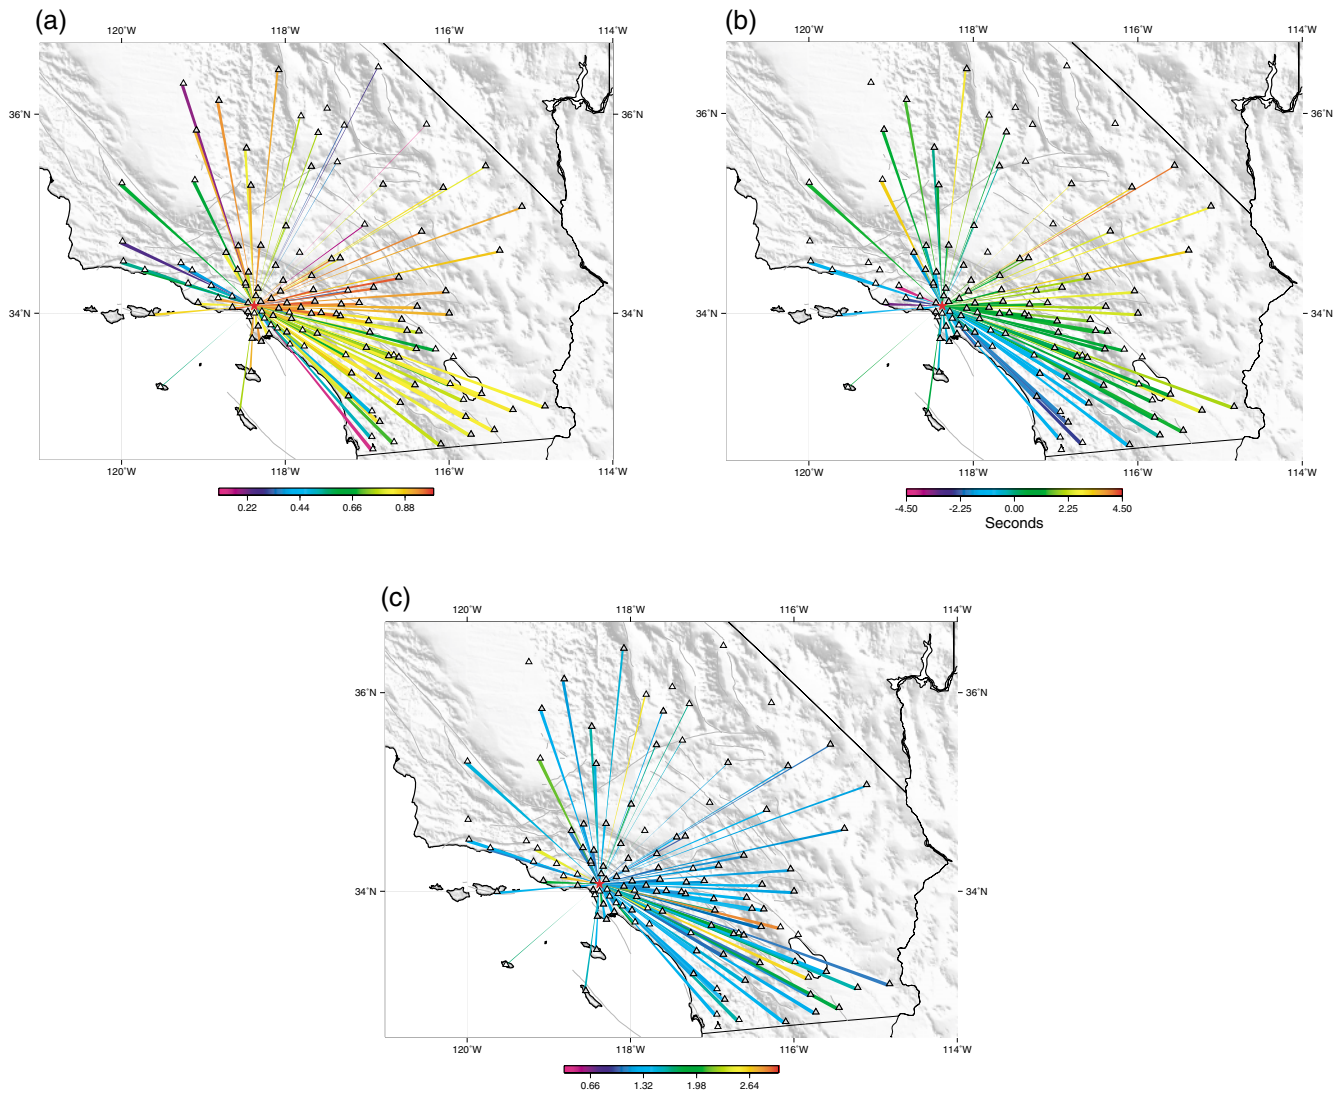

Figure 9. We use cross correlation to determine the time shift between the data and the SEM synthetic seismograms. We show the results for the transverse component of displacement for the Hollywood event bandpass filtered between 6 and 35 sec with a four-pole two-pass Butterworth filter. (a) Correlation between the data and synthetic seismograms. Color-coded lines between event–station pairs indicate the correlation coefficients, with red denoting the highest correlations and blue lower correlations. The stations selected for this figure have a correlation coefficient of 0.1 or larger. (b) Time shifts are plotted as color-coded lines between event–station pairs and are typically between $+2$ and -2 sec. A positive (red) anomaly indicates that the synthetic seismograms are faster than the data, whereas negative (blue) values indicate that the synthetic seismograms arrive slower than the data. The stations selected for this figure have a time shift smaller than 4.5 sec and a correlation coefficient greater than 0.4. (c) Amplitude anomalies between the data and 3D SEM synthetic seismograms. Color-coded lines between event–station pairs indicate the amplitude ratio between data and synthetic seismograms. An amplitude ratio greater than 1 (red) indicates the SEM amplitude is larger than the data, whereas a ratio smaller than 1 (blue) denotes SEM amplitudes smaller than the data. These amplitude anomalies are due to effects related to focusing and defocusing, attenuation, and the source. The stations selected for this figure have an amplitude ratio smaller than 3.0 sec and a correlation coefficient greater than 0.3.

course, not realistic. However, it is difficult to improve, because very few available data sets constrain attenuation. Olsen *et al.* (2003) recently started to address this issue based upon 3D finite-difference numerical simulations for the SCEC-II Los Angeles basin model (Magistrale *et al.*, 2000).

With present-day computer hardware, it is technically feasible to simulate ground motion for a given wave-speed model at much higher frequencies (at least 2 Hz or more). As is often the case in regional or local seismology (e.g., Graves, 1999), we are presently limited by our knowledge

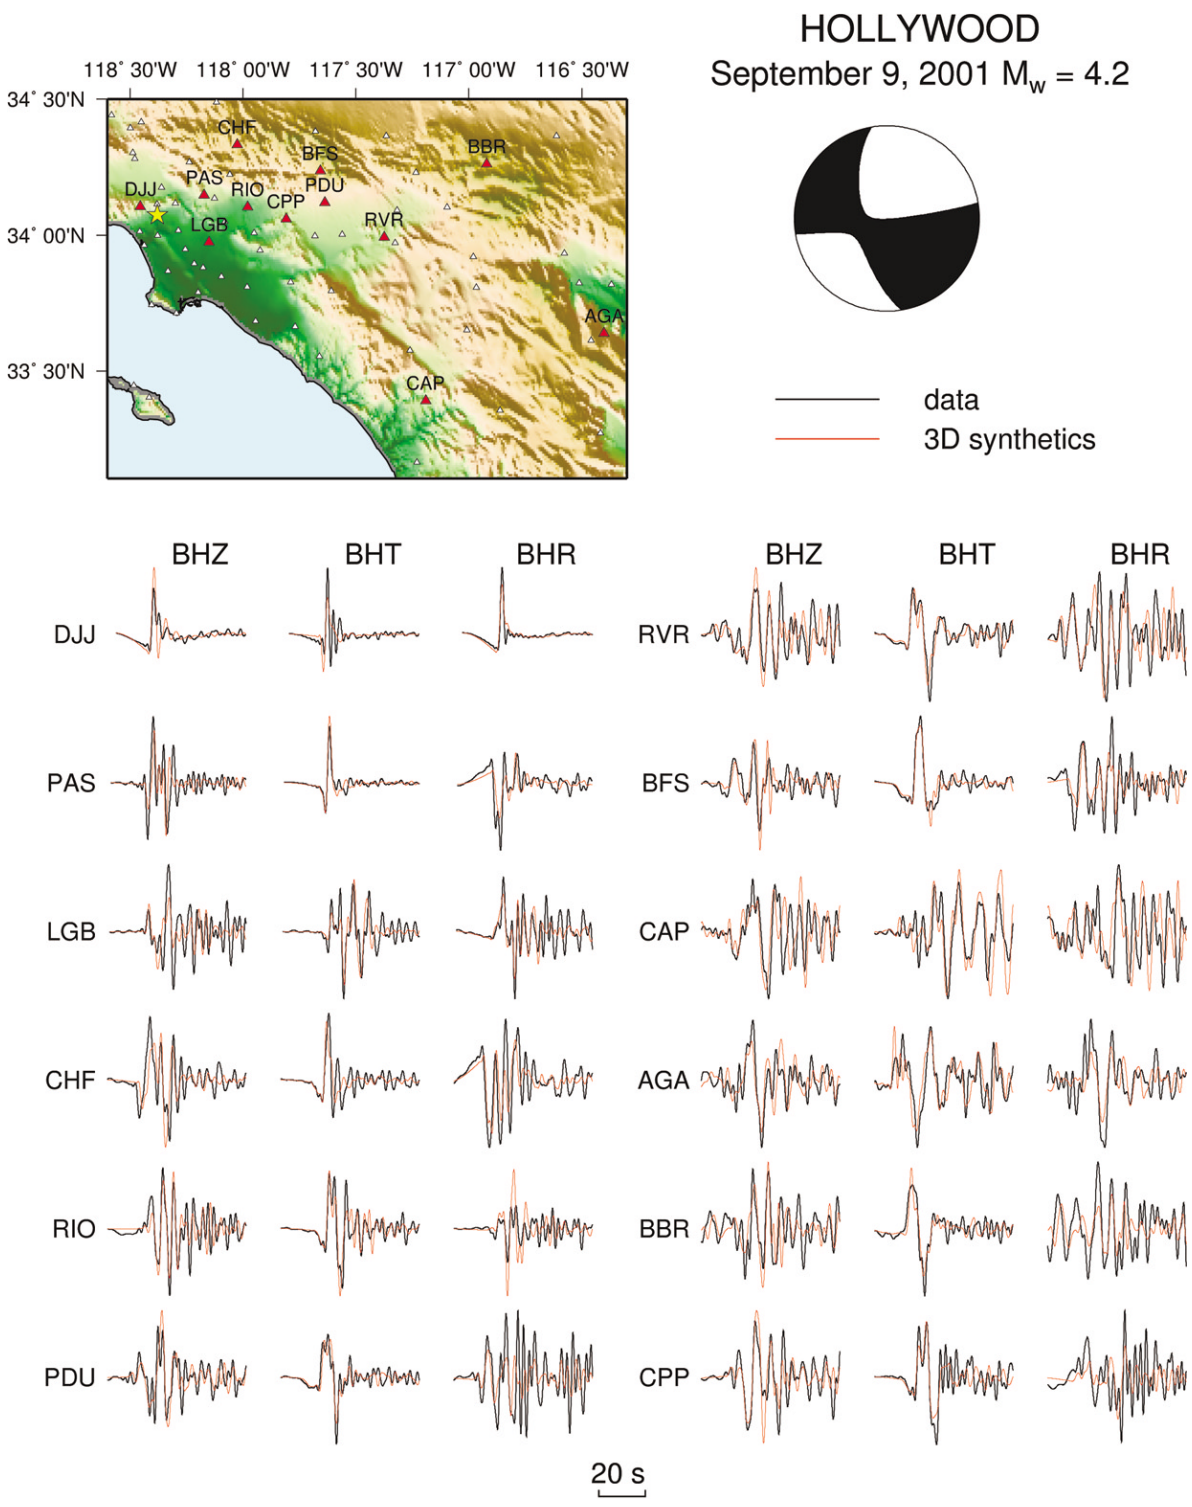

Figure 10. (Top left) Map showing the epicenter (yellow star) and stations (red triangles with black labels) for which data and synthetic seismograms bandpass filtered between 2 and 35 sec with a four-pole two-pass Butterworth filter are plotted in the bottom panel. The source mechanism of the 9 September 2001 M_w 4.2 Hollywood earthquake is shown in the top right. Vertical (left columns), transverse (middle columns), and radial (right columns) components of displacement at 12 stations are shown in the bottom panel. SEM results are in red and data in black. The timescale is indicated by the scale bar at the bottom. Amplitudes are normalized independently at each station. We selected 12 among the stations where the best fit is obtained. Fit is determined by calculating the cross correlation and the amplitude difference between data and synthetic seismograms.

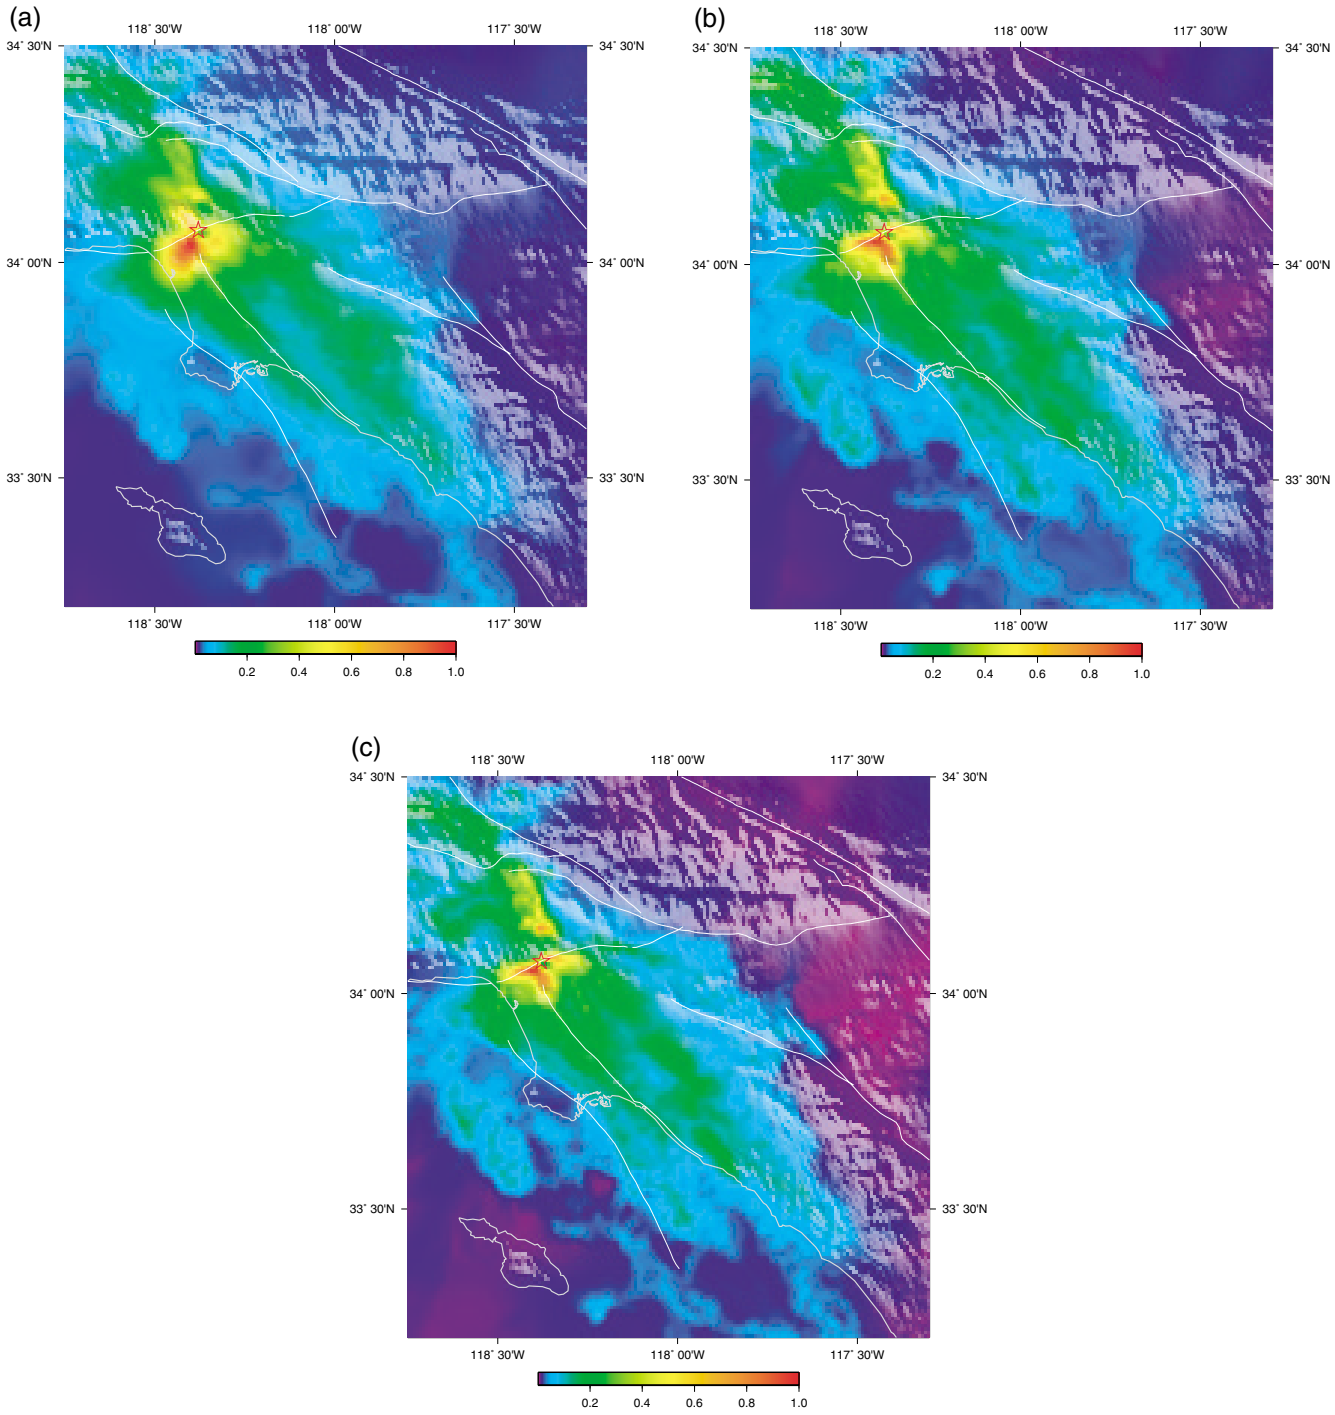

Figure 11. Peak ground displacement (a), velocity (b), and acceleration (c) for the Hollywood earthquake. Shown is a close-up on the Los Angeles basin. A value of 1 on the color scale corresponds to maxima of 0.80 mm, 0.92 mm s^{-1} and 2.15 mm s^{-2} for the norm of displacement, velocity, and acceleration at the surface, respectively. One can notice that amplification occurs in the basin, where most of the energy is trapped, while hard-rock sites such as Palos Verdes, or the mountains surrounding the Los Angeles and San Fernando basins, show little acceleration. Significant amplification occurs in the San Fernando valley, north of the epicenter, in particular near its eastern edge. Note that the peak ground velocity and acceleration maps are similar in character, while the peak ground displacement map is smoother in nature.

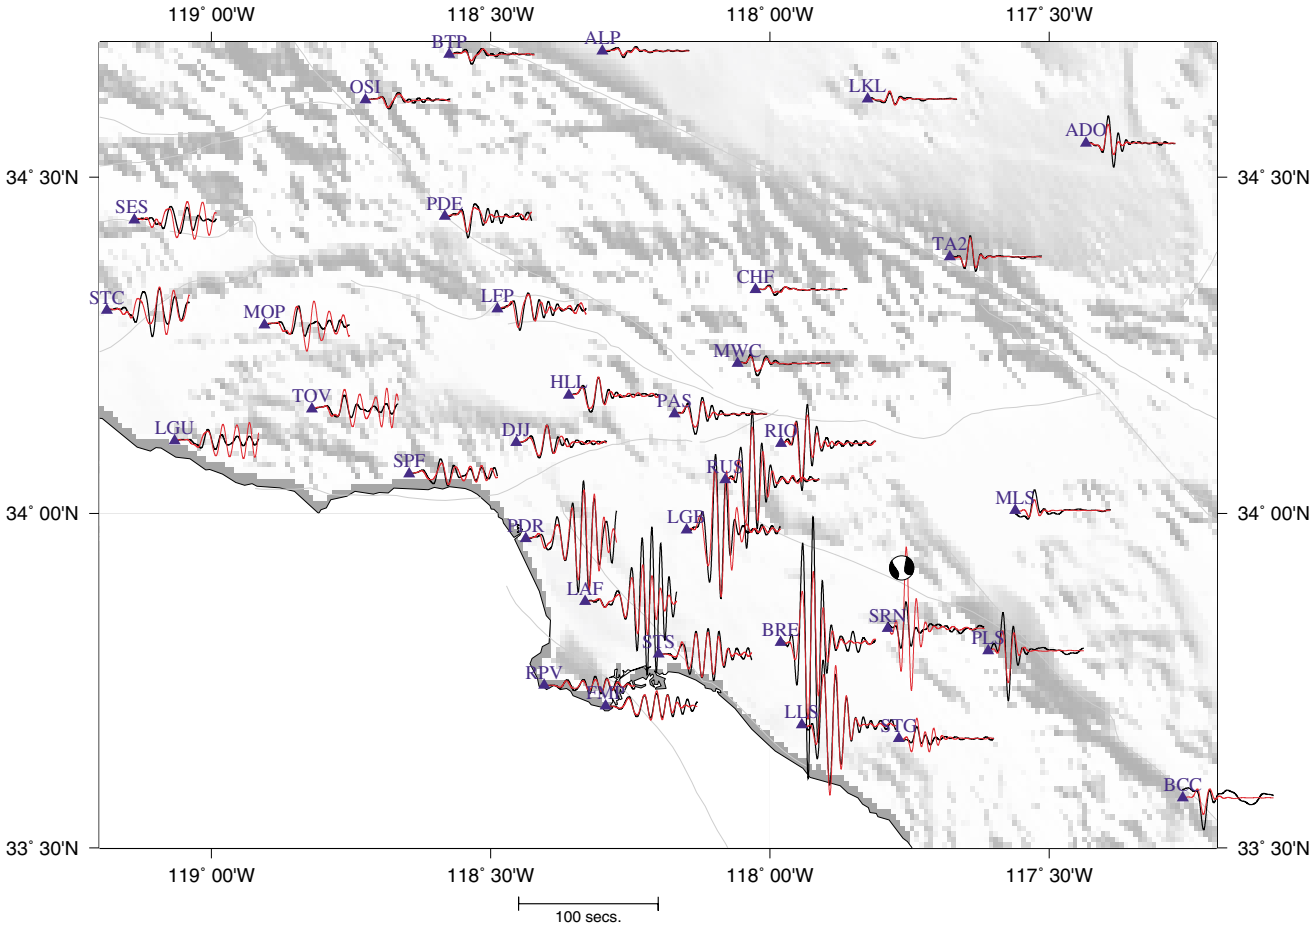

Figure 12. Transverse component data (black) and 3D SEM synthetic seismograms (red) for the 3 September 2002 Yorba Linda event are plotted on a map of the Los Angeles area. Stations are denoted by blue triangles and labeled by their station codes. The instrument response was deconvolved from the data to obtain ground displacement. Both the data and the synthetic seismograms were subsequently bandpass filtered between 6 and 35 sec with a four-pole two-pass Butterworth filter. The mechanism and location of the event are indicated by the black-and-white beach ball. The timescale is indicated by the scale bar at the bottom.

of the 3D model, not by the accuracy or the cost of the calculations. Our current basin model is largely based upon *P*-wave speed information. Ground motions in the basin are to a large extent determined by *S*-wave speeds, which we estimate based upon a simple scaling relationship. Therefore, the basin model could be improved by adding constraints on the *S*-wave speed and density structure, for instance based upon borehole data (Stidham *et al.*, 2001), as well as more precise *P*-wave speed constraints in subregions of the model. In a related effort, we are planning to use surface-wave phase delays, such as those shown in Figure 9, as the starting point for an inversion for an improved *S*-wave model.

Because we are trying to fit signals in both amplitude and phase, it is crucial that instruments are properly calibrated, in particular in terms of timing, and that their orientation is precisely known. Otherwise, the inversion of amplitude anomalies could be compromised by uncertainties related to station parameters.

Conclusions and Perspectives

We have demonstrated that ground motion in the Los Angeles basin can be modeled accurately based upon a recently developed basin model and a very precise numerical technique. The basin model is constrained by hundreds of petroleum-industry well logs and more than 20,000 km of seismic reflection profiles. The numerical simulations are based upon the SEM, which accounts for 3D variations of seismic-wave speeds and density, topography and bathymetry, and attenuation. They demonstrate that it is feasible to predict ground motion at periods longer than 2 sec using realistically complex models, thus improving our ability to assess seismic hazard. Peak ground displacement, velocity, and acceleration maps clearly illustrate that large amplification occurs within the basin.

Making use of the basin model in combination with the SEM allows one to invert for earthquake source parameters

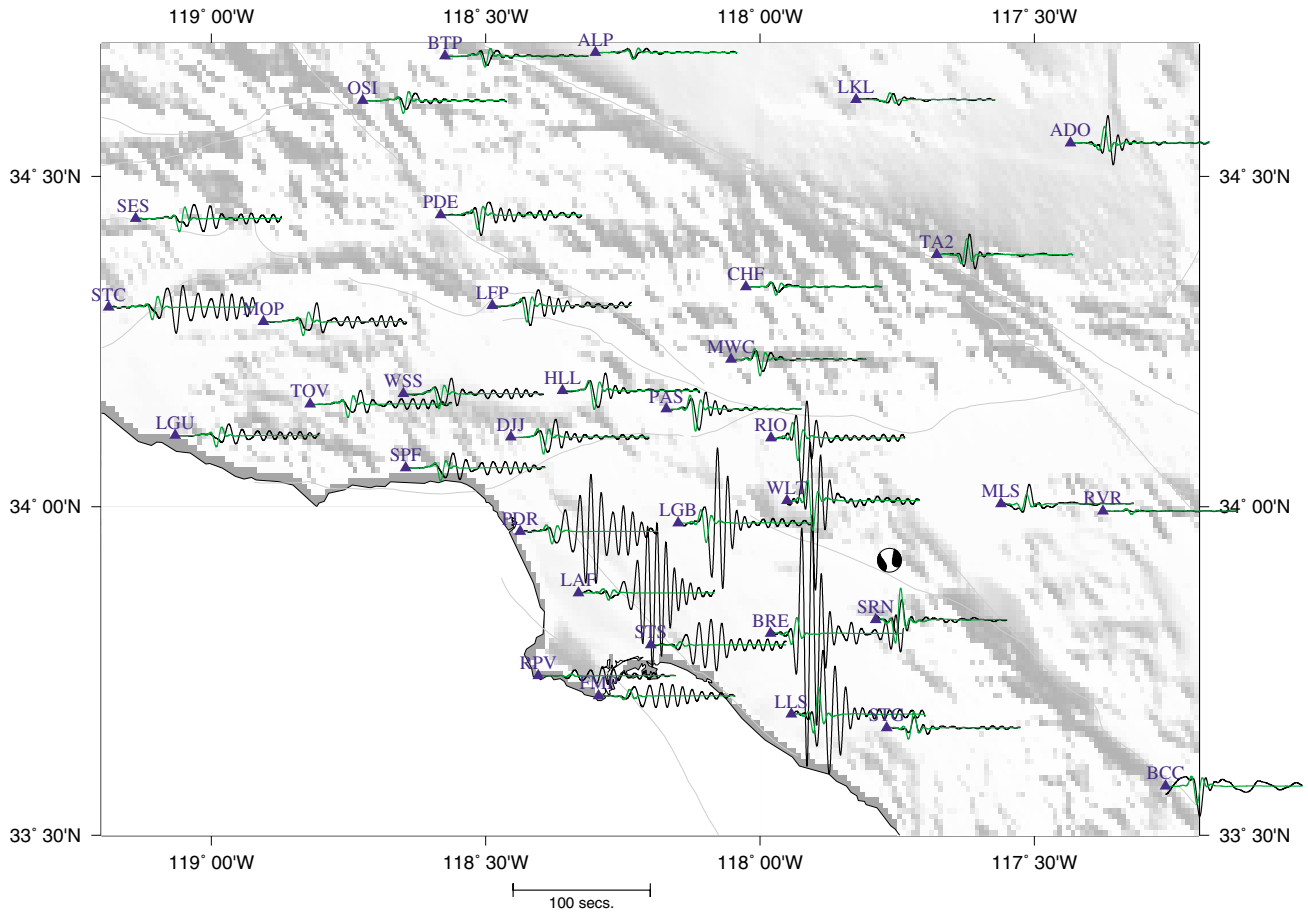

Figure 13. Transverse component data (black) and 1D SEM synthetic seismograms (green) for the 3 September 2002 Yorba Linda event are plotted on a map of the Los Angeles area. The background regional 1D model is that of Dreger and Helmberger (1990). Stations are denoted by blue triangles and labeled by their station codes. The instrument response was deconvolved from the data to obtain ground displacement. Both the data and the synthetic seismograms were subsequently bandpass filtered between 6 and 35 sec with a four-pole two-pass Butterworth filter. The mechanism and location of the event are indicated by the black-and-white beach ball. The timescale is indicated by the scale bar at the bottom. Attenuation was not included in this 1D calculation.

by numerically calculating the necessary Fréchet derivatives (Liu *et al.*, 2002) and obtaining the estimated source parameters by minimizing the waveform misfit between the data and synthetic seismograms. Since a CMT inversion involves of order 10 model parameters, the required simulations can be done easily from a computational perspective. Our intent is to start performing CMT inversions routinely for all well-recorded future and past events above a certain magnitude threshold. The resulting catalog of regional 3D CMT solutions should be very useful to the community and would complement existing catalogs based upon first-motion studies and long-period surface waves.

An important future goal is to assess seismic risk for hypothetical large events by performing parametric studies for a number of earthquake scenarios. In this article, we have used two small events to validate the basin model and the numerical technique, while avoiding difficulties related to finite-size sources and rupture velocity models for larger events. However, the SEM is not limited to point sources: a finite-size source can be used by summing individual contributions from points located along the fault plane. This approach can be used to calculate synthetic peak ground displacement, velocity, and acceleration maps, such as those in Figures 11 and 14, to assess seismic hazards associated with such large events.

Acknowledgments

The authors would like to thank Egill Hauksson and Jascha Polet for first-motion and surface-wave centroid moment tensor estimates, Hiroo Kanamori for fruitful discussion, Steven M. Day for the analytical solution of the SCEC LOH.3 benchmark, and TriNet for access to the data. They

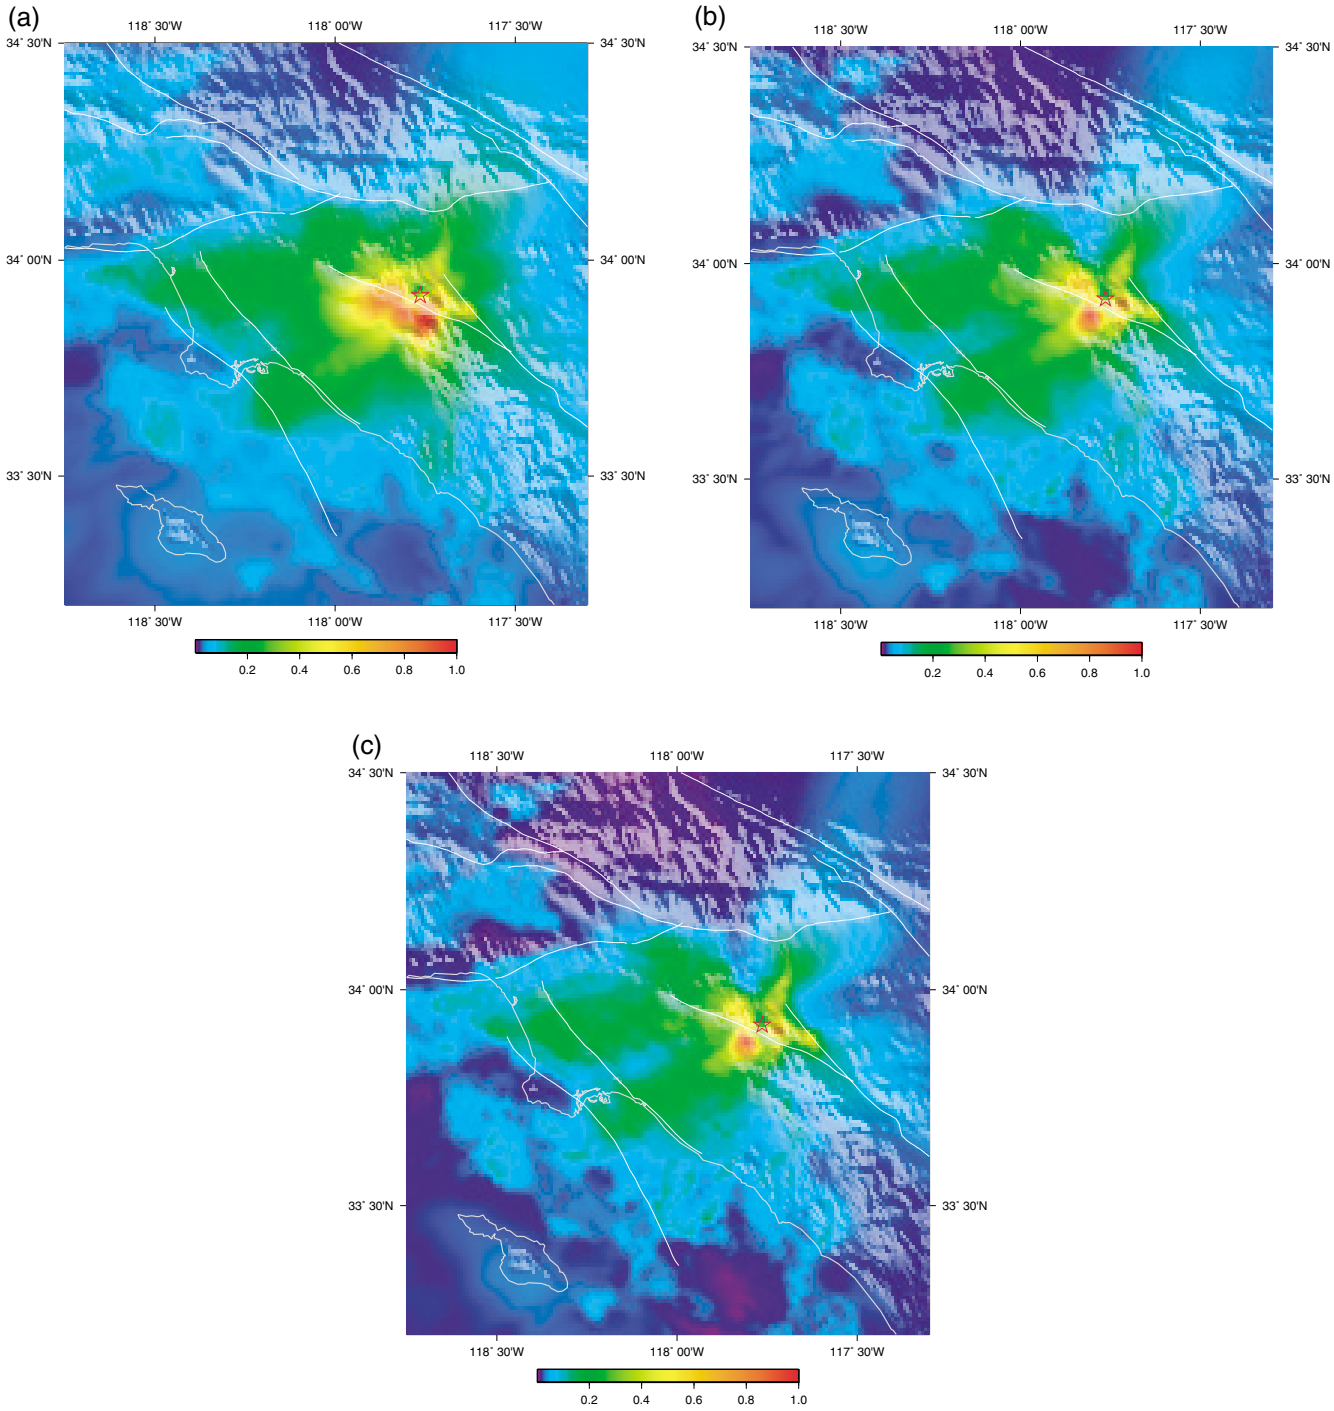

Figure 14. Peak ground displacement (a), velocity (b), and acceleration (c) for the Yorba Linda earthquake. A value of 1 corresponds to maxima of 0.64 mm, 0.94 mm s^{-1} and 2.02 mm s^{-2} for the norm of displacement, velocity, and acceleration at the surface, respectively. Note that, as for the Hollywood event in Figure 11, the peak ground velocity and acceleration maps are similar in character, but that the peak ground displacement map is smoother in nature. Again, hard-rock sites such as Palos Verdes and the mountains exhibit less amplification.

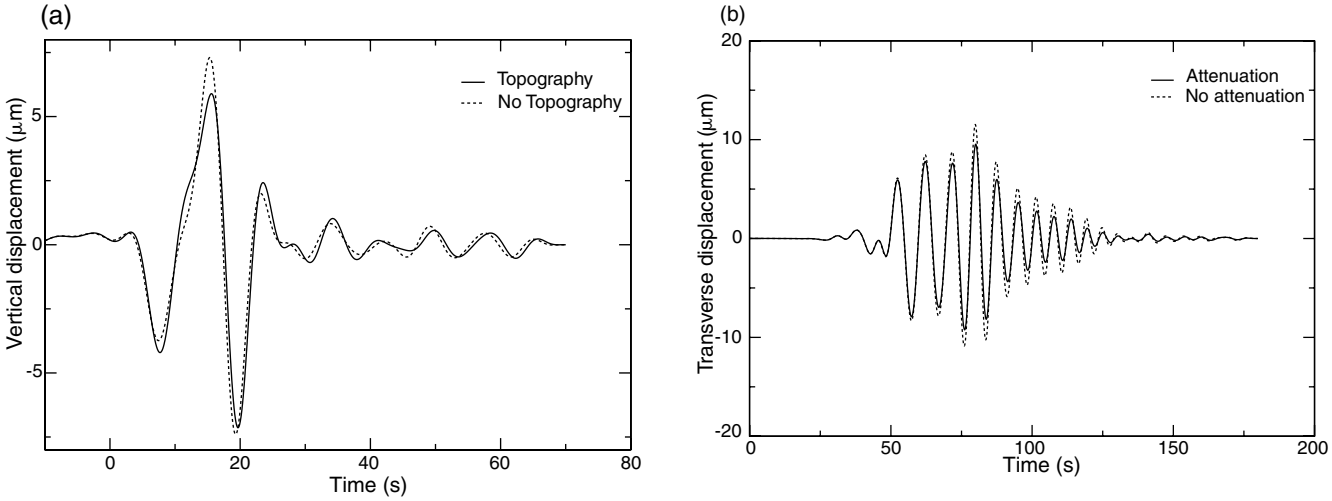

Figure 15. (a) Vertical component displacement SEM synthetic seismogram for the Yorba Linda earthquake recorded at MWC (Mount Wilson) when topography is included in the 3D simulations (solid line) and when a flat free surface is used (dashed line). (b) Transverse component for the Hollywood earthquake at station CAP (Capra Ranch) with (solid line) and without (dashed line) attenuation. The results are filtered between 6 and 35 sec with a four-pole two-pass Butterworth filter. These seismograms clearly show that the effect of topography and attenuation on seismic-wave propagation in the basin is not negligible.

also thank Thomas Pratt and an anonymous reviewer for comments that improved the manuscript. Figure 16. Transverse component data (black) and 3D SEM synthetic seismograms (red) for the 3 September 2002 Yorba Linda event are plotted on a map of southern California. Stations are denoted by blue triangles and labeled by their station codes. The instrument response was deconvolved from the data to obtain ground displacement. Both the data and the synthetic seismograms were subsequently bandpass filtered between 6 and 35 sec with a four-pole two-pass Butterworth filter. In the Salton Sea area (for instance at stations SAL, ERR, and WES) and in the Mojave Desert (e.g., at station ADO), there is substantial low wave-speed sediment cover that is not yet included in our model, which causes resonance in the data that is not correctly reproduced.
